with an H_2O-H_2 atmosphere, the error in the equilibrium constant could be as much as 40 pct. Chipman and Dastur⁹ have shown that the same effect arises in a *dynamic* system if the gas was insufficiently preheated before it reached the condensed phase.

In the present work, special precautions have been taken to avoid this source of error. The gas must be expected to be sufficiently preheated before it reaches the metal as it passes from below, through the resistance heated furnace, up outside the crucible and then down into it.

The fact that the gas circulates at a rather high rate (about 30 to 50 cm³ per min.) prevents inhomogeneity when going from the hot to the cold zone. No appreciable change occurred in the gas composition when the flow rate was varied by a factor of two (by speeding up or slowing down the propeller) indicating that the flow rate was sufficient to eliminate the thermal diffusion. That inhomogeneity would occur if there were no circulation, was shown in one experiment: A "dynamic equilibrium" was established at 1055°C (Run 17) and a gas ratio of 0.218 (corr), 0.220 (obs), was found. Then the circulation was arrested by turning the ground joint top of the apparatus. After the system had been left overnight at the same temperature, a gas ratio of 0.325 (obs) was measured. This is about 50 pct higher than the "dynamic composition." The original value was reproduced when the circulation was started.

EXPERIMENTAL RESULTS

After a number of preliminary runs (which were made to work out the

FIG 3—Ratio H_2S/H_2 for runs 1–22.

FIG 4—Equilibrium ratios as a function of composition of the alloy.

method) 22 main runs were done with sulphur contents varying from 0.4–33.3 at. pct (0.14–13.9 wt pct). In most of these runs the initial gas was pure hydrogen. However, some runs were started with an initial H_2S/H_2 mixture of a ratio 0.25, thus approaching the equilibrium from the high side. These runs gave values in agreement with the rest of the work.

In Table 1, the runs are tabulated in the order they were made; likewise are the readings at different temperatures listed in the sequence in which they

were carried out. In the first column is given the number of the run, the weight of the alloy, and the volume of the gas. The volume is reduced to 760 mm pressure and 0°C. The composition of the silver/sulphur alloys is given in atomic per cent. The compositions which are *italicized* are the ones obtained by chemical analysis. The compositions at other temperatures of the same run are recalculated from the analytical data, on the basis of the change in gas composition with temperature, the weight of the alloy, and

the volume of the gas. For a few runs in the medium composition range, the alloys were not analyzed but their sulphur contents calculated from their original composition by correcting for the sulphur losses to the atmosphere. These values are given with one decimal place less than the others and are not underlined.

In Fig 3 is plotted the gas ratio, H₂S/H₂(corr), as a function of temperature for all runs.

Fig 4 gives the variation of the gas ratio with composition of the alloy for four different temperatures: 900, 1000, 1100, and 1250°C. When no experimental value existed for the exact temperature, the points were obtained by interpolation from Fig 3.

In Fig 5 is plotted log H₂S/H₂ against 1/T for a number of compositions as they are taken from Fig 4. It is obvious that the data given in Fig 5 do not represent the experimental data directly, but are obtained by

interpolating between them. Therefore they give an idealized picture where experimental scatterings are smoothed out. On the other hand, they are derived from a large number of experimental data, and no appreciable error should be introduced by this procedure.

Discussion of Results

COMPARISON WITH THE RESULTS OF PREVIOUS INVESTIGATORS

The heterogeneous equilibria between phases rich in Ag₂S and Ag have been investigated by Pelabon,² Keyes and Felsing,³ Jellinek and Zakowski,⁴ Watanabe,⁵ and Britzke and Kapustinsky.⁶ Their data are plotted in Fig 6, together with the present data for the same heterogeneous equilibria.

The data of the previous investigators are derived by using different techniques. Pelabon as well as Keyes and Felsing established the equilibrium composition of the gas mixture inside a container kept at constant high temperature. The gas mixture was then quenched to room temperature and analyzed. Pelabon quenched the entire container (a quartz tube); Keyes and Felsing withdrew the gas from the hot zone into an evacuated burette. As seen, there is poor agreement between their values. It should be noted that Pelabon worked with rather small gas volumes and that an inaccuracy in the chemical analysis is possible. Keyes and Felsing's values are the averages of a series of parallel runs which in themselves deviated as much as 10 pct from the mean value.

Watanabe established his gas equilibrium in the hot end of a tube, and withdrew gas for analysis from the cold end. It is obvious that this leads to inhomogeneity of the gas by thermal diffusion, and that his values for the gas-ratio must be too high. In fact the value which in the present investigation was obtained by closing off the circulation, and which in Fig 6 is denoted by an *, agrees with what one should expect by extrapolation from Watanabe's data.

The data of Jellinek and Zakowski run rather parallel to those of the present investigation but are about 25 pct higher. Their method was a dynamic one in which the gas passed only once over the condensed phase. In order to correct for incomplete reaction, they made several runs of different flow rates, and the equilibrium compo-

sitions were obtained by extrapolation to zero flow rate. By this extrapolation they actually introduce to some extent, the effect of thermal diffusion. Their experimental runs were made at flow rates from 6 to 1 cm³ per min., flow rates at which the thermal diffusion already plays an important role.

The data of Britzke and Kapustinsky are in best agreement with those of the present work. They were obtained by a static method of measuring the partial pressure of hydrogen in the hot zone by letting it diffuse through the walls of a platinum bulb. However, some uncertainty must exist in this method too; their data show a minimum for the gas ratio at 957°C, although no break in the curve is to be expected at this temperature from the equilibrium diagram.

THE EQUILIBRIUM DIAGRAM OF THE SYSTEM

The experimental data confirm previous data that a region of liquid immiscibility exists in the system. At the monotectic temperature of about 900°C,* the silver-rich phase has a composition of 5.5 at. pct sulphur (corresponding to run 5) and the sulphur rich phase about 31.0 at. pct. This agrees with the compositions obtained from thermal analysis by Kracek: 5.8 and 31.1 at. pct sulphur.¹⁰ At higher temperatures, the immiscibility gap becomes narrower and disappears at a critical temperature of about 1125°C (±25°C) and a critical composition of 24 at. pct sulphur. This corresponds to a rather unsymmetrical shape of the immiscibility region. The immiscibility region and the neighboring parts of the equilibrium diagram are shown in Fig 7.

The present investigation gives little information as to the solid solubility of sulphur in silver. Run 9 shows that the solid solubility at 800°C is not greater than 0.50 at. pct (0.15 wt pct) sulphur. The actual solid solubility is probably much less.

Thermodynamic Calculations

Thermodynamic calculations will be carried out separately for the different regions of the system.

* Kracek¹⁰ found the monotectic temperature equals 906°C. The present work indicates a temperature of 895–900°C. However, the temperature reading in this work may be a few degrees off, and it is further probable that hydrogen dissolved in the liquid metal will lower the freezing point another couple of degrees. Therefore, the value of Kracek is regarded as most reliable.

FIG 5—Log H_2S/H_2 as a function of $1/T$.
Figures to the left give sulphur content of the alloy in atomic per cent.

1. Below 800°C , the investigated equilibrium corresponds to the reaction:

The equilibrium gas ratio is independent of the relative amounts of the two solid phases, as long as they are both present.

The mean values of the equilibrium constant, averages of five runs, are listed in Table 2 for four different temperatures.

The standard Gibb's free energy ΔF° for the reaction is derived by the expression $\Delta F^\circ = -RT \ln Kp$

The slope of $\log Kp$ plotted against $1/T$ as done in Fig 5, gives us the heat of the reaction:

$$\Delta H = \frac{-R d \ln Kp}{1/T}$$

Furthermore:

$$\left[\frac{d\Delta H}{dT} \right]_P = \Delta Cp$$

where ΔCp is the increase in specific heat resulting from the reaction.

In the following, a calculation will be carried out to derive expressions for the heat and Gibb's free energy of the reaction, as a function of temperature, on the basis of the experimental data and the specific heats of the components involved. The procedure for these calculations is the same as that used by Watanabe, except that more recent data are applied for the specific heats. For the specific heats Cp , the values listed by Spencer,¹¹ for the gases, and by Kelley,¹² for the solids, are used.

Silver sulphide exists, according to Kracek,¹⁰ in three modifications de-

noted III (below 176°C), II (176 – 586°C), and I (586 – mp). The heat of transformation at $176^\circ\text{C} = 449^\circ\text{K}$ is given by Kelley.

$$\Delta H_{449} = 1000 \text{ cal/mol}$$

The heat of transformation $Ag_2S_{II} \rightarrow Ag_2S_I$ is not known. Kracek finds that the heat effect at 586°C is less than one-tenth of the heat effect at 176°C . This indicates that the heat of the reaction $Ag_2S_{II} \rightarrow Ag_2S_I$ is less than 100 cal which is inside the experimental error of the present work.

Likewise no data exist on the specific heat of Ag_2S_I . It cannot, however, be much different from that of Ag_2S_{II} , and no appreciable error will be introduced by using this value above 586°C also.

Thus, the transformation at 586°C is entirely disregarded in the present calculations.

For the reaction:

and

$$\Delta H = 4720 - 9.683T$$

$$+ 3.526 \cdot 10^{-3}T^2 + 1.01 \cdot 10^{-6}T^3$$

$$- 0.159 \cdot 10^{-9}T^4 \quad [1]$$

$$\Delta F^\circ = 4720 + 22.29T \log T$$

$$- 3.526 \cdot 10^{-3}T^2 - 0.051 \cdot 10^{-6}T^3$$

$$+ 0.053 \cdot 10^{-9}T^4 - 65.11T \quad [2]$$

From the last expression, ΔF° and $\log Kp$ are calculated for comparison with the experimental data. They are listed in the last columns in Table 2. The agreement is satisfactory.

If the expressions 1 and 2 are com-

Table 2 . . . Mean Values of Equilibrium Constant

| $Ag_2S_{(s)} + H_{2(g)} \rightleftharpoons 2Ag_{(s)} + H_2S_{(g)} \quad Kp = \frac{H_2S}{H_2}$ | | | | | |
|--|-------------------|-----------|------------|-----------------------|------------------------|
| $t^\circ\text{C}$ | $T^\circ\text{K}$ | Kp exp. | Kp calc. | ΔF° exp. | ΔF° calc. |
| 500 | 773 | 0.263 | 0.264 | 2050 cal | 2043 cal |
| 600 | 873 | 0.249 | 0.248 | 2414 cal | 2418 cal |
| 700 | 973 | 0.232 | 0.231 | 2830 cal | 2836 cal |
| 800 | 1073 | 0.215 | 0.214 | 3281 cal | 3289 cal |

bined with corresponding expressions for the reaction $H_2S \rightarrow H_2 + \frac{1}{2}S_2$, one obtains the heat and free energy for the reaction $Ag_2S \rightarrow 2Ag + \frac{1}{2}S_{2(gas)}$; and one can also derive the partial pressure of S_2 vapor. These calculations will not be done here.

On the basis of Eq 1 and 2, the values for the heat and free energy at the transformation temperature 449°K are obtained.

For the reaction $Ag_2S_{II} + H_2 \rightarrow 2Ag + H_2S$

$$\Delta H_{449} = 1084 \text{ cal and } \Delta F^\circ_{449} = 1316 \text{ cal}$$

and for the reaction $Ag_2S_{III} + H_2 \rightarrow 2Ag + H_2S$

$$\Delta H_{449} = 1084 + 1000 = 2084 \text{ cal}$$

$$\Delta F^\circ_{449} = 1316 \text{ cal}$$

Below 449°K , one has:

$$Ag_2S_{III} + H_2 \rightarrow 2Ag + H_2S$$

$$\Delta H = 4370 - 6.683T$$

$$+ 3.526 \cdot 10^{-3}T^2 + 0.101 \cdot 10^{-6}T^3$$

$$- 0.159 \cdot 10^{-9}T^4 \quad [3]$$

$$\Delta F^\circ = 4370 + 15.39T \log T$$

$$- 3.526 \cdot 10^{-3}T^2 - 0.051 \cdot 10^{-6}T^3$$

$$+ 0.053 \cdot 10^{-9}T^4 + 46.01T \quad [4]$$

This gives for $298^\circ\text{K} = 25^\circ\text{C}$

$$\Delta H_{298} = 2693 \text{ cal} \quad \Delta F^\circ_{298} = 1692 \text{ cal}$$

The heat and free energy of the reaction $H_2S = H_2 + S_{rh}$ at 298°K are known¹

$$\Delta H_{298} = 4800 \text{ cal} \quad \Delta F^\circ_{298} = 7865 \text{ cal}$$

Combining these two sets of values, one obtains for the formation of 1 mol of silver sulphide from the elements at room temperature:

$$2Ag + S_{rh} = Ag_2S_{III}$$

$$\Delta H_{298} = -7493 \text{ cal}$$

$$\Delta F^\circ_{298} = -9557 \text{ cal}$$

The largest uncertainties in the present calculation are in specific heats of the silver-sulphides which are known with an accuracy of only 5 pct, which causes an uncertainty of 600 cal in the calculation of the heat and free energy at room temperature. The determination of the heat of reaction at high temperature is probably correct to ± 200 cal; hence the total uncertainty in ΔH_{298} and ΔF°_{298} will be 800 cal.

FIG 6—Comparison of present results with results of previous investigators.

P = Pelabon
K & F = Keyes and Felsing
J & Z = Jellinek and Zakowski
ECBTC = Result of the present work
W = Watanabe
B & K = Britzke and Kapustinsky
* = Gas ratio for run without circulation allowing thermal diffusion to take place

The heat of formation of Ag_2S from the elements has been determined experimentally by Zeumer and Roth¹³ to $\Delta H_{293} = -6,660 \pm 200$ cal.

The standard free energy of formation is listed by Latimer¹⁴ as $-9,500$ cal, a value with which the present result is in very good agreement. Latimer's value is the average of independent measurements of equilibrium constants in aqueous solutions.

The standard free energy has also been given by Kelley as $-8,680$ cal, but his value is based on the equilibrium constants at high temperature by Keyes and Felsing, Jellinek and Zakowski, and Watanabe in combination with the heat of reaction adapted from Zeumer and Roth.

THERMODYNAMIC RELATIONS IN THE MOLTEN STATE

Calculations of the heats of reaction and free energies for the heterogeneous reactions above the melting point, for instance Ag_2S -rich melt + $\text{H}_2 \rightarrow \text{Ag}$ -rich melt + H_2S , can be done in the same way as for the solid equilibrium. Such calculations have rather little physical significance as they involve phases in which the composition changes considerably with the temperature.

A clearer description of the thermodynamics in the molten state is obtained by plotting the partial thermodynamic functions for sulphur and silver as a function of the composition. The partial atomic heat content of sulphur dissolved in the melt can be expressed in different ways, depending on what standard state is chosen:

The heat of the reaction $\text{H}_2\text{S} \rightarrow \text{H}_2$

+ $\text{S}_{(\text{dissolved})}$ will be denoted by $\Delta \bar{H}_S$ and is the heat required to transfer one gram atom of sulphur from hydrogen sulphide to the melt—the melt being kept at constant composition.* $\Delta \bar{H}_S$ is given by the expression

$$\Delta \bar{H}_S = R \frac{d \ln \text{H}_2\text{S}/\text{H}_2}{d \ln T}$$

and can be obtained from the slope of the curves in Fig 5.

If, on the other hand, the partial heat content of sulphur is referred to monoatomic sulphur vapor as the standard state, it will be denoted by $\Delta \bar{H}_S'$. In the temperature region 1000 – 1250°C $\Delta \bar{H}_S$ and $\Delta \bar{H}_S'$ will differ by $74,680$ cal which is the heat of the reaction $\text{H}_2\text{S} \rightarrow \text{H}_2 + \text{S}_{(g)}$ in this temperature range, calculated from Kelley's data.¹

The partial heat content of silver, $\Delta \bar{H}_{\text{Ag}}$, is related to the corresponding value for sulphur by the equation

$$N_{\text{Ag}} d\Delta \bar{H}_{\text{Ag}} + N_{\text{S}} d\Delta \bar{H}_S = 0$$

N_{Ag} and N_{S} mean the atomic fractions of silver and sulphur respectively. This equation is independent of what standard state is chosen for sulphur. Integrating this equation graphically, the partial heat content of silver referred to pure molten silver as standard state, can be derived. The partial heats $\Delta \bar{H}_S$, $\Delta \bar{H}_S'$ and $\Delta \bar{H}_{\text{Ag}}$ are plotted in Fig 8, all as a function of composition.

A few points became apparent from Fig 8; the partial atomic heat of sulphur is independent of concentration in the dilute range 0 – 3 at. pct sulphur, that is, Henry's law is followed.

Between 3 and 30 at. pct sulphur, the

* $\Delta \bar{H}_S$ is independent of the partial pressure of H_2S , which behaves as a perfect gas.

FIG 7—Phase diagram for the melting region of the system silver/silver-sulphide.

partial heat of sulphur $\Delta \bar{H}_S$ decreases linearly with the sulphur content. Between 30 and $33\frac{1}{3}$ at. pct sulphur, the atomic heat seems to increase somewhat. The experimental data are not too good here, however, and a considerable error is possible.

Contrary to what is usually the case for a solute, the partial heat of sulphur decreases with increasing concentration. In a later section this phenomenon will be more thoroughly discussed, as well as its relation to the immiscibility phenomenon in this system.

The chemical potential μ_S and the chemical activity a_S of sulphur in the melt are given by the equations

$$\mu_S = RT \ln \text{H}_2\text{S}/\text{H}_2 + \mu_S^0$$

$$a_S = K_1 \cdot \text{H}_2\text{S}/\text{H}_2$$

The standard potential μ_S^0 and the constant K_1 depend again on what standard state is chosen for sulphur.

Using the Gibbs-Duhem equation, we can derive the chemical activity of silver a_{Ag} :

$$N_{\text{Ag}} d \ln a_{\text{Ag}} + N_{\text{S}} d \ln \text{H}_2\text{S}/\text{H}_2 = 0$$

This equation is integrated graphically and pure molten silver is given the activity one.

The chemical activity of Ag_2S is defined by the expression

$$a_{\text{Ag}_2\text{S}} = K_2 (a_{\text{Ag}})^2 \cdot \text{H}_2\text{S}/\text{H}_2$$

The constant K_2 is so chosen as to make $a_{\text{Ag}_2\text{S}}$ unity at the stoichiometric composition.

In Fig 9, the chemical activity of silver, the $\text{H}_2\text{S}/\text{H}_2$ ratio and the chemical activity of Ag_2S are plotted for the temperature 1125°C (the critical temperature of immiscibility).

FIG 8—Partial atomic heat content of silver and sulphur.

Figures along the abscissa indicate atomic pct sulphur.
 $\Delta \bar{H}_S$ and $\Delta \bar{H}_{Ag}$ are read on the scale to the left.
 $\Delta \bar{H}_S'$ is read on the scale to the right.

The typical positive deviation from Raoult's law is apparent for all three curves, and they all have a horizontal tangent at 24 at. pct sulphur, corresponding to the critical composition.

One can further see that the activity of silver has a considerable value even for a melt of composition Ag_2S . Thus, the system $Ag-Ag_2S$ cannot be treated thermodynamically as a simple binary system but only as part of the system $Ag-S$.

The activity of silver follows Raoult's law in the silver rich part of the system—the activity of sulphur following Henry's law.

THE HEAT OF FUSION OF Ag_2S

The heat of fusion of Ag_2S may be determined in two different ways:

1. The break in the curve ECB (Fig 5) at the eutectic temperature $804^\circ C$ corresponds to about 900 cal. This would be equal to the heat of fusion if there were no change in the partial heat content and partial free energy of molten Ag_2S between 31 and $33\frac{1}{3}$ at. pct sulphur. Because this assumption is not strictly correct, the actual heat of fusion will be somewhat less than 900 cal.

2. Knowing the variation of the activity of Ag_2S in the melt between 31 and $33\frac{1}{3}$ at. pct sulphur, and the lowering of the freezing point of Ag_2S by addition of silver, the heat of fusion can be determined by the equation

$$\frac{dT_m}{dx} = \frac{RT_m^2}{\Delta H_m} \left(\frac{\partial \ln a_{Ag_2S}}{\partial x} \right)_T$$

x = atomic fraction of silver

T_m = freezing temperatures

ΔH_m = heat of fusion of Ag_2S

The chemical activity of Ag_2S is proportional to the product $(a_{Ag})^2$. H_2S/H_2 ; the freezing point lowering is

obtained from the work of Kracek,¹⁰ and a value for ΔH_m of about 700 cal is obtained.

This method involves a considerable degree of uncertainty and the obtained value must be regarded as preliminary.

It seems likely, however, that the heat of fusion is considerably lower than the 3400 cal per mol listed by Kelley.¹⁵ The disagreement is so large that a redetermination by more accurate methods is desirable.

A value for the heat of fusion of 700–900 cal is amazingly low and would correspond to an entropy of fusion of less than one calorie per degree per mol. Very few substances are known to have an entropy of fusion that low (a value from 2–5 units per mol is usual). On the other hand, a very low entropy of fusion is to be expected from the crystal structure of solid Ag_2S which according to Rahlfs¹⁶ shows a high degree of disorder. In this crystal structure the silver atoms are almost randomly distributed and can be compared with the atoms in a liquid, whereas only the sulphur atoms form a regular lattice. Therefore, the entropy of fusion should correspond to the breaking down of the sulphur lattice only.

A Tentative Theory for the Relation between Thermodynamics and Structure of the Melt

Little is known about the structure of molten metals and alloys and especially meager is our knowledge of the structure and chemical forces in molten metal-sulphur systems. For the following treatment, a few known facts will be summarized:

1. Solid silver crystallizes in a close packed cubic structure with coordination number 12 and distance between nearest neighbors = 2.88\AA .

2. Molten silver has a structure closely related to that of solid silver but lacks the long range regularity of the solid state. The coordination number is 11–12 and nearest neighbor distance slightly more than in the solid. In the following, an average coordination number of 11.5 will be assumed. In both solid and liquid silver, the interatomic bond is metallic.

3. Solid Ag_2S (modification II) crystallizes in a cubic structure, where the silver atoms are almost randomly distributed (per unit cell 4 silver atoms can occupy 42 positions).¹⁶ Each sulphur atom has about seven nearest silver neighbors at a distance of about 2.6\AA . The distance to the nearest eight sulphur atoms is 4.225\AA . Each silver atom has on the average about ten nearest silver neighbors at a distance of about 3.0\AA . The crystal structures of modifications I and III are not known in detail but are regarded as closely related to modification II. Therefore, the number of nearest neighbors and the distance between them should be about the same as in modification II. As the heat of fusion of Ag_2S seems to be very low, the structure of the melt should not be expected to differ very much from the solid state.

The nature of the interatomic bond in Ag_2S can be described as predominantly metallic since the compound exhibits electronic conductivity with a negative temperature coefficient.¹⁷ There is no reason to assume the nature of the interatomic bond to be any different in the liquid than in the solid state.

FIG 9—Chemical activities for silver and silver sulphide and the ratio H_2S/H_2 at $t = 1125^\circ C$.

The gas ratio is a measure of the chemical activity of sulphur.

One should, therefore, in this compound apply the atomic radii for metallically bonded atoms rather than the ionic radii. The atomic radii which are in best harmony with the interatomic distances are 1.5\AA for silver and 1.1\AA for sulphur.

The ratio R_s/R_{Ag} is close to 0.73. For a close packing of atoms, this would correspond to a coordination number: 8 (silver neighbors around each sulphur atom) while 7 is actually found in solid Ag_2S . For the discussion of the structure of the melt, the average coordination number is assumed equal 7.5.

We will discuss the energy required to introduce one gram-atom of sulphur from monatomic vapor into molten silver or into a silver-sulphur melt, the melt being kept at constant temperature. This energy equals $\Delta\bar{H}_S'$ from the preceding section. It will be necessary to expand one of the interstitial positions in the silver melt to make room for each sulphur atom. Structural consideration indicates that this requires the breaking an average of 1.5 Ag-Ag bonds, and a slight adjustment of the silver atoms. If more and more sulphur atoms are added to the melt, more interstitial positions are expanded, each requiring the breaking of 1.5 Ag-Ag bond. When one gram atom sulphur has been added to 2 g atoms silver corresponding to a composition Ag_2S , 1.5 N out of 11.5 N Ag-Ag bonds have been broken, leaving 10 N bonds unbroken, corresponding to each silver atom being surrounded by 10 silver neighbors. This agrees with the coordination number 10 which is actually found in solid Ag_2S .

The energy required to introduce one gram atom of sulphur from monatomic vapor into the melt will be the energy required to break $N \cdot 1.5$ Ag-Ag bond minus the energy liberated by the formation of new interatomic bonds. The energies of the interatomic bonds will be denoted by the symbol V .

For a diluted solution of sulphur in molten silver, the individual sulphur atoms will be sufficiently separated not to interact and

$$\Delta\bar{H}_S' = N \cdot (1.5V_{Ag-Ag} - 7.5 V_{Ag-S})$$

As $|\Delta\bar{H}_S'|$ according to Fig 8 equals $-69,500$ cal for a dilute solution, and $N \cdot V_{Ag-Ag}$ is calculated from the heat of vaporization of liquid silver equal $12,000$ cal, one obtains the energy of N silver-sulphur bonds, $N \cdot V_{Ag-S}$, equal $11,650$ cal.

With increasing sulphur concentration, we find that $\Delta\bar{H}_S'$ decreases and reaches a value of about $-82,000$ cal when the composition approaches Ag_2S .

This decrease in heat content is very likely due to the fact that more and more sulphur atoms will occupy neighboring "expanded interstitial" positions, that is, they will be second nearest neighbors in the melt, and that these sulphur neighbors exhibit attractive forces on each other. Thus, bringing two sulphur atoms into neighboring "interstitial" positions will liberate a certain energy V_{S-S} .

The fact that the energy of the sulphur-sulphur bond has a positive value means that each sulphur atom will tend to attract other sulphur atoms to have as large a number of sulphur neighbors as possible. On the other hand, thermal

agitation will tend to distribute the sulphur atoms statistically among the available positions to make the entropy as large as possible. The net effect is a distribution of the atoms which gives the lowest free energy. The number of sulphur neighbors in neighboring "interstitial" positions will be somewhat larger than corresponds to random distribution. We will have a type of short range order in the melt. (See Fig 10.)

The total free energy of mixing can, for a given temperature, be expressed in the following terms:

$$\Delta F(x, n) = \Delta H(x, n) - T\Delta S(x, n)$$

x is the mol fraction of sulphur and n the number of sulphur-sulphur bonds. ΔH will decrease with increasing value of n , and ΔS will decrease with increasing value of n in excess of what corresponds to random distribution.

If the exact dependencies of ΔH and ΔS with respect to n were known, the minimum value of ΔF and the degree of short range order could be obtained by setting

$$\left(\frac{\partial \Delta F}{\partial n}\right)_x = 0$$

Such a statistical derivation, especially of the entropy, cannot at the present be carried out.

The energy of the sulphur-sulphur bond can be derived from the difference in $\Delta\bar{H}_S$ for a stoichiometric and a diluted melt. This difference is $12,500$ cal. On the assumption that each sulphur atom has 8 sulphur neighbors in a melt of stoichiometric composition, as it has in solid Ag_2S , the energy of N sulphur-sulphur bonds will be: $N \cdot V_{S-S} = 1560$ cal.

The energy of the interatomic bonds will not vary much with temperature. By decreasing temperature however, the term $T\Delta S$ in the free energy expression will decrease, allowing an increase in the degree of short range order. But an increase in short range order of this kind cannot go on indefinitely with maintenance of the homogeneity of the melt. The sulphur atoms will more and more accumulate into clusters separated from each other by regions where concentration of sulphur atoms is small. When the cluster formation has reached a certain extent, large enough to overcome the surface tension, the melt will break down into two liquids, one rich in sulphur corresponding to the Ag_2S -rich phase and one low in sulphur corresponding to the Ag-rich phase.

Thus there is a close relationship between the decrease in $\Delta\bar{H}_s$ with increasing sulphur concentration, the degree of short range order in the melt, and the fact that it separates into two layers by cooling.

The author is aware of the fact that this last section has been rather speculative and suffers from errors of oversimplification. Thus, for example, it is not strictly correct to assume the size of the atoms, and consequently the coordination number, to be absolutely constant all through the system. The assumption that the energy of the individual interatomic bonds are independent of the composition is also probably incorrect. But the errors thus introduced will be small compared with the large variation of $\Delta\bar{H}_s$ going from diluted to stoichiometric composition.

The main idea has been to introduce a general concept of the structure of a metal/sulphur melt and show that such a concept is consistent with observed thermodynamic properties. It is unlikely that the atomic arrangement in other metal/sulphur systems is in principle different from that of the system silver/sulphur. Most metal/sulphur systems show either immiscibility between a metal melt and a sulphide melt, or miscibility with a pronounced positive deviation from Raoult's law. Also in these cases, short range order should exist in the melt, although there is no reason to assume the existence of defined sulphide molecules. It follows therefore, that the discussion of which sulphides do exist, for example, in molten steel (a discussion which is common among metallurgists) is somewhat beside the point. One should rather discuss the influence of different

FIG 10—Two dimensional sketch of the suggested atomic arrangement for a silver-sulphur melt containing about 20 at. pct sulphur, indicating short range ordering of the sulphur atoms.

alloying elements on the chemical activity of dissolved sulphur, and on the interatomic arrangement.

The author hopes, in another paper, to return to this last subject.

Summary

A thermodynamic investigation of the system silver-silver sulphide has been undertaken. The principle of this investigation is the reaction of sulphur from the silver sulphur alloys with hydrogen to form hydrogen sulphide, the equilibrium ratio $\text{H}_2\text{S}/\text{H}_2$ being a measure of the escaping tendency of sulphur.

An apparatus was designed in which the equilibrium gas ratio was obtained by circulating the gas mixture over the specimen, and the composition of the gas mixture was subsequently determined from its density by means of a buoyancy-balance (see Fig 1). The possible sources of error were discussed.

Altogether, 22 samples containing up to 33.3 at. pct sulphur have been studied over the temperature range 500–1300°C. The equilibrium ratios $\text{H}_2\text{S}/\text{H}_2$ are plotted as a function of temperature in Fig 3 and 5 and as a function of alloy composition in Fig 4.

It was shown that the immiscibility region in the system has a critical temperature of about 1125°C corresponding to a critical composition of 24 at. pct sulphur (see Fig 7).

The heat and standard free energy of the reaction $\text{Ag}_2\text{S}_{(s)} + \text{H}_{2(g)} \rightarrow 2\text{Ag}_{(s)} + \text{H}_2\text{S}_{(g)}$ were obtained from the experimental data and are expressed as functions of temperature.

The heat and standard free energy of formation of Ag_2S from the elements have been calculated for room temperature,

$$\Delta H_{298} = -7493 \text{ cal and}$$

$$\Delta F^\circ_{298} = -9557 \text{ cal}$$

The heat of fusion of Ag_2S has been estimated to 700–900 cal.

The partial heat content and chemical activity of sulphur in the liquid phase have been computed and the corresponding values for silver have been calculated by means of the Gibbs-Duhem equation (see Fig 8 and 9).

The last section contains a discussion of the relation between thermodynamics and the structure of the silver-silver sulphide melts. A model of the structure is suggested, the model being consistent with observed thermodynamic data and also with the existence of immiscibility in the system. (See Fig 10.)

Acknowledgment

This research has been supported in part by grants from Union Carbide and Carbon Corporation.

It is a pleasure for the author to acknowledge the help of many members of this Institute. Thanks are especially due to Professor A. Skapski (now at University of Nebraska) for interesting discussions, and Professor N. H. Nachtrieb and Professor J. W. Stout for reading the manuscript with valuable criticism.

Autogenous Roasting of Low Grade Zinc Concentrate in Multiple Hearth Furnaces at Risdon, Tasmania

J. A. B. FORSTER*

The operations of the Electrolytic Zinc Co. of Australasia Ltd. involve the preliminary roasting of zinc concentrate from Broken Hill, New South Wales, at a number of acid-making centers on the Australian mainland. The partially roasted material is shipped to the Tasmanian plant where it was formerly re-roasted prior to leaching,¹ but this practice was gradually abandoned in favor of the flotation of leach residue for the recovery of a concentrate containing about 22 pct sulphide sulphur and known as secondary or Risdon concentrate.² This change, together with increased zinc production, called for new furnaces at Risdon for the roasting of 40-50 tons† of secondary concentrate and 90 tons of new concentrate per day.

The war situation made it imperative that construction be commenced without delay and to save time it was decided to base the design on that of Skinner type furnaces which had been built in South Australia twenty years earlier.

This involved some sacrifice of desirable features but did not prevent the incorporation of provisions which had enabled small Herreshoff type furnaces to roast secondary concentrate autogenously. The roasting rate in existing furnaces was 10-12 lb sulphide sulphur per sq ft of hearth area per day, and eleven hearths, 20 ft in diam, were provided in the two new furnaces in anticipation that they would prove capable of the autogenous roasting of 130-140 tons of concentrate per day from 28-29 pct sulphur down to 4.5-5 pct, with an oxidation rate of 11-11.5 lb S/S per sq ft of hearth area per day.

It was soon realized, when the first of the furnaces went into operation, that a much better performance than this might be given, and the purpose

of this paper is to show how a treatment rate of 100 tons per furnace day, and oxidation rates approaching 15 lb S/S per sq ft per day have been reached.

Furnace Design

General specifications for the design were based on the results of experience with several other types of furnace and on the special operating conditions

FIG 2—Plan A-B (See Fig 1).

expected. The general arrangement is shown in Fig 1, 2 and 3.

The original hearths had a camber of 8 in. and were very difficult to keep clean. To build flat hearths involved major changes in design, and a compromise was reached by thickening the haunch blocks and five outer rings of hearth blocks as much as minimum door size would allow, but the original camber remains in the central portions of the hearths.

The working doors are covered by outer doors which form chutes right down the face of the furnace to hoppers in the basement where spillage and cake from the hearths are collected. These chutes are ventilated by a fan which exhausts from both top and bottom of each chute so as to be effective when any door is open.

The column and rabble arms are air cooled, and the air leaving the bottom of the column is distributed

to three mains rising alongside the furnace. Air is supplied to the hearths from these mains through ports controlled by disc valves. The tops of the mains are connected through a damper to the fan supplying the rabble-cooling air. This arrangement permits hot air to be supplied to all hearths when necessary, while cold air may be used down to any desired level of the furnace. Hot air may be exhausted to atmosphere when desired.

In the second furnace, Nos. 6, 7, and 8 hearths are each provided with an additional port for the injection of dust recovered from the furnace gases by means of cyclones. An additional port in No. 9 hearth accommodates a small oil burner which is not in continuous use.

Rabble arms are of cast iron and have an indefinite life. The rabble teeth in No. 1 hearth are of special cast iron and last 2-3 years; all other

teeth are 27 pct Cr and the average life is 3½ years.

Design and Arrangement of Rabble Teeth

A large contribution to the present performance of these furnaces has been made by improvement in the design and arrangement of rabble teeth. There are five factors of importance in design: angle of approach, throw, spacing, depth and overlap. These have not always had the attention they deserve, though this may mean the difference between failure and success of a furnace.

Angle of approach is the angle between the blade of the tooth and the tangent to its circle of movement. If this angle is too large the material being rabbled will not slip across the blade but will tend to build up in front

and to be pushed around the furnace; an overloaded condition will quickly develop. If the angle is smaller than need be the blade of the tooth will be too long and heavy in relation to the work required of it. The smaller the angle and the longer the tooth the more difficult it will be to clean the blades when necessary. The angle may be relatively large for material moving down a slope or outward across the hearth, but must be smaller for the same material on upward slopes and for inward rabbling. Free moving material like dry sand can be worked with the most economical angle, 45° , on outward traverses, but angles of less than 30° may be necessary for sluggish or "sticky" material on inward traverses.

The throw is the radial distance between the leading and trailing edges of the teeth; it is rather more than the effective radial distance of the movement of material because of "slip"—that is, the material which, as the trailing edge passes on, slips back from the rill of the tooth into its path. In the first place the throw determines the number of times the roasting material will be turned over during its traverse of the hearth; consequently it has an important bearing on the amount of roasting done on the hearth. Long throw thins the mobile bed and may be a factor in overcoming an overloading tendency. Throw also determines, to some extent, the spacing of the teeth, and hence the convenience with which tooth cleaning is done, and its frequency.

Spacing, the center to center distance of the teeth on the arm, must not be too small or the cleaning of teeth becomes a difficult operation likely to result in mishap. Under heavy loads close spacing also means increased friction in the passage of material between teeth and makes the development of overloading more probable, besides decreasing the exposure of the material to the furnace atmosphere. In determining spacing, allowance must be made for any tendency of the material to crust on the teeth as this of course decreases the effective spacing between successive cleanings. Spacing must not exceed the throw multiplied by the number of arms in the hearth if the whole of the hearth is to be swept by the teeth, but if the material rills easily and a deep mobile bed is desired, it is possible even to double this figure and have considerable bands of unswept hearth, par-

ticularly if the throw is relatively small.

The depth of the teeth determines firstly the depth of immobile bed on the hearth, and secondly, in conjunction with spacing, the maximum cross section of material which can be moved effectively at each pass of the arm. Where the material has to traverse a slope it is the depth of tooth nearest the crest which is the determining or effective depth of all teeth on the hearth. If the effective depth of tooth divided by the spacing is less than the tangent of the angle of rest of the material, the furnace will be unable to attain its possible transport capacity, but it is not of much advantage for this value to be exceeded greatly unless a deep, slow-moving bed is to be maintained by having the spacing exceed the throw multiplied by the number of arms, or unless two teeth of opposite throw are used together to form a "scoop" for gathering material into a drophole.

On a flat hearth "slip" is normally a little less than one-eighth of the mobile load gathered by the tooth; on downward slopes and outward traverses it is less, on upward slopes and inward traverses it is more. On cambered inward rabbling hearths, the greater slip tends to increase slip still further, so that there is a distinct tendency for such hearths to become overloaded and, finally, completely choked. It is important in such cases to keep the upward slope to a minimum by having as little immobile bed as possible near the crest. A further

and effective remedy is the use of some overlap, that is, having the paths of teeth on one arm overlap the paths of those on the preceding and following arms. It is present when spacing is less than throw multiplied by the number of arms; (by 2 in the special case where four arms operate as two effective pairs). This is, of course, a particular case of the general principle that increased throw tends to thin the mobile bed, for the simplest way of getting overlap is to increase the throw of the teeth without altering the spacing.

Where two teeth of opposite throw are used to form a V or scoop for gathering large quantities of material, as in the case of a final hearth where the whole load has to be concentrated to a single drophole, it is essential that the base of the scoop be sufficiently open to leave a considerable trail of material behind it. The ideal opening will permit so much to escape that the scoop will have accumulated its full load only shortly before it reaches the drophole. In the final hearth it is also desirable, if the load is large, that each arm should carry a scoop commanding the drophole, but these scoops should not work over identical paths.

A significant factor in all rabbling is that on outward rabbling hearths the load is being spread over a larger and larger area, as it progresses, while the reverse is the case on inward rabbling hearths. To secure the best possible combination of roasting and transport capacities the throw of teeth

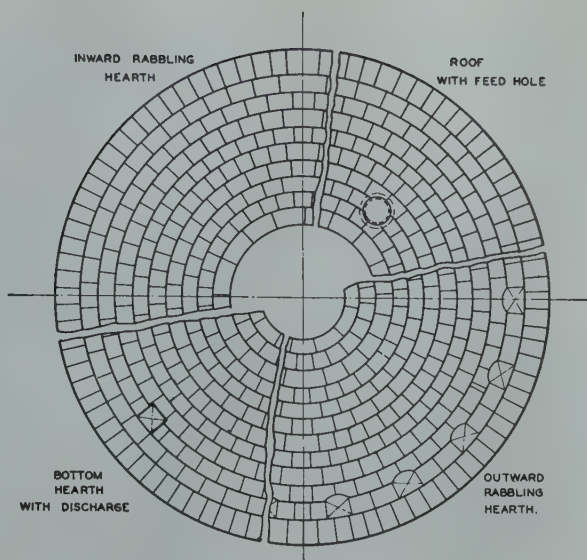

FIG 3—Composite hearth plan.

should be at the practical minimum at the outer ends of the arms and increase progressively inwards. This calls for a great diversity of patterns, and, except for the use of some overlap, has not been adopted in the Risdon furnaces, mainly because roasting capacity has already reached a level which makes gas velocity through the third hearth dropholes as high as is desirable; the use of shorter throw teeth in the outer parts of the lower hearths is contemplated as a means of still further improving the completeness of the roast.

Within a few weeks of starting, the first furnace was being operated to the full capacity of its hearth transport system, which proved, under test, to be about 75 tons per day, nonstop. It was obvious that the furnace had by no means attained its full roasting capacity, and if this were to be realised an increase of transport capacity must be obtained. In fact, a very big increase would be necessary for, in any furnace roasting galena bearing concentrate, the transport capacity must considerably exceed roasting capacity if smooth, efficient operation is to be obtained. The reasons for this are that the best roasting temperature is not far below the softening point of galena, and that hearth temperatures tend to rise with deepening of the mobile bed. If the furnace is being operated at near its full transport capacity a slight increase of feed rate, or delay in the routine of tooth cleaning will deepen the beds slightly, and the consequent rise of temperature may make the galena sticky; mobility decreases, teeth become dirtier, and in consequence of this vicious circle the hearth soon becomes seriously overloaded.

The functioning of the teeth was studied in all parts of the furnace and also in wooden model hearths constructed to scale and using dry sand and pigments. New teeth were designed for special purposes in different parts of the furnace; new combinations were worked out, and within a few months transport capacity was raised to over 100 tons per day. An average rate of 105 tons per 24 hr, nonstop, has been maintained for weeks on end, but the actual maximum transport capacity is uncertain, as there must always be some safety margin to guard against overloading. The above rates refer to operation at the normal column speed of 0.52 rpm; 120 tons per day has been reached at 0.61 rpm.

The first problem was the outward rabbling top hearth. The secondary concentrate carries 14 pct moisture, and having been filtered from a strong zinc sulphate solution, it has a very "sticky" stage during drying. The concentrate tended to reach the dropholes in this condition and grew and baked in the openings to the detriment of draught. As the cover arch is similar to an inward rabbling hearth, and the feed-hole is outside the gas offtake, the inner fifth of the first hearth was not being used. From immediately under the feed-hole inwards, one arm was dressed with narrow angle, short throw teeth, the remainder of this arm and all the other being dressed with narrow angle, long throw teeth in place of the original wide angle, short throw teeth. This arrangement caused feed to be spread over the central portion of the hearth; but as the inward throw is less than the outward throw there is no congestion. The arrangement is shown diagrammatically in Fig 4. The narrow angle permitted the concentrate to be moved more freely in the sticky stage and the long throw thinned the bed. Drying was now completed on the first hearth, and at most of the dropholes roasting had begun, so that a second sticky stage, caused by the presence in secondary concentrate of a small amount of elemental sulphur, had also been passed.

The second major problem was the congestion of the inward rabbling hearths, especially the most active fourth, mainly due to camber. Some alleviation was obtained by lengthening the inner teeth at the expense of making the immobile bed rather too thin to permit easy removal of hearth cake. The later, fully effective solution was the use of teeth with overlap across the whole cambered portion of the inward rabbling hearths. A subsequent modification was to reduce the number of overlap teeth in the eighth hearth and to eliminate them from the tenth to increase the depth of mobile bed and consequently the time of passage of these hearths. The reason for this is that it was observed, when the furnace was stopped for some hours except for a half-turn half-hourly, that the prolonged soaking greatly increased the penetration of the roast into the small aggregates which form very freely during the drying of secondary concentrate, owing to the zinc sulphate content. It is quite practicable to operate these lower

hearth with lower transport capacity because galena is no longer present.

At higher loading rates spill from the inside of outward rabbling hearths increased. The teeth nearest the column on these hearths were elongated so that the leading edges of the blades almost touch the column.

The outward teeth most generally used in the Risdon furnaces have the following characteristics:

| | Outward Teeth | | | Inward Teeth | | |
|-------------------|---------------|-----|-----|--------------|-----|-----|
| Throw—in..... | 6½ | 5 | 4* | 8 | 6½ | 5 |
| Spacing—in..... | 13 | 10 | 8 | 13 | 13 | 10 |
| Angle of approach | 32° | 45° | 30° | 32° | 32° | 28° |

* Designed for lower hearths but not yet installed.

Fig 4 shows, diagrammatically, the arrangements used in various positions.

Operation

Consistent roasting performance depends on regular feeding of an evenly graded concentrate, effective temperature control, clean rabbling and a smoothly running furnace.

Because of the characteristics of the feed components and the necessary arrangements for their delivery to the furnaces, the labor needed to obtain satisfactory feed control is much more than the average for other roasting plants. About half the feed consists of secondary concentrate delivered direct from a continuous disc leaf filter liable to vary from hour to hour in amount and from day to day in grade. The remainder, known as the "high grade" feed, is a mixture of screened dross and flue dust from the zinc melting furnaces with high grade zinc concentrate derived from any of four sources and with distinctly differing characteristics; this mixture carries from 26.5 to 28.5 pct sulphide sulphur whereas the secondary concentrate has from 21 to 24 pct. The general effects of this diversity of feed material are described in connection with furnace performance; as far as feed control is concerned it makes feeding at a constant tonnage rate entirely unsuitable. Effort must be directed at keeping the input of sulphide constant.

Secondary concentrate is weighed on a belt conveyor as it leaves the filter and begins its half-hour journey to the furnaces. The rate of high grade feed is adjusted hourly in accordance with the delivery rate and current grade of secondary concentrate. It is a cumbersome system needing conscientious

operators but the sulphide input is consistently within 2 pct of the set figure, and adjustments of other major controls because of changes in effective input are not frequent.

Temperature control is maintained through the draughting and blast system. The following values are under regular observation and are logged hourly:

1. Gas temperatures in hearths 2, 3, 4, 5, 6, 8, 10, and column exit.
2. Furnace load (ammeter reading also continuously recorded.)
3. Blast pressure at column exit.
4. Draught between main damper and first hearth.
5. Sulphur dioxide in offtake gas (continuous recorder).

Control is exercised through adjustments of one or more of the following:

1. Furnace main damper: normal draught on the furnace side of the damper is 0.04 in., water gauge.
2. Blast fan damper: requisite settings for any given sulphur input are known and any need for departure from normal, as indicated by marked rise or fall of blast pressure at the column exit from the normal 0.5 in. w.g., is an indication of irregularity in rate or grade of feed.

3. Cold air by-pass damper: the fourth and fifth hearths are always fed with cold air in normal circumstances and hearths below the seventh with hot air; operation of the damper mainly determines the extent to which the sixth hearth receives cold air or hot. When regaining temperatures after a stoppage no cold air is fed to begin with but as temperatures rise an increasing amount is used.

4. The disc valves on blast ports: the three ports on any hearth are all opened to the same extent, and the close regulation of the temperature of each hearth is effected by variation of these openings as deemed necessary.

The current feed rate and the settings of all dampers and valves, as made, are recorded on blackboards mounted near the instrument panel.

The temperature objectives in autogenous and "higher sulphate"* roasting are:

| | Autogenous | "Higher Sulphate" |
|---------------------|------------|-------------------|
| Hearths 3 to 6..... | 820°C | 820°C |
| Hearth 8..... | 770-780°C | 800-820°C |
| Hearth 10..... | 700-750°C | 680-700°C |

The condition of hearths and teeth

* See later in this section.

FIG 4—Tooth dressing.

is examined at the beginning and toward the end of each 8 hr shift; where necessary a rough cleaning is carried out. During the main part of the shift the furnacemen start at the top of the furnaces and work down, cleaning all teeth thoroughly and also cleaning such of the arms, shields and portions of the walls and hearths as are allocated to them. The teeth in the lower hearths are changed once in a few months for inspection and for removal of any hard crust, but on hearths 3 to 6 they are changed every two weeks. This is made necessary by the presence of galena which has a significant vapor pressure at 850°C. Some volatilized lead sulphide comes in contact with the teeth, which are at a lower temperature because of the cooling of the arms, and condenses on them in a finely crystalline form, too adherent to be removed by the ordinary process of cleaning. The deposit occurs on the underside of the teeth as well as on the sides and soon causes a "drag" which raises the power input and will ultimately become sufficient to stop the furnace.

It is characteristic of all zinc concentrate roasting that the immobile bed cakes hard and if not broken up regularly begins to exert an excessive drag which will either break arms or stop the furnace. The treatment of these beds differs in practically all plants, and practice at Risdon has

passed through several phases. Initially the hearths were barred or chiselled at intervals of several days. The work proved to be much less arduous, less material was removed and no more labor was required when the intervals were reduced, but it has been found preferable to fill the hearths to tooth level with coarse sand.

It was found impossible to maintain these beds intact; owing to changes of temperature in hearths, column and rabbles, to the disturbance caused by tooth cleaning and to the growth of galena "shoes" on teeth, the upper part of the sand is displaced and a crust of calcine is formed which behaves to some extent like ordinary hearth cake. These developments take time, however, and it has been found that a furnace can be maintained in free running condition provided the sand beds are renewed periodically. The fourth and fifth hearths are resanded every three months, and the other hearths every six months except the first which is done yearly when its teeth are inspected.

During the week before two hearths are to be resanded, they are chiselled thoroughly, the work being in the opposite direction to the rotation of the arms. The hearths done together (except in the case of the first hearth) are always an inward rabbling hearth and the one below it. The feed is cut off for one and a half hours. When material has practically ceased coming into the first hearth to be sanded, a few teeth are removed from the hearth above it and the furnace is restarted. Furnacemen at each door push material off the inward rabbling hearth at a steady rate until the hearth is clean. They then start to pull off the hearth below while sand is shovelled into the clean hearth—sufficient to form the immobile bed of two hearths—about 7 cu yd. As soon as the surplus sand has worked in from the outer part of the hearth the tynes are replaced in the hearth above. The one and a half hours allowed is ample, and it should be noted that, in the case of lower hearths, the feed will be on again long before the hearth cleaning starts. Temperatures are regained very rapidly and the furnace is usually normal within four hours.

After allowing for the cost of sand and of putting it in place, the wage saving resulting from the almost complete elimination of chiselling is not very great but the ultimate benefit from the reduction of wear and tear on the hearths and mechanism will be

quite considerable.

A recording ammeter gives invaluable guidance as to the general condition of the furnace and reveals irregularities or neglect unfailingly. Typical records are shown in Fig 5a, 5b, and 5c.

The furnace section must be closed down for about five hours once a fortnight to permit cleaning of gas fans.

Auxiliary equipment is overhauled and every effort is made to have all maintenance work involving stoppage carried out at the same time; big jobs may extend the stoppage to eight hours, but these are infrequent now. Supplementary equipment is provided for disposing of the gas which is emitted at the feed-hole, and full feed is kept on the furnaces right up till shut-down

time, but all blast valves are shut off earlier; column cooling air is reduced to a minimum and turned to atmosphere. Some air leaks into the furnace through rabble sockets, and the chimney effect of the furnace causes ingress of air to the lower half of the furnace wherever doors are not air-tight. Unless the column drive or bearing is being overhauled, the column is turned for

one minute every half hour. This prevents the crusting of beds and presents new surfaces to the air available; a fair amount of roasting goes on, so that for several hours temperatures do not fall much except in the lower hearths where there is little sulphide available. A typical example of such temperatures is given in Table 1.

If the roasting is strictly autogenous, the recovery of the lower hearth temperatures is rather slow, taking about four hours for each hour of shut down, unless calcine grade is sacrificed to a serious extent. If an oil burner is used at Hearth 9 to assist recovery, the time is reduced by half at an expenditure of about 6 gal of oil per furnace per hr, and calcine grade does not suffer appreciably.

If a stoppage extends beyond eight hours for external reasons the furnaces are then run and fed for five minutes in every thirty or forty. This retards further temperature drop almost completely. If the bottom hearth becomes seriously overloaded, it may be relieved by discharging into the basement.

The addition of the cyclone dust from both furnaces to the middle hearths of one furnace results in about 100°C drop in bed temperature and necessarily affects roasting rate. The lowering of feed grade resulting from the addition of dross also causes a drop in roasting performance. It was decided to abandon strictly autogenous roasting, therefore, and use a small oil-burner on each furnace as required, to help restore temperatures after the furnace stoppages and to make good the effect of cyclone dust addition. Experience shows that the burners are used to best advantage in the ninth hearth, and consumption of fuel oil amounts to about 0.15 pct on the material roasted or about 0.7 pct on the sulphur oxidized.

Additional fuel oil has been used during most of the last year in order to increase the formation of sulphate, which is done by reducing the sulphide much below the level attainable with autogenous roasting at high feed rates. The temperature objectives have been given earlier in this section, and the consumption of fuel oil is shown in Table 6.

Equipment designed for the changing of rabble arms and teeth is very satisfactory and good team work has developed in its use. Where changing is frequent the set of teeth on an arm is removed and replaced in 3-5 min.

Lost time was very heavy initially.

| Av. | 46.3 | | | 18.1 | | | 31.1 | | |

To a large extent this was caused by blockage or breakdown of auxiliary equipment much of which was 20 yr old, but there were many short stoppages in connection with furnace work. Much effort was concentrated on eliminating causes of trouble and the progress made is shown in Table 2.

The final column gives the minimum times in which it is considered possible to carry out essential operations such as fan cleaning, teeth changing and renewal of sand beds.

Roasting Characteristics of Feed Components

The feed to the furnaces is always a mixture of concentrates from any or all of four sources, three Broken Hill mills and the Company's own mill at Rosebery, together with secondary concentrate (called Risdon) recovered from leached calcine residues, and latterly about 5 pct of dross and flue dust from zinc melting furnaces. (See Table 6.) Since feed composition inevitably varies, a knowledge of the roasting characteristics of the different components and mixtures is essential.

The objectives are not constant. The requirements of the zinc plant as a whole, the position in regard to stocks and certain subsidiary operations lead to variations in the stress laid on obtaining maximum oxidation of sulphides which is incompatible with relative completeness of oxidation and production of sulphate.

Table 3 gives analyses of typical samples of the five concentrates. In the Broken Hill concentrates the iron is largely present as the zinc-iron sulphide, marmatite, whereas in Rosebery concentrate there is both zinc-iron sulphide and pyrite; and in Risdon concentrate the iron is present partly as oxide but principally as zinc ferrite. Lead is present as galena in the primary concentrates but as sulphate in Risdon concentrate while the latter also contains a little elemental sulphur.

The gross thermal values of the concentrates on complete oxidation, as calculated from analyses (a), (d) and (e), Table 3, range from 1180 to 1150 C.H.U. per lb for the Broken Hill concentrates and are 1125 and 720 C.H.U. per lb for Rosebery and Risdon concentrate respectively. Particle sizes are more important than minor differences in gross thermal value in influencing roasting rate, and relative roasting rates for the various dried

concentrates have been studied under controlled conditions in the laboratory (by E. Z. Research Department).

An iron roasting dish with a false bottom was used in an electrically heated muffle with and without a small exhaust chimney, and temperature was closely controlled throughout. A half inch bed of material was well rabbled every five minutes and the most difficult concentrate was dead-roasted in 2 hr at 800°C under these conditions. In all cases roasting was faster at a bed temperature of 800°C than at 750 or 850°C, and the rates for the various concentrates always fell in the same order. Sulphate is formed to any extent only when sulphide content is relatively low, and under these conditions is more prevalent in the coarse fraction containing aggregates than in -10 mesh material. Rosebery and Risdon concentrates sulphate much more readily in both coarse and fine fractions than the Broken Hill materials. Table 4 gives assays, sizings, roasting rates and sulphate formation in the tests described and it should be noted that, in general, the progressive or instantaneous isothermal roasting rate for any concentrate is directly proportional to the progressive sulphide concentration and to a proportionality factor which is characteristic of the material and of the conditions of the roast.

The sizing relationships are perhaps more clearly expressed through the specific surfaces as determined by the Fisher sub-sieve sizer; typical concentrate samples gave the following results:

| | Specific surface |
|-----------------------|-----------------------|
| B. H. North | 740- 810 sq cm per g |
| B. H. South | 680- 710 sq cm per g |
| B.H. Zinc Corporation | 545- 600 sq cm per g |
| Rosebery | 1310-1520 sq cm per g |
| Risdon | 1940 sq cm per g |

For the several Broken Hill concentrates, the ratios of specific surface and roasting rates are close enough to indicate some connection, and it can be assumed that the low grade of the Risdon concentrate tends to offset the advantage of its fineness. The rates for Rosebery concentrate are not nearly as high as its fineness would lead one to expect. The explanation is to be found in its high galena content. It ignites much more rapidly than the others and roasts so actively that it is almost impossible to prevent fusion of galena which makes the roast become "sticky" and "ball-up."

The same facts explain why the

Rosebery-Risdon mixture has better rates than the averages of the rates of the components. The ready ignition of the Rosebery concentrate gives the roast a good start, while its high activity which tends to run temperature out of control is moderated by the low grade material.

Experimental roasting times are well borne out in practice. It is impossible to get satisfactory results with mixtures containing much Broken Hill concentrate at above the normal speed of furnace column. With Rosebery-Risdon mixture the speed may be raised from 0.52 rpm to 0.615 rpm, an increase of 18 pct.

While the sizings of the various concentrates are fairly consistent when long term samples are examined, there is a by no means insignificant day to day variation. Table 5 gives a clear indication of the extent to which these variations are experienced.

Performance

The complete performance record of the furnaces has been summarized in Table 6 and shown graphically in Fig 6. In this summary, the results have been arranged for periods of varying length, each period having some common feature which more or less determined or characterized the performance. The reference letters in the table and graph refer to the following explanations of the grouping:

A. The first four-weekly period during which furnace crews were becoming accustomed to the equipment, and initial difficulties were being overcome.

B. A period during which it was apparent that roasting capacity exceeded hearth transport capacity, and the lower hearths were doing very little roasting. Efforts were made to raise the temperatures of the hearths by "split drafting." Gas offtakes were connected to the bottom hearth, and from Hearth 7 the furnace was drafted downward. The temperatures of the lower hearths improved, but drying was slower and the activity of the upper hearths decreased. With a drier and higher grade feed, very active on the upper hearths, the method has definite advantages, but feed grade was tending to fall.

C. The effect of hearth camber was reduced by deepening the inner teeth of inward rabbling hearths, and column speed was increased from 0.52 to 0.61 rpm. More feed was handled and

temperatures in the lower hearths improved.

D. Teeth with longer throw, giving overlap, were introduced on the inner half of inward rabbling arms. Higher feed rate resulted and the greater roasting capacity of the furnaces, even with a very low grade feed, was clearly demonstrated.

E. The second furnace came into operation, and the gas disposal system which was shared with two other furnaces proved inadequate for the operation of both the new furnaces at the higher roasting rate achieved in the previous period.

F. One of the other furnaces was shut down, and draught improved but appreciable quantities of B.H.S. and B.H.Z. concentrate were introduced for the first time, and considerable difficulty was experienced in producing an acceptable grade of calcine. Column speeds were restored to 0.52 rpm and were even reduced to 0.46 rpm for part of the period, but for no month did calcine average below 5.5 pct S/S.

G. During this period the feed mixture varied several times, the high grade portion being alternately all Rosebery and all Broken Hill concentrate, but the several changes afforded opportunities for close comparison of techniques. Traverse rates were reduced in Hearths 8 and 10, and calcine of under 5 pct S/S was eventually produced from Broken Hill-Risdon mixture, with a roasting rate of 12.5 lb S per sq ft per day which was then regarded as the acceptable minimum.

H. New supplies of Broken Hill concentrate contained no B.H.Z. and were mainly B.H.N. No difficulty was experienced in increasing roasting rates

to 14.5 lb S per sq ft per day, even when there was no Rosebery concentrate present and while maintaining calcine at less than 5 pct S/S.

J. A four-week period during which shortage of concentrate occurred and the furnaces were run, for a time, on the minimum load at which temperatures could be maintained. During this feed shortage the last of the old furnaces was shut down, and it became necessary to include zinc melting furnace dross and flue dust in the roaster feed to the extent of about 5 pct. Dust from the cyclones, formerly roasted in the old furnace, now had to be returned, at first to the feed though soon afterwards provision was made for delivering it to the middle hearths of No. 2 furnace.

K. This period was, in most respects, a continuation of period H, but marked by the dilution of the feed with dross and the effect of returning cyclone dust, which combined to reduce roasting rate from 14.4 to 13.4 lb S per sq ft per day. The admixture of dross with concentrates results in more rapid hardening of hearth beds and quicker fouling of teeth. Fortunately the developmental work on sand beds had been completed and both furnaces were soon bedded throughout. The labor saved from hearth cleaning was more than enough to enable better attention to be given to tooth cleaning.

The dust addition reduced the middle hearth temperatures of No. 2 furnace and therewith the roasting rate. Continuous addition at one point causes a drop of 100°C in bed temperature, but as the addition was spread over two hearths, the effect of the dust was not so sharply evident in

temperatures. The most noticeable effect was in calcine assays, those of No. 2 furnace being consistently about 1 pct S/S higher than those of No. 1 in spite of adjustment of feed distribution to insure equal overall sulphur inputs to the two furnaces.

The higher calcine assays, now tending to be just over the acceptable 5 pct S/S, prevented any attempt to restore sulphide input by increasing feed rate to make up for the dilution. Excluding from period K four weeks during which 40 pct of the feed was B.H.Z. concentrate, and calcine went to 8 pct S/S, the effects of dross and cyclone dust can be fairly assessed over two comparable 40 week periods. The feed rates were nearly equal, 93.8 and 92.6 tons per furnace-day respectively.

Dilution caused sulphur input to fall from 17.2 to 16.4 lb per sq ft per day. Temperature reduction by dust caused oxidation efficiency to fall from 83.6 pct to 81.6 pct so that sulphur oxidized fell from 14.4 to 13.4 lb per sq ft per day. The chief effect is caused by dilution, though it may not be immediately clear why, with a lower sulphide input, the oxidation efficiency should not be expected to increase.

The reason is that, in autogenous roasting, maintenance of temperature and of the limited roasting rate in the lower hearths is dependent on the carriage of sufficient amounts and concentrations of heat and sulphide in the calcine from the middle hearths, and on close control of air input. The addition of cyclone dust to the middle hearths affects the balance; calcine temperature is reduced while more sulphide is carried down. The latter can be corrected, as was done, by feed ad-

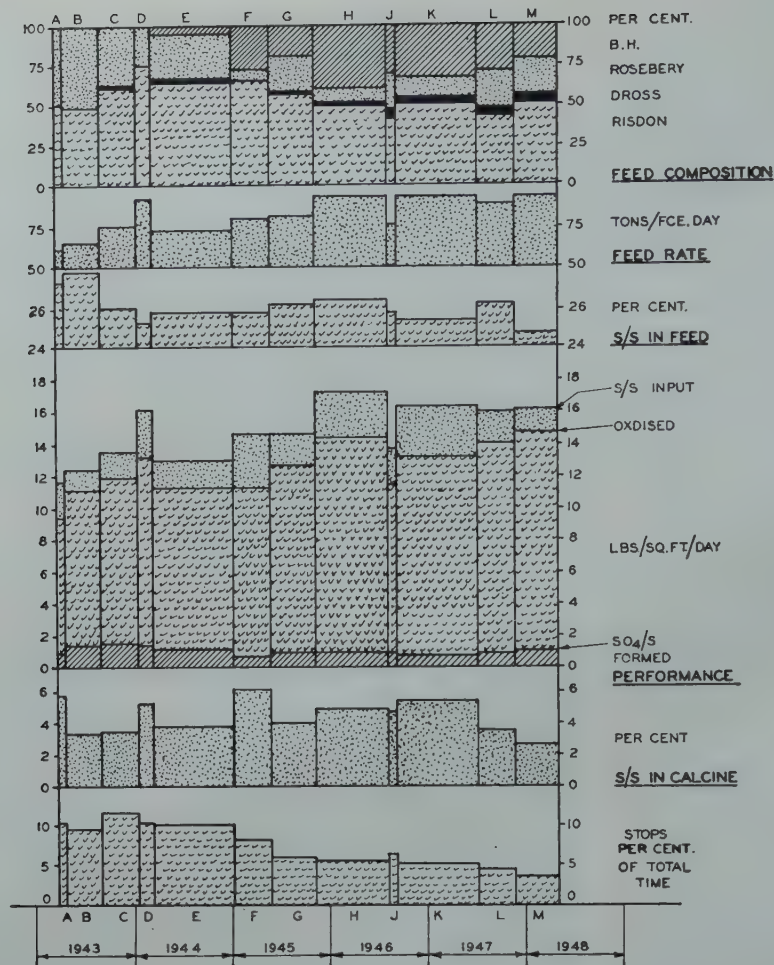

FIG 6—Performance data.

justment, but the temperature effect cannot be remedied without use of extraneous fuel.

On the upper middle hearths, where the roast is most active, it is usually necessary to depress that activity by use of cold air in order to avoid overheating. Even low grade concentrates are more than sufficiently active and by increasing input it is possible, up to a point, to maintain oxidation rate on these hearths. The limit is reached when the amount and concentration of sulphide passing to the lower hearths tend to get out of balance.

By comparing the work of different months in periods *H* and *K*, in which feed grade and sulphide input are nearly the same, it is found that the effect due to cyclone dust addition is only one-third of that due to dilution by dross, that is, about 25 pct of the total decrease of 1 lb per sq ft per day.

It appears, then, that the dust addition is being made too low in the furnace, and that it should be made in

the zone in which depression of activity is required. Gas velocity through the dropholes is so high in this zone however that return of dust to it would cause a large circulating load to build up. The dust is added to the moderately active sixth and seventh hearths.

L. It was decided to make use of small oil-burners to overcome the temperature drop due to cyclone dust in No. 2 furnace and to hasten recovery of both furnaces after long stoppages. At the time the burners became available there was a demand for an increase of sulphate formation and as this increases with decrease of sulphide, it was decided to operate the burners more or less continuously to stimulate roasting in the lower part of the furnace.

A short test was made to determine the consumption of oil for the original purposes; it was 0.17 pct of the tonnage roasted or 0.75 pct of the sulphur oxidized. To stimulate sulphate production, about three times as much is

Table 7 . . . Autogenous vs. Moderately Assisted Roasting

| Duration | Period <i>K</i> , Best 24 Weeks of 44 | Period <i>M</i> , Consecutive 24 Weeks |
|---|--|---|
| Feed rate, tons per furnace per day | 93.2 | 93.8 |
| Feed grade, pct S/S | 25.7 | 24.7 |
| Sulphide input, lb per sq ft per day | 16.6 | 16.1 |
| Sulphide oxidized, lb per sq ft per day | 13.7 | 14.6 |
| Sulphur oxidation pct. | 82.6 | 90.8 |
| Calcine assay, pct SO ₄ /S | 1.30 | 1.68 |
| Calcine assay, pct S/S | 4.94 | 2.50 |
| Fuel oil used pct of S oxidized | | 2.19 |

used. The most effective position for an oil burner was found to be the ninth hearth.

M. The experimental work on the application of fuel oil being completed and good supplies of high grade concentrates being available to give a regular feed mixture, the furnaces settled down to a long run of extraordinarily consistent performance. Both the quick recovery from the fortnightly stoppages due to the use of fuel oil and

a greater stability of furnace crews than existed in wartime and immediately afterwards, contributed to these results. By way of making allowance for the latter factor in comparing periods *K* and *M*, the best 24 weeks' work in the former period has been selected to compare with the 24 consecutive weeks' work of the latter; the results are given in Table 7.

The benefits derived have been calculated on the basis of 90 pct of unroasted sulphide being recovered as secondary concentrate from calcine leach residue and are found to be, for each ton of fuel oil used:

- 2.69 tons sulphur oxidized,
- 2.24 tons sulphuric acid, equivalent of extra sulphate formed,
- 1.34 tons of high grade concentrate (32 pct S/S) saved,
- 18.5 tons of low grade concentrate (22.5 pct S/S) which does not have to be returned for roasting.

The last item in this saving is more important than it may seem at first sight; it means not merely a decrease by one-sixth in the secondary concentrate to be treated by the furnaces, but it effects an increase of 0.6 pct in a feed grade already uncomfortably low for the maintenance of high roasting activity. That this increase was not actually obtained was due to a greater intake by the zinc plant of less well roasted calcine from other sources.

Heat Balances and Gas Tenors

Some heat balances were made in 1944 and showed radiation losses slightly in excess of 20 pct of the heat input. The work was done under great practical difficulties, including irregular operation, and there is some reason to believe that the loss is scarcely so high; but whether the actual loss is 10 pct or 20 pct is immaterial to the discussion of gas tenor in relation to heat balance which follows.

In Table 8 there are shown three balances calculated from recent performance figures, and average gas tenors, and an assumed radiation loss which is proportional to average furnace temperature, using the observed figure of the 1944 balances as basis. To simplify presentation, heat contents have been referred to atmospheric temperature instead of the more usual 0°C.

| Sulphur eliminated, lb per sq ft per day..... | 13.5 | | 14.2 | | 15.3 | |

The conditions chosen for these balances are:

A. The best 24 weeks performance for autogenous roasting of mixtures including dross, as shown in Table 7.

B. The comparable performance when using some fuel oil continuously to improve sulphate formation, also as shown in Table 7, except that feed grade is raised to that which would have resulted had other calcine received by the zinc plant remained of the same grade as in the first period.

C. Performance when using fuel oil only intermittently to make good losses of temperature due to stoppages and the introduction of cyclone dust. The furnaces have been operated under this condition for a short time only but actual performance has been slightly better than that assumed for Table 8.

The amount of heat radiated does not vary much and so a larger fraction of the heat must be carried away by the gases when the space rate of roasting is increased. The upper temperature of the gases is limited to that which gives the fastest roasting and consequently an increase in the space rate must be accompanied by a fall in gas strength. It is nevertheless true that the whole of the heat input to the furnace could be carried by better grade gas than is actually being made, and without exceeding the maximum desirable temperature of 820°C. As low gas tenor is the chief disadvantage of hearth roasters in comparison with

flash roasters it is worth examining why the gas from these furnaces is so low.

In the first place an open feed-hole and main damper slot together account for a dilution of at least 10 pct. Secondly, activity is so great on the fourth hearth that 20-25 pct of the roasting is done there and an excess of air must be used to prevent the desired temperature being exceeded. Finally, in the lower hearths hot air is used as blast and this air can never attain the same percentage of sulphur dioxide as the cold air input because of the imposed maximum temperature.

Apart from the sealing of the feed-hole, the grade of gas produced could be increased by moving the material much more quickly over the most active hearths and much more slowly over the lower hearths. Differential rabbling rates are already being used in these furnaces almost to the limit of practical convenience but with furnaces having three or four arms per hearth greater differentiation is possible and it is by no means certain that the hearth roaster will be finally outmoded by the flash roaster.

El Paso Slag Treatment Plant

T. J. WOODSIDE*

Prior to 1927 the lead blast furnace charge at El Paso consisted principally of direct-smelting carbonate ores, very low in zinc, and the resulting slag seldom carried more than 4.0 pct. With the exhaustion of the mines in Northern Mexico which supplied these ores, they were supplanted with a much smaller tonnage of sulphide concentrates containing appreciable amounts of zinc, and the zinc content of the slag rose to 10.0 pct.

The Anaconda Company's slag fuming plant at East Helena, Montana, had then been in successful operation for several years, and it was immediately recognized that, while at that time the production of high zinc slag was small, if the grade held, a plant for the recovery of zinc from the accumulated slag might some day be practical. The grade not only held but became increasingly higher so that by 1946 sufficient slag had been accumulated to warrant the construction of a fuming plant regardless of future slag production from the blast furnaces, and with the removal of Government restrictions on construction at the end of the war the project was undertaken.

The general design of the plant follows that at Bunker Hill, with waste heat boiler, unit coal pulverizers and even more extensive instrumentation and automatic control.

The area around the lead blast furnaces is rather congested, being cut off from the nearest feasible site for the fuming plant by the copper plant, so that the most practical route for hot slag transfer is through the converter aisle. For this reason and also to make use of the existing converter cranes to serve the fuming furnace, an unused reverberatory at the north end of the converter building was dismantled and the fuming furnace and boiler located in its place. A flue at right angles to the furnace and boiler runs northward to the U-tube coolers and baghouse (Fig 1). From the baghouse a steel flue runs eastward to an existing and long unused 300 ft con-

crete stack. The coal handling system and de-leading plant lie north of the furnace and east of the cooling tubes and baghouse.

The furnace is conventional, 8 × 21 × 33 ft high inside and completely water jacketed (Fig 2). There are 21

FIG 3—Soot blowers.

double-inlet tuyeres on each side of the furnace, with center line of tuyeres $5\frac{1}{2}$ in. above the furnace bottom, and tuyere pipes extending 7 in. inside the furnace. Tuyere pipes were originally water-jacketed, but since these proved to have very short life they have been replaced with $3\frac{1}{2}$ in. od \times $1\frac{1}{2}$ in. id hydraulic tubing. Slag is tapped through two 5 in. water jacketed tap holes simultaneously into two 300 cf air dumped slag pots.

A water jacketed flue connects the furnace to the water-wall combustion chamber of the B. & W. two drum sterling type boiler which is rated at 72,000 lb of steam per hr at 400 lb pressure and 700° total temperature. Combustion chamber, boiler and economizer are equipped with a total of 35 fully automatic Diamond soot-blowers, Fig 3, operating on compressed air. The soot-blower installation has been very satisfactory, no hand lancing being required to keep tubes free of fume. Two motor driven A B C fans, each rated at 51,000 cfm, and connected in parallel, deliver gases from the economizer outlet to a 7 ft diam balloon flue leading to the U-tube coolers. Furnace draft is automatically controlled by louvre dampers in the fan inlets. The U-tube coolers are in two banks, each bank consisting of forty 30 in. \times 58 ft tubes. Additional cooling is supplied when required by an automatically operated damper which admits air into the gases as they leave the U-tubes. A second pair of fans

with capacity of 75,000 cfm each and automatically dampered like the boiler fans deliver gases to the baghouse.

The baghouse is constructed entirely of concrete, including roof and thimble floor, and is divided into seven chambers each containing 160 18 in. \times 30 ft woolen fume bags. Six chambers are used to collect zinc fume from the furnace gases and the other collects lead oxide fume from the deleading kilns.

The bags are shaken automatically when the pressure differential across the bags reaches a predetermined maximum, the chambers being shaken consecutively until the pressure drops to the desired minimum. In order to keep a slight draft on the inlet side of the baghouse, and thus prevent leakage of fume through screw conveyors, the outlet flue is evacuated by a Sirroco type induced draft fan with a capacity of 180,000 cfm, delivering gas to the stack.

Combustion chamber, boiler, economizer, balloon flue, U-tubes and baghouse chambers are equipped throughout their length with screw conveyors which operate continuously and discharge fume into a system of drag and belt conveyors which carry it to the de-leading plant.

Washed 1 \times 0 in. slack coal from Dawson, New Mexico, is dumped into a track hopper. Coal analysis is approximately as follows:

| Ash | Volatile | Fixed Carbon | Btu |
|------|----------|--------------|--------|
| 12.0 | 38.0 | 49.00 | 13,000 |

From the track hopper, coal is passed through a hammer mill and is pneumatically conveyed to a 300 ton storage tank. A Merrick Feedoweight delivers coal from the tank to a Redler elevator and rotary conveyor which distribute it to the three 30 ton pulverizer bins. The pulverizers are B. &

FIG 4—Coal pulverizers.

FIG 5—Control panel.

W. type E, size 47, two being operated with the third in reserve (Fig 4). Furnace blast is supplied by an Elliott turbine driven blower with a capacity of 18,000 cfm at 10 lb. The blast is divided by automatically operated butterfly dampers into primary and secondary air. The primary air passes through the pulverizers, picking up the coal and carrying it to the primary inlets of the tuyeres. The secondary air goes directly to the tuyeres. A 15,000 cfm motor driven blower was installed to inject low pressure air through a number of 2½ in. pipes into the upper part of the furnace and the crossover flue to oxidize completely all coal and metallic zinc. This was found to be unnecessary, however, as furnace draft pulls in enough air through the charging hole, and the blower is no longer in use.

A central control room located at the furnace contains a very complete set of Bailey indicating and recording instruments and control devices, with turbo-blower, pulverizers and flue system drafts all being controlled automatically from that point (Fig 5).

The furnace is now treating 20,000 tons of slag per month. Dump slag is mined by a bulldozer and ripper and remelted in the blast furnaces, no cold dump slag being charged direct to the fuming furnace. Molten slag is brought to the converter aisle in 12.5 ton ladles carried on transfer cars. Four ladles, including the shells, constitute a charge. Blowing time varies from 90 to 110 min., depending on rate of slag production at the blast furnaces.

Coal flow to the furnace is controlled by the velocity of primary air passing through the pulverizers. Since back pressure at the tuyeres is 6 lb when the furnace is empty and increases to 11 or 12 lb when it is fully charged, the volume of primary air, measured in terms of free air at sea level, must be constantly increased to maintain the same velocity. When charging starts, coal flow is reduced in order more nearly to complete combustion, the resulting high temperature serving to heat up the slag and smelt the shells. During this period, total air is held at 14,000 cfm and primary air ranges between 5,000 and 6,000 cfm, maintaining a coal flow of 140 lb per min. After the last shell is charged, usually in about 20 min., total air is reduced to 13,000 cfm and primary air increased to 6,500 cfm, raising coal flow to 190 lb per min. Volume of primary air is never allowed to exceed that of the secondary to prevent blow-back of coal into the secondary lines. The best indicator of rate of fuel consumption is the steam flow from the boiler and under charging conditions this is held at 40,000 lb per hr. During the reducing blow it is maintained at 58,000 lb per hr. Gases enter the boiler at a temperature of 2300° and leave the economizer at 590°. Temperature at inlet to U-tubes is 540 and 225° entering the baghouse. Jacket cooling water amounts to 3,700 gpm and absorbs 2 million Btu's per min. or 44 pct of total heat input.

The blast furnace slag now averages 13 pct zinc and de-zincd slag 1.8 pct

zinc, which indicates a recovery of 89.2 pct after allowance for shrinkage. Lead is reduced from 0.80 pct in the heads to 0.03 in the tails. Combined fume from the boiler flues, coolers and baghouse weighs 50 lb per cf and has the following analysis:

| Zn | Pb | Cu | SiO ₂ | Fe | As |
|------|-----|------|------------------|-----|------|
| 68.0 | 6.0 | 0.25 | 0.9 | 0.8 | 0.20 |

This fume is deleaded by the process developed at Tooele, which consists of roasting in rotary kilns with a small amount of coke breeze to volatilize lead oxide. From a 300 ton surge bin, the fume is carried by screw conveyor and bucket elevator to a hopper which feeds either or both kilns. 1.0 pct coke breeze is added by screw feeder. The two kilns are 5 ft 6 in. id by 75 in. long, and are fired with natural gas. Temperature is automatically maintained at 2300°F by radiation pyrometers focused on the clinker at the point of discharge. Lead oxide fume is drawn from the kilns through twenty-four U-tubes, by a 20,000 cfm fan and discharged into the lead section of the baghouse. The collected fume, carrying 38 pct Pb and 30 pct Zn is returned to the lead plant. The de-leaded clinker, weighing 150 lb per cf and carrying 76.0 pct Zn and 2.0 pct Pb drops into a Traylor tube cooler, one of which is provided for each kiln, is crushed to pass a ⅜ in. screen, and is loaded into cars for shipment to a re-tort smelter.

Electrical Resistivity Measurements on Iron-silicon Compacts Prepared by the Powder Metallurgy Procedure

FRANK W. GLASER*

Introduction

Iron-silicon alloys have had a great influence, in many ways, in modern industry. Silicon steels have been used almost exclusively for the construction of electrical machinery, but have also become an important material for structures which benefit by the high tensile and yield strengths of this material. In elaborating on the early history of work done on iron-silicon alloys, Greiner, Marsh and Stoughton¹ went back as far as 1808, and pointed to Berzelius as the first producer of ferrosilicon. During the last twenty years some very important contributions in the form of studies of the iron-silicon system, as well as of the physical properties of these alloys, have been published. In consideration of the brittleness and poor machinability of alloys containing more than 5-6 pct Si, commercial interests have stimulated the research done on iron-silicon alloys, but mainly in the range of 0 to 6 pct Si. Yensen² has shown the influence of im-

purities, such as carbon, sulphur and phosphorus on the magnetic properties of 2, 4, and 6 pct Si alloys. Corson³ extended his investigation of physical properties to approximately 32 pct Si, and attributed the brittleness of the high-silicon material to the particular constitutional features of the alloys. Though mentioned earlier in the literature, the effect of nitrogen on crystal growth and magnetic permeability of iron-silicon alloys has been demonstrated recently by Morrill⁴ and Rostoker,⁵ respectively. In all the above quoted investigations, except that of Rostoker,⁵ sand or chill casting processes were employed for the preparation of samples.

A major advantage of the powder metallurgy process is that it does away with time-consuming machining in many applications. The powder metal industry is always interested in pro-

ducing a finished product employing a material which has presented considerably greater difficulties in manufacture by other methods. Steinitz⁶ described preparation and testing of various Fe-Si alloys which were produced by the powder metallurgy process for the manufacture of armatures for small electric motors or generators. While Steinitz investigated alloys up to 6 pct Si, Rostoker⁵ went as high as 9 pct Si. The author⁷ previously discussed the diffusion of iron-silicon compacts containing 6 and 10 pct silicon.

It is the object of this paper to study the progress of diffusion occurring in iron-silicon alloys by electrical resistivity measurements. All samples were prepared by pressing and sintering of compacts. Iron, silicon, and Fe-Si powders of various mesh size and compositions were employed to obtain test samples. It was assumed that complete diffusion had been obtained when the electrical resistivity reached a constant value characteristic for that particular alloy. To this end, electrical resistance measurements were used to follow the progress of alloying under various conditions.

The difficulty of microscopic evaluation of the degree of diffusion and of approach to homogenization in Fe-Si alloys was a prime cause for this investigation. Although there have been some important publications during recent years, they have not helped to clarify the rather complex situation occurring in compacts wherein diffusion may be only partial.

Materials, Preparation of Samples and Testing Methods

Table 1 gives data concerning the powders employed for this work. All powders were mixed in appropriate proportions to give the desired overall silicon content, and were subsequently tumbled for one hour.

Samples 2.5 cm × 1 cm × 1 cm were produced by single action hot pressing in graphite dies heated by direct conduction. The hot pressing procedure was chosen in order to avoid compacting difficulties which otherwise occur during cold pressing operations with high silicon-containing powders. Relatively high initial densities were obtained by this method. In certain cases an expansion of samples was observed during the initial subsequent heating period, and was attributed mainly to the evolution of gases, an occurrence

frequently encountered in Fe-Si materials. This effect was never large enough to interfere with subsequent and continued densification, although sintering was slowed down to some extent. Pressures employed during hot pressing ranged from 1 to 2 tsi, and the hot-pressing temperature was selected to be below the melting point of the alloy.

Heating was done in a Globar-heated furnace in an atmosphere of either hydrogen or cracked ammonia. Atmosphere purity was controlled to a high degree by the use of drying towers and gettering.

Electrical testing was done with a Kelvin Bridge in which the potential drop for a current of 10 amp was measured over a length of 1.5 cm at room temperature.

In 1932 Bedel⁸ published data of experimentally determined densities of cast specimens. The data of Table 2

are as reported by Bedel and have been accepted as a theoretical density basis for all specimens prepared during this investigation. These are in good agreement with results obtained in this investigation. The comparison is given in Table 2.

Homogenization Study of Individual Alloy Compositions

50 PCT SILICON

Samples containing 50 pct silicon were prepared from: (1) silicon powder mixed with electrolytic iron powder (*powders 1 and 5*) and (2) prealloyed 50/50 ferrosilicon (*powder 4*).

Only coarse powders, through 100 mesh, could be employed during the processing of this composition, since all compacts of finer powders could not be prevented from oxidizing during heat treatment.

Samples in group (1), above, which were hot pressed at 1080°C, showed an initial increase of electrical resistivity during the first hours of heat treatment at 1180°C. After reaching a maximum, the resistivity dropped to a constant level after about 8 hr at temperature. This is similar to previously reported behavior for hot-pressed samples.⁷ Fig

FIG 1—Density and electrical resistivity vs. time at 1180°C after hot pressing. Alloy: 50 pct silicon.

FIG 2—Density and electrical resistivity vs. time at 1180°C after hot pressing. Alloy: 33.5 pct silicon.

1 shows density and electrical resistivity behavior after hot pressing and during the heating cycle. The minimum resistance value in the "as hot pressed" state is far above that of pure iron, and it is therefore believed that some diffusion had already taken place during hot pressing, thereby setting up high silicon grain boundary "barriers" to the current through a "series-resistance" network. The formation of this high resistance skeleton continued with time at temperature and increasing diffusion. After approximately 1 hr and 50 min. at temperature (1180°C), a maximum resistivity was reached for the 50 pct Si material, whereas, as previously reported, only 25 min. were necessary for the 6 and 10 pct Si materials to reach this peak value.⁷

Another possible explanation for this maximum is the formation of an Fe-Si-C phase, since some carbon was introduced during hot pressing through the use of graphite dies, and was still present at this point in the heat treatment. An intergranular phase was visible upon microscopic examination. The microhardness of this phase was much closer to that of an iron-silicon alloy than that of silicon carbide. This seems to favor the first theory. It was found that progressive decarburization of the compacts occurs during heat treatment.

Diffusion seemed to be completed after approximately 8 hr, at which point a resistivity value of 350 microhm-cm was reached. The density was relatively high for this material throughout the heat treatment and seemed to reach a maximum point of densification after only 4 hr of heating.

When prealloyed 50/50 ferrosilicon powder was hot pressed at 1080°C and heat treated at 1180°C, both the density and resistivity showed behavior

Table 3 . . . Density and Resistivity of Homogenized Material After Hot Pressing

| Hot Pressing Temp. °C. | Density Pct | Resistivity Microhm-cm |
|------------------------|-------------|------------------------|
| 1080 | 86.0 | 255 |
| 1150 | 95.5 | 250 |
| 1200 | 96.0 | 250 |

otherwise encountered only after sintering operations (see Fig 1). Contact resistance showed a gradual decrease as continued solid bonding took place between the particles. As soon as pore space was greatly reduced by densification and the measured cross-section became a true measurement (after approximately 6 hr), the same resistivity of 350 microhm-cm was reached. When this prealloyed material was hot pressed at 1200°C, this resistivity value was reached immediately, and the concomitant density was approximately 100 pct. The use of higher hot pressing temperature thus eliminates approximately 6 to 8 hr of heat treatment.

The density of iron-silicon powder mixtures, initially hot pressed at this higher temperature (1200°C), did not differ from that obtained at a lower hot pressing temperature (1080°C). Resistivity, however, was approximately 125 microhm-cm higher at this initial stage, due, presumably, to further progress of diffusion. The curve then followed substantially the aforementioned trend of peak and decrease, reaching complete diffusion at similar time and resistivity values. Samples containing 48.3, 44.1 and 42.2 pct Si, by analysis, were prepared by this same method and showed similar behavior in the relationship between time at temperature and both resistivity and density. Resistivity data for these

compositions are reported in a subsequent portion of the text.

33.5 PCT SILICON

This composition was prepared by mixing silicon powder with electrolytic iron powder and hot pressing at 1080°C. Coarse and fine powders behaved alike, and in general it can be said that resistivity and density followed the same general trend as the 50 pct Si alloys throughout the heating period (Fig 2). Only after 10-12 hr was homogenization accomplished. The final resistivity value reached, at complete diffusion, was 235 microhm-cm. This is in agreement with values obtained by Corson³ for cast materials of similar composition. Some of the completely homogenized material was crushed to powder (through 100 mesh), and re-pressed at various temperatures. Table 3 gives the results for these homogenized materials when hot pressed at various temperatures.

It is obvious from Table 3 that the resistivity is not dependent on the density in this range. Complete diffusion had occurred in all three cases during the prealloying, and the slightly higher resistivity of these samples was attributed to thin grain boundary oxide films which were found to be present during metallographic examinations. The structure of the above three specimens was substantially the same as for samples fully homogenized by heating for 11 hr.

20 TO 27.5 PCT SILICON

A 27.5 pct Si alloy was prepared by mixing a 50/50 Fe/Si master alloy with electrolytic iron powder. The powders (-325 and -100 mesh mixtures) were hot pressed at 1080°C and after a subsequent heat treatment of

FIG 3—Density and electrical resistivity vs. time at 1180°C after hot pressing. Alloy: 27.5 pct silicon.

FIG 4—Density and electrical resistivity vs. time at 1180°C after hot pressing. Alloy: 25 pct silicon.

†Extrapolated.

approximately 6 hr at 1180°C a constant resistivity level was reached.

The 25 pct Si alloy was made up by hot pressing a commercial, pre-alloyed 75/25 alloy at 1080°C with a subsequent heat treatment at 1180°C. A state of constant resistivity was obtained after approximately 8 hr of heat treatment for both fine and coarse powders.

The 20 pct Si sample was produced by mixing a 75/25 master alloy with electrolytic iron powder. Only a -325 mesh powder was employed for this composition.

Fig 3, 4 and 5 show the relationship of both the resistivity and density to time at temperature. Trends substantially similar to those observed in previous experiments are noted. Some difference in behavior is noticeable if one considers the particle sizes employed.

For the 27.5 pct Si alloy, the coarse powder follows a rather normal pattern to complete homogenization. The process was slowed down considerably in the case of finer powder because relatively more surface area is exposed to oxidation. This is contrary to the usual alloying process occurring in powders, where the finer powder mixes usually

Table 6 . . . Fe-Si Alloys Annealed in H₂ and Cracked NH₃ Atmospheres

| Approx. Pct Si | Resistivity, Microhm-cm | |

| 25 | 210 | 205 |
| 32 | 239 | 235 |
| 50 | 355 | 350 |

reach equilibrium faster.

The 25 pct Fe-Si alloy behaved normally; the finer powder was densified in about half the time required for the coarser powder. Apparently the 50/50 Fe/Si master alloy which was employed in producing the 27.5 pct Si sample had a greater tendency to oxidize than did the 75/25 master alloy.

When fully homogenized 20 pct and 27.5 pct Si alloys were crushed to pass through a 100 mesh and hot pressed at 1080°C, their final resistivity values were obtained immediately on hot pressing. For the commercial, pre-alloyed 75/25 Fe/Si alloy, the hot pressing temperature had to be raised to 1200°C, in order to reach the final

Table 5 . . . Percent Carbon in Fe-Si Compacts After Various Heat Treatments

| Pct Si | Pct Carbon | | | | |
|--------|----------------|-------------------|------|-------|-------|
| | As Hot Pressed | 25 Min. at 1180°C | 4 Hr | 10 Hr | 15 Hr |
| 6 | 0.12 | 0.10 | 0.08 | 0.07 | 0.04 |
| 10.1 | 0.13 | 0.04 | 0.04 | 0.04 | |
| 12.5 | 0.13 | 0.03 | 0.03 | | |

resistivity value of this material immediately after hot pressing. When pressed at a lower temperature (1080°C) 8 hr of subsequent heat treatment were needed to attain constant resistivity.

A similar behavior had been noticed with regard to the 50/50 alloy. The precise reason for this difference is not known. Also, the method of manufacture of the commercial material is not known. It is known, however, that the homogenized powders used in this investigation (made by hot pressing and heat treating) were used within a fairly short time after crushing (12 hr max.), and were stored in desiccators even during this interval. Surface oxide film on the commercial powder may account for the increased resistance values found in the hot pressed (1080°C) condition.

6 TO 18 PCT SILICON

All compositions were prepared as shown in Table 4. Testing was done for heat treating times ranging from 25 min. to 17 hr and, with regard to electrical resistivity and density, all materials followed the trends discussed before for other Si alloys. Final resistivity values are also given in Table 4. Some values found in the literature have been entered in the table for comparison.

FIG 5—Density and electrical resistivity vs. time at 1180°C after hot pressing. Alloy: 20 pct silicon.

FIG 6—Time needed for complete diffusion for iron-silicon samples prepared from different master alloys. Hot pressing temperature 1080°C. Subsequent heat treatment at 1180°C.

Table 7 . . . Resistivity Values for Fe-Si Alloys After Complete Diffusion

| Pct Si (by analysis) | Resistivity (microhm-cm) | Pct Si (by analysis) | Resistivity (microhm-cm) |
|----------------------|--------------------------|----------------------|--------------------------|
| 6.0 | 85 | 20.1 | 152 |
| 9.0 | 110 | 25.2, 25 | 182, 180.5 |
| 10.1 | 115 | 27.6 | 200 |
| 11.5 | 116 | 33.5 | 240 |
| 12.5 | 60 | 42.2 | 303 |
| 13.1 | 55 | 44.1 | 320 |
| 15.2 | 55 | 48.3 | 340 |
| 16.6 | 62 | 49.8 | 350 |
| 18.2 | 65 | | |

Fig 6 indicates the time needed for different samples to reach complete diffusion. It is interesting to note that when master alloys are sintered by themselves, both the 50/50 and the 75/25 require the same time (7 hr at 1180°C) to reach constant resistivity.

For a given alloy mixture, 85/15 master alloy requires a somewhat shorter time at temperature, as compared with 75/25, to reach constant resistivity. Also, the less iron added to the 75/25 mixtures (approaching the composition of the master alloy), the longer the time required for equilibrium. If not hot pressed, much longer times at temperature than those reported in Fig 6 are necessary to obtain

complete diffusion in iron-silicon materials produced by powder metallurgy processes. Hot pressing temperatures were controlled optically and it is probable that the indicated temperatures were no more precise than plus or minus 20–30°C. Considering the fact that a few degrees C in this temperature range, which is quite critical for these Fe-Si materials, will influence the speed of diffusion considerably, the times reported in Fig 6 represent approximate values.

Carbon analyses have been run for some materials containing 6, 10.1 and 12.5 pct Si, and the results are tabulated in Table 5.

Inasmuch as the original raw material contained less than 0.03 pct C, the C picked up during hot pressing seems to be as high as 0.09 to 0.10 pct.

Metallographic examination disclosed substantial surface carburization of the compacts, and certainly a good portion of both the increased carbon found on hot pressing and the loss of carbon observed after heat treating can be attributed to the carburization and subsequent decarburization going on in the skin of the compact during its cycle.

A comparison has also been made for resistivities obtained with samples annealed in H₂ vs. samples annealed in

cracked ammonia. Table 6 shows that the nitrogen contained in this latter atmosphere does not seem to have much influence on the electrical resistivities of Fe-Si alloys.

A characteristic trend of minimum, maximum and constant resistivity level was established as a function of diffusion time for iron-silicon samples prepared from powder mixes.

At the minimum resistivity (the “as hot pressed” stage), diffusion of the silicon into the iron was far from complete, but a certain amount of bonding between particles had taken place. The current passed through a low resistance network. After a given time interval at temperature, diffusion created a high resistance silicon-iron network, accounting for the maximum resistivity. Diffusion, progressing with time, reduced the resistivity to a constant level. If a given ferrosilicon composition was prealloyed by the hot pressing and heat treating procedure, and subsequently crushed to –100 mesh, final resistivity was obtained immediately on hot pressing at 1080°C.

Hot pressing temperatures, higher by 120°C, were required for commercial prealloyed powders to obtain final resistivity immediately upon hot pressing. Grain boundary oxide films are

believed to be the cause for the necessity of this higher hot pressing temperature. If a commercial, prealloyed, powder was hot pressed at normal hot pressing temperature, 8 hr of subsequent sintering time was needed to arrive at final resistivity values.

General Discussion of Results

Table 7 shows the resistivity values the author measured for various Fe-Si alloys after complete diffusion. Data as given by Corson³ have been plotted together with these values in Fig 7.

Distinct differences between the values obtained in these two investigations, especially in the 20–30 pct Si ranges, can be noticed in Fig 7. The present values are generally higher than those reported by Corson, whose specimens were prepared by casting. A comparison of grain size of the alloys employed during the respective investigations disclosed striking similarities. Since no comparisons with regard to chemical purity can be made it can only be pointed out that all Si percentages employed in this investigation have been carefully checked by chemical analysis, and tests have frequently been repeated to minimize any source of error. It will also be recalled that while the samples for the author's experiments have been produced by several methods, the final test results have never varied more than 3 to 5 pct.

All samples were tested for hardness, and Fig 8 shows the relationship of Rockwell hardness vs. silicon content for the fully homogenized samples. Hardness values in Fig 8 are higher for the higher silicon ranges than the values reported by Corson. There may be some relationship between the higher hardness and the higher resistivities as reported in Fig 7.

Metallographic examination of specimens in the 11–25 pct region suggest no cause for the shape of curves for hardness and resistivity. One explanation, recorded by Hansen,¹⁰ was the presence of an order-disorder transformation. An X ray diffraction study of 12.5 pct and 16.6 pct Si alloys showed the presence of lines which were absent in a 10.1 pct Si alloy. These lines corresponded to the calculated positions of the 111 and 200 reflection, and thus are taken to indicate the existence of an ordered state. In this connection it

FIG 7—Electrical resistivity vs silicon content for fully homogenized samples.

FIG 8—Hardness vs silicon content for fully homogenized samples.

might be of interest to note that some heat treatment experiments have been made with a 15.2 pct Si-containing material. One specimen was kept at 1180°C for 72 hr and cooled to room temperature over a period of approximately 5 hr, while another specimen was quenched in water after this prolonged time at temperature. In both cases the resistivity values as reported for this composition in Fig 7 were still found and no marked difference in structure between these two specimens could be found upon metallographic examination.

Summary

1. It has been shown that the degree of diffusion in iron-silicon alloys prepared by the powder metallurgy process

can be followed by electrical resistivity measurements. In the higher density ranges, the electrical resistivity is a function only of the diffusion process and is very much influenced by changes of the Si concentration in a non-homogeneous Fe-Si alloy.

2. Values for the specific electrical resistivity of iron-silicon alloys containing between 6 and 50 pct silicon have been determined.

3. It has been further shown that the hot pressing and heat treating process can be used to produce iron-silicon materials in suitable forms.

4. No major effects upon the electrical resistivity of an atmosphere containing nitrogen were detected for iron-silicon alloys.

5. The resistivity curve shows a break between approximately 11 and 25 pct Si.

Acknowledgment

A portion of this investigation was carried out under Contract NOa(s)-8959, of the U.S. Navy, Bureau of Aeronautics, and the results are presented with the permission of this agency. The author wishes to express his thanks to this Bureau for permission to publish these data.

The writer also wishes to express his gratitude to Messrs. W. Ivanick, R. Steinitz, S. J. Sindeland and R. Wachtell, for their advice and assistance in the preparation of this paper, as well as to Professor J. T. Norton for his cooperation in carrying out the X ray diffraction study.

A Metallographic Description of Fracture in Impact Specimens of a Structural Steel

M. BAEYERTZ,* Member AIME, W. F. CRAIG, JR.* and E. S. BUMPS*

Metallurgists have looked at fractures macroscopically for many years and have evolved a vocabulary in which such words as "cleavage," "brittle," "shear," "ductile," "granular," "fibrous," and "silky" are used to describe the appearance of the fractured surface; but the meaning of these words in terms of metal structure is not well established. Observations of the structural meaning of "brittle" and "ductile" fractures in plate steels have been made, notably, by Kramer and coworkers¹ and by Tipper.² Grossman³ has studied the fracture of tempered martensite and combinations of ferrite and martensite. Notwithstanding these and other less concerted attacks on the problem, present understanding of fracture rests more on assumptions and logic than on experiment. It is the purpose of this paper to add a little to the growing fund of experimental observations of the nature of fractures in steel. The particular fractures to be described were obtained in conventional impact testing of an ordinary structural steel shape.

In impact tests of the Charpy type, the specimens fail in a characteristic manner that depends on the steel and the temperature of testing. With ordinary structural and many other steel products, an appropriate range of testing temperature will cause a considerable change in the energy absorbed before fracture. This change is known as the energy transition and is accompanied, more or less closely, by alteration in the appearance of the fracture. At testing temperatures below the transition, the terms "brittle," "cleavage," or "granular" are used to describe the fracture; above it, "ductile" or "shear" are often used. Within the transition, the fracture changes from "brittle" to "ductile" by a progression in appearance, wherein the "brittle" portion of the fracture becomes restricted to a smaller and smaller central area of the fracture, as the testing temperature is

FIG 1—Relation of energy to testing temperature obtained from V-notch Charpy specimens from an ordinary structural steel shape.

raised and the "ductile" type of fracture is approached. All this is well known to metallurgists.

The specimens under consideration are of the conventional V-notch Charpy type. They were taken from a structural steel shape of the following analysis:

| C | Mn | P | S | Si |
|------|------|-------|-------|------|
| 0.17 | 0.46 | 0.009 | 0.029 | 0.03 |

Both longitudinal and transverse specimens were tested and examined. Fig 1 shows the energy values plotted against testing temperatures in the usual way. The curves for both longitudinal and transverse specimens show an energy transition, although the maximum energy absorbed at testing

temperatures above the transition is greater in the case of the longitudinal specimens.

Fig 2 illustrates the changes in the macroscopic appearance of the fractures that are associated with the energy transitions shown in Fig 1. Macrographs of the fractured surfaces of the specimens have been identified with the fracture ratings at intervals on each fracture curve. The numerical fracture rating on the ordinate of Fig 2 indicates the percentage of the area of each fracture that was considered to be "brittle" on macroscopic observation. Such rating of the fracture type in impact tests is now customary in many laboratories. Hereafter the specimens will be identified by reference to Fig 2 as 90 pct "brittle," 80 pct "brittle," and so on, in accordance with this macroscopic evaluation of the appearance of the fractured surface.

The discussion of the fractures is divided into three parts. The first two are concerned with the mode of fracture and its relation to general structural features. As the same metallographic features occur in both longi-

FIG 2—Relation of type of fracture to testing temperature obtained from V-notch Charpy specimens from an ordinary structural steel shape. Corresponding energy curves are shown in Fig 1.

tudinal and transverse fractures, differing in degree and distribution but not in kind, the illustrations and description are drawn from both types of specimens. The third part of the discussion deals with some relations between the structural features of fracture and the energy values obtained in the test. In this part the relation between longitudinal and transverse data will be discussed.

Character of the Fractured Surface

Leaving aside for the moment consideration of "ductile" fracture, the most prominent feature of the fractured surfaces in Fig 2 is the group of shiny facets to be seen on the "brittle" regions. These facets look alike and are of about the same size regardless of testing temperature, as

Fig 5—(Continued)

long as they appear at all. This suggests a relation to the structure of the steel.

On raising the magnification, but still looking toward the fractured surface, the facets have the appearance illustrated by Fig 3. It now becomes apparent that the facets are not alike, as they seemed at lower magnification. Instead, straight cleavage planes characterize the low temperature end of the transition range, while definite and then pronounced evidence of deformation is observed on the cleavage facets as the high temperature end of the transition range is approached. "Cleavage" as used here and in the rest of the paper is crystallographic cleavage, not the loose application of the term to describe the macroscopic appearance of the fracture.

At low testing temperatures, represented by the specimens with 100 pct

and 90 pct "brittle" fractures, the cleavage planes are flat and resemble the cleavage facets of ferrite described by Zapffe and Moore⁴ and by Kramer and coworkers.² The cleavage planes make well defined angles with each other that appear to be the 90° angles to be expected from the {100} cleavage observed in ferrite by Barrett, Ansel and Mehl.⁵ Tipper² has found that the {100} cleavage is that shown by the ferrite in ship plate fractures.

As the testing temperature is raised, the tendency for multiple cleavage on several of the {100} family appears to diminish, giving rise to the larger, comparatively smooth facets shown by the 80 pct "brittle" fracture. Also there is another change in the character of the fracture. Small ripples appear on the cleavage surfaces. These ripples are believed to be caused by cold work, either prior to or at the time of

cleavage. It is difficult to distinguish between prior and concurrent cold work, but the complexity of slip directions to be seen as the testing temperature is raised suggests that at least a part of the slip occurs in the ferrite before cleavage takes place. A part of the rippling may be caused by the stress waves set up by the operation of cleavage.

Multiple slip in three directions on single cleavage facets may be seen in the micrographs of the 30 pct and 10 pct "brittle" fractures. The extent of such slip probably is related to the orientation of the ferrite grain with respect to the stress pattern. Two micrographs are included in Fig 3 for the 60 pct and 10 pct "brittle" fractures. Each pair of photographs shows qualitatively the range in the amount of slip observed on the various cleavages of the fracture.

The final micrographs in the series in Fig 3 illustrate the highly distorted cleavage planes observed in the 0 pct "brittle" fracture obtained with a testing temperature of 210°F. Macroscopically this fracture appeared to be 100 pct "ductile," as may be seen in Fig 2. Microscopically the same sort of cleavage facets are to be seen in the central region of this "ductile" fracture as were observed on the "brittle" regions of the other fractures, with the exception that the cleavage facets of the "ductile" fracture are so rumpled by cold work that they do not reflect enough light to be detected macroscopically as cleavage facets. Thus, under the triaxial loading in an impact specimen during testing, "ductile" fracture appears to be initiated by ferrite cleavage in essentially the same way as in the more "brittle" fractures that are obtained at lower testing temperatures.

The Mode of Fractures

Turning from examination of the fractured surface to the metal below the surface, even more light is shed on the mode of impact fracture in ordinary structural steel. For this part of the study, the fractured specimens were plated with nickel, sectioned and prepared for metallographic examination. In each specimen the section studied lay on a plane that was normal to the fractured surface and extended from the notch to the back of the specimen.

Fig 4 and 5 are illustrations of the

structural features observed in the metal below the "brittle" and "ductile" portions of fractures. Fig 4 shows a section normal to a 90 pct "brittle" fracture. The portion on which the ferrite cleavages were observed is included by the bracket. Similarly, Fig 5 shows a section normal to a 60 pct "brittle" fracture. The thickness of the specimen after fracture (distance between the notch and the back of the specimen) indicated the greater reduction before final rupture in the specimen having the 60 pct "brittle" fracture. In Fig 5, the region of ferrite cleavage is restricted and cold work, especially at the notch, has become more apparent than in the 90 pct "brittle" specimen in Fig 4. For the purpose of orienting the reader, the figure numbers of photographs at higher magnification to be described below have been placed in their respective positions along the fracture in Fig 5.

On examination of the metallographic sections at higher magnifications, the mode of development of the fracture becomes evident. With the exception of shock twinning at low testing temperatures, to be discussed later, the essential details of cleavage, deformation and fracture did not vary throughout the transition range, although these features apparently differed in amount with change in testing temperature. Because of this similarity in the mode of cleavage, deformation and fracture, illustrations will be drawn from several of the specimens broken within the transition.

The metallographic evidence sup-

ports the following sequence of events leading to the final rupture of the specimens. As the hammer of the impact testing machine strikes the specimen and bends it, elastic and then plastic deformation occurs. Within the general region of greatest triaxiality of loading located somewhat back of the notch in the specimen, the restraint to deformation and the nature and temperature of the steel are such as to cause cleavage within the ferrite grains when the tensile stress normal to a cleavage plane reaches an appropriate value. The ferrite cleavage may occur either within the elastic or the plastic portion of deformation depending upon the testing temperature. The cleavage occurs only in grains or groups of grains whose cleavage planes are favorably oriented with respect to the stress pattern. Such cleavage involving two ferrite grains is indicated by the arrow on the right side of Fig 6, and is shown at higher magnification in Fig 7. Other similar cleavages are shown in Fig 8. In the fractured specimens, such cleavages were observed only in the immediate vicinity of the fracture.

As described previously and illustrated by Fig 3, cleavage at the low temperature end of the transition apparently occurs before the yield point is reached. At the high temperature end of the transition, there is evidence of cold work preceding cleavage. Intermediate stages between these two extremes occur within the transition range. Evidence of deformation before cleavage at the high temperature end of the transition is to be seen also in the samples prepared for metallographic study. Fig 9 shows cleavage involving three ferrite grains in a 10 pct "brittle" specimen. The bent cleavage on the right side of the micrograph is taken as an indication of cold work before cleavage. Deformation after cleavage would be expected to separate the two surfaces of the cleavage in the manner illustrated by the cleavage at the fracture surface in Fig 8.

To continue with the events preceding final rupture, the greater the extent of cleavage the less will be the effective section of the metal left to withstand subsequent loading during the test. Also the stress pattern will be altered, because each cleavage will now have become an internal notch. In the next stage the metal between the cleavages, and that in the peripheral regions of low triaxiality of

stressing, deform and fracture. Evidences of deformation in the peripheral "ductile" region have been illustrated already in Fig 2, 4 and 5. Microscopically, the fracture of such regions is illustrated by Fig 10.

In the central "brittle" region, one feature of the deformation after the cleavage is the pulling apart of cleavages formed earlier. Numerous cleavages are formed in the general region of the final rupture, but only a limited number form a part of the path of ultimate rupture. Some of the cleavages remain intact as indicated by the

arrow on the right side of Fig 6 and in Fig 7. Others are pulled apart as indicated by the arrow on the left side of Fig 6. This crack was filled with nickel when the specimen was plated. It may be seen in more detail in Fig 11. The upper surface of the cleavage has pulled away from the lower surface, and in so doing, has broken apart two colonies of pearlite. Similar pulling apart of cleavages may be seen in Fig 8. Fig 12 shows an instance in which stepwise slip occurred on the upper half of the cleavage during deformation subsequent to cleavage but

preceding final rupture. Apparently ferrite grain boundaries constitute a weak region where the cleavage extends through adjacent grains, as illustrated by Fig 13.

When more than one cleavage occurs in a ferrite grain, as on the left of Fig 8, the final path of fracture may include the several cleavages. In such a case the final rupture occurs by tearing between the cleavages, as indicated in Fig 14. The arrows indicate the torn edges.

In the absence of experimental observations, there has been an inclination

FIG 12—Evidence of stepwise slip that preceded final rupture in a 60 pct "brittle" fracture.

on the part of some metallurgists to blame the initiation of "brittle" fracture on phases of little ductility such as carbides or nonmetallic inclusions. No evidence of this has been obtained in this study. On the contrary, the evidence suggests that the cleavage of ferrite initiates "brittle" fracture. To support this viewpoint are the observations of intact pearlite colonies, as in Fig 7 where the cleavage has involved ferrite grains on both sides of the pearlite colony.

There were far fewer inclusions than pearlite colonies in the steel, so that the opportunity to observe their role was limited; however, none of the observed ferrite cleavages could be definitely attributed to inclusions. The inclusions were as apt to be present in the torn regions between the cleavages as near the cleavages. Fig 15 shows a (Mn, Fe)S inclusion

still adhering to a torn region of the fracture. While the evidence presented here does not prove conclusively that cementite or inclusions do not initiate the cleavage, yet it seems sufficient to cast doubt on this explanation as the primary cause of the cleaving of ferrite in the impact test. More experimental observations are needed.

Shock twins occurred frequently near the fracture in specimens broken at the low temperature end of the transition, and grew infrequent and then practically disappeared as the testing temperature was raised. Thus a greater proportion of energy went into the formation of twins at the lower than at the higher testing temperatures. Typical shock twins are indicated by the arrows in Fig 16. There was no evidence that the observed ferrite cleavage follows the plane of shock twinning. This was to be antici-

pated from the work of others⁴ who have reported that the twinning and cleavage planes in ferrite are {112} and {100} respectively. The lack of coincidence is illustrated by Fig 16 in which the shock twins and a cleavage facet occur at a slight but definite angle with respect to each other. If the cleavage had resulted from weakness of lattice registry along the interface between the shock twin and the parent ferrite grain, one would not expect the structure shown in Fig 16.

Dependence of Transverse and Longitudinal Energy Values on Structure

This portion of the discussion is based on more limited observations than the foregoing description of the mode of fracture; however, it seems

FIG 16—(above) The arrows indicate shock twins near the surface of a 90 pct "brittle" fracture.

Note that the shock twins and the cleavage facets occur at a slightly different angle.
1500 X. Etchant 2 pct nital.

FIG 17—(below) Evidence that cleavage is sometimes arrested by pearlite colonies.

500 X. Etchant 2 pct nital.

worthwhile to present it in an attempt to explain the differences between longitudinal and transverse energy values. It may be noted in Fig 1 that the energy curves for both longitudinal and transverse specimens start to rise at about the same testing temperature. Also, although the maximum energy values differ, both types of specimens reach their maximum energy value at about the same testing temperature. Furthermore, the macroscopic fracture appearance is similar for both longitudinal and transverse specimens at each testing temperature. These observations strongly suggest that the mechanism of the fracture is the same in both longitudinal and transverse specimens, but that the ease of fracture is altered by the well known anisotropy of rolled steel products such

as the structural shape used in this work. We believe that the explanation of the ease of fracture in the transverse specimens is to be found in the ferrite banding in the steel.

In Fig 4, ferrite cleavage occurs quite generally throughout the "brittle" region of the fracture. This is the case for both longitudinal and transverse specimens of 80 pct and 90 pct "brittle" fractures. There is not much divergence of the energy curves in Fig 1 with these fractures.

The situation is quite different with fractures from the middle of the transition. In these fractures ferrite cleavage is more prevalent in the ferrite bands, whereas the bands containing more pearlite show greater deformation before fracture. It may be that pearlite even arrests the

cleavage. There is some evidence for this, as illustrated by Fig 17, where the cleavage that ends in the pearlite colony has not advanced. Instead, the steel to the right of the cleavage has deformed considerably after the formation of the ferrite cleavage. Whether pearlite stops the cleavage may be open to some question, although it seems to be the case.

It has been shown already that ferrite cleavage constitutes the initial stage of the failure. Now, in the transverse specimens the uninterrupted bands of ferrite lie roughly parallel to the surface of final fracture, as illustrated by Fig 18. It seems reasonable to suppose that there would be more ferrite cleavage in these bands in the initial stages of fracture than in the rest of the structure. In this case the

FIG 18—Cleavage in a ferrite band in a 50 pct "brittle" fracture of a transverse specimen.
100 X. Etchant 2 pct nital.

ferrite bands would form a potential path of fracture, only needing to be joined by rupture of the intervening bands that contain pearlite. This explanation assumes a greater amount of ferrite cleavage in the "brittle" part of the fracture of transverse specimens, in order that the absorbed energy of the transverse specimens be less than for the corresponding longitudinal specimen in the middle and upper portions of the transition range. This was not checked quantitatively because of the experimental difficulties involved, so that the above explanation is to be considered only as a reasonable assumption based on the observed mode of fracture.

Summary

It cannot be too strongly emphasized that the fractures that have been described were observed in impact specimens from a single structural steel shape. The essential details of the mode of fracture are thought to be common to mild steel of this type,

but more observations are needed to round out the general picture.

Throughout the transition revealed by the impact test, fracture in this steel was initiated by cleavage of ferrite grains situated in the general region of maximum triaxiality of stressing during the test. At the low temperature end of the transition, ferrite cleavage occurred during or soon after the end of elastic deformation. It was often accompanied or preceded by shock twinning of the ferrite. At higher testing temperatures within the transition, shock twinning gave way to deformation by slip. In the high temperature end of the transition, cold work apparently occurred both before and after the ferrite cleaved.

After the initiation of the fracture by ferrite cleavage, a second stage of the fracture consisted of opening up the ferrite cleavages and deformation and rupture of the metal between the cleavages. Deformation and rupture of the peripheral regions of the specimen also formed a part of the second stage of fracture.

The experimental observations sug-

gest that hard phases such as cementite and inclusions are not to blame for initiating ferrite cleavage in mild steel. In fact, there was some evidence that pearlite could arrest ferrite cleavage and confine it to a ferrite band, at least in the middle and the high temperature end of the transition.

The tendency for the initial ferrite cleavage to extend quite generally throughout the ferrite band and the directional extent of these bands in rolled mild steel products is offered as a possible explanation of the difference in the energy values obtained with longitudinal and transverse specimens.

Recovery and Recrystallization in Brass

B. L. AVERBACH,* Junior Member AIME

Recovery and primary recrystallization in cold worked metals are usually considered as two competing processes. Some of the effects which usually accompany recovery are: alleviation of stress corrosion tendencies, changes in thermal emf,¹ damping capacity,² electrical resistivity,² and magnetic properties,³ and only minor changes in hardness or the related strength properties. During primary recrystallization new unstrained grains are formed at the expense of the strained matrix. These new grains eventually become visible metallographically, and nucleation and growth kinetics have been indicated for this process.^{4,5}

Frequent attempts have been made to study the cold-working phenomenon by observations on the line broadening by X ray diffraction patterns. Relatively few measurements of line intensities have been made, although Brindley and his collaborators,^{6,7,8} by means of film techniques, compared the intensities of cold worked Cu, Ni, and Rh patterns with those from chemically precipitated powders. These precipitated powders were presumed to be strain free, and it was found that the intensities for the cold-worked materials progressively decreased as the Bragg angle increased except for the first line, where there was an increase due to reduction in extinction. This was interpreted as a randomness in atomic position induced by cold work. Such randomness is similar to that caused by thermal agitation and has been described as "frozen heat" displacement of 0.08–0.10 Å from the mean atomic position.

In a recent study⁹ on the effect of cold work in metals on their powder pattern intensities, the changes in integrated intensity for heavily cold worked alpha brass were observed as a function of the annealing temperature. These measurements were made with a manually operated Geiger-counter spectrometer using $\text{CuK}\alpha$ radiation monochromated with a rock salt crystal. Intensity measurements were made with a scaling meter over small intervals of angle, and the equipment

was so arranged that the diffracted and incident beams made equal angles with the specimen. Intensities could be compared directly by simply interchanging specimens, and comparisons from day to day were made with a standard whose line intensities did not change on aging. It was shown that a cold worked alpha brass standard was stable for at least a year.

Table 1 indicates the results of the integrated intensity measurements on a 70 Cu-30 Zn brass. In the sample preparation, a brass plate was first cold rolled 50 pct and then filed, screened to -325 mesh, compacted into briquettes at a pressure of 60,000 psi and finally annealed for one hour at various temperatures up to 400°C. The briquetting pressure did not seem to influence the integrated intensities, and most of the cold work was introduced by the filing. Although this method of cold work is not quantitative, it was used to obtain random orientation (and thus uniform diffraction lines) in order to make accurate measurements of integrated intensity. Back reflection patterns were taken in each case to check the uniformity of the lines, and from the observed line broadening it was apparent that this type of plastic deformation was quite severe.

Care was taken to traverse the entire background of the pattern and to assign to each peak the total intensity above this background. The bases of the diffraction lines were quite broad and spread out over several degrees, even for the narrow peaks. The theoretical intensities were calculated to include a temperature correction, a dispersion correction, and a Lorenz-

FIG 1—(above) Change of extinction coefficient with annealing temperature for cold worked brass (70 Cu-30 Zn).

FIG 2 (below)—Effective particle sizes calculated from extinction coefficients.

polarization factor corrected for the crystal monochromated beam. In Table 1 it was necessary to match the calculated and observed values at only one point, and the rest of the experimental values were converted directly to this arbitrary scale. The integrated intensities in Table 1 are listed in arbitrary units, and the accuracy was sufficient to reproduce any of the measured line intensities to within ± 1.5 units. It is evident that the percentage error on the strongest line (111) was quite low.

The calculated values and the observed intensities for the cold worked material matched reasonably well. As the annealing temperature was raised, however, the intensity of the strongest reflections, particularly the (111), decreased measurably. Since the background intensities of all of these patterns were identical, such behavior could be interpreted as a primary

↔ Indicates where calculated and measured intensities were matched.

extinction effect, and it is apparent that cold work reduces this extinction considerably. The calculated values take no account of extinction, and the agreement between the cold worked and calculated intensities indicates that the deformation induced by filing was severe enough to practically eliminate extinction. The extinction coefficient, $\frac{I \text{ (with extinction)}}{I \text{ (without extinction)}}$, was calculated from the (111) lines, since the accuracy is greatest here, and these coefficients are plotted in Fig 1.* There is a sharp break at 200°C, and this sudden increase in extinction was subsequently associated with the onset of primary recrystallization.

The data presented in Table 1 are not sufficiently accurate to determine whether the intensities of the back reflection lines in the cold worked material were measurably lower than those of the annealed samples. The observations listed here were made in such a way as to accentuate the accuracy of the low angle high intensity lines. When more accurate intensity determinations were made in the high angle region,⁹ it was shown that both cold worked and annealed materials diffracted the same integrated intensity for the relatively weak (400) line if all of the intensity above the true background was considered. The determinations based on film measurements can suffer inherent difficulties in the comparison of intensities from one film to another, and in the determination of the true background. These discrepancies may be sufficient to account for the diminished intensity originally observed in the high angle lines of cold worked materials.

In order to determine the cause for the sudden change in the extinction curve in Fig 1, observations were made on the hardness, the half-maximum

diffraction line width, and on the metallographic structure. For the hardness test, the surfaces of the compacts were first given a metallographic polish with diamond dust and a large number of Tukon hardness readings were made on the individual filings at a load of 25 g. Although some scatter was obtained because of insufficient support under individual filings it was felt that the hardness readings from one specimen to another were comparable and the results are plotted in Fig 3. Each point in the figure is the average of at least five readings. The sharp dip in the hardness at about 225°C is usually taken as indicating the inception of primary recrystallization. Similarly the half-maximum line widths (plotted in minutes) also fall rapidly at about 225°C and this is indicated in Fig 4. It should also be noted that prior to this sharp dip the lines did not behave in uniform fashion, some lines increasing in width and others decreasing in width as the recovery temperature was raised.

From the microstructures, which are shown in Fig 5 and 6, it is difficult to determine the inception of recrystallization. Because of the heavy cold working the recrystallized grain size is very small and although there seems to be a subtle difference between the structures at 200 and 225°C, the strain-free grains are not observed in the microstructure until considerable growth has occurred. The X ray pattern first became spotty after a 400°C treatment and the microstructure in Fig 5 indicates that visible growth has occurred by then. The combined evidence can be taken, however, to indicate that recrystallization takes place starting at 225°C.

It is difficult to assign directly the cause for the reduction in primary extinction by plastic flow in a crystal. Above 200°C, recrystallization, and therefore grain growth, is involved and the extinction could be assumed to be a particle size effect. If the classical Darwin formula* is applied to these data one obtains an "effective particle size" of $2-6 \times 10^{-5}$ cm. These particle sizes are plotted in Fig 2 as a function of annealing temperature, and if the data are extrapolated below 100°C, one obtains an effective particle size of 2×10^{-5} cm at room temperature. Each of the measured particle sizes

FIG 5—Micrographs of brass filings. 750 \times .

a. Cold worked. b. Annealed 1 hr at 150°C. c. Annealed 1 hr at 200°C. d. Annealed 1 hr at 225°C.

is accurate to at least one significant figure and if the experimental error in the measurement of the cold worked (111) line is computed it can be seen that the cold worked particle size is probably not smaller than 1×10^{-5} cm and is probably closer to the extrapolated value of 2×10^{-5} cm. If the recrystallized grain size is estimated at 400°C from the micrographs in Fig 6 one obtains about 20×10^{-5} cm. The X ray beam averages the extinction of both the cold worked and the annealed regions, so that for the entire specimen one obtains a weighted average value of about 7×10^{-5} cm and this fits the extrapolated X ray-values quite well.

The presence of a nonuniform strain, even if it is an elastic strain, can also reduce extinction in crystals. It would be possible, therefore, to ascribe at least part of the extinction effect to nonuniform strains introduced by the deformation. However, Heidenreich and Shockley,¹⁰ using an electron microscope technique obtained a particle size of about 0.2×10^{-5} cm in cold worked aluminum, and observed in addition a two stage process of

growth. The first stage consisted of a rather slow growth of a few small strain-free areas, and this corresponded to the usual recovery stage. In the second stage a very rapid growth of strain-free areas occurred and this is the phenomenon usually observed during recrystallization. It would be difficult to interpret Heidenreich's results in terms of an overall strain relief, so that it seemed reasonable to assume that the small change in extinction during the recovery stage could have been caused by the slow growth of strain free areas by a method entirely analogous to what is later called recrystallization. Some overall relief would also occur simultaneously. Since recrystallization is a process of nucleation and growth the early stage corresponds to a prolonged incubation period and it seems unnecessary to specify a separate mechanism for recovery. The data presented here, however, are not accurate enough to show definitely whether there is a slow growth of particle size during recovery, and a more extended study on materials with a greater temperature range for recovery is needed.

Table 2 . . . Broadening of X ray Diffraction Lines in Brass (70 Cu-30 Zn) Cold worked at 23°C and annealed for 1 hour at temperatures indicated.

| Line | θ° | Annealing Temperature °C | | | | |
|-------|----------------|--------------------------------|-----|-----|-----|-----|
| | | 25 | 100 | 200 | 225 | 250 |
| | | Reduced Line Widths— (min.) | | | | |
| (111) | 21°10' | 36 | 39 | 33 | 20 | 0 |
| (200) | 24°35' | 68 | 70 | 58 | 30 | 0 |
| (220) | 36°10' | 80 | 68 | 63 | 40 | 14 |
| (311) | 43°47' | 101 | 90 | 74 | 44 | 15 |
| (222) | 46°20' | 72 | 91 | 77 | 36 | |
| (400) | 56°30' | 118 | 138 | 157 | 94 | 30 |

These data do indicate, however, that the most important process during the recovery stage may not be stress relief. If any substantial stress relief had occurred, it would have been reflected in a rather large change in extinction coefficient prior to recrystallization. Since the extinction remained virtually constant during recovery, it is suggested that the mechanism of recovery consists of the slow growth of existing strain free nuclei with a linear dimension of about 2×10^{-5} cm.

Fig 6—Micrographs of brass filings. 750 X.

a. Annealed 1 hr at 250°C. b. Annealed 1 hr at 300°C. c. Annealed 1 hr at 350°C. d. Annealed 1 hr at 400°C.

The line broadening observed for these cold worked materials is also consistent with such an interpretation. Perfect crystals have a very narrow range of perfect reflection, but if the crystal is cold worked, the intensity distribution can be taken as an indication of the deviation from ideality of the radial distance to successive nearest neighbors. As recrystallization starts, certain small regions become strain-free, they reflect sharply, and the line broadening decreases.

The half-maximum line widths were reduced to include only the broadening due to cold work by assuming that the lines at 300°C and beyond did not contain cold work broadening. Then: B (due to cold work)

$$= \sqrt{B^2 (\text{cold worked}) - B^2(300^\circ\text{C})}$$

and the resulting line widths are shown in Table 2. It has been suggested that the cold-work broadening should be a linear function of $\tan \theta$, and Fig 7 indicates that there is too much scatter in the data to check this concept. Greater precision in line widths is needed to put this phase of the work on a more satisfactory basis.

FIG 7—Line broadening due to cold work in brass (70 cu-30 Zn).
Annealed 1 hr at temperatures indicated.

Summary

On the basis of X ray extinction measurements it is concluded that recovery may be a process analogous to recrystallization. It is possible that small strain-free grains are formed during recovery, and that recrystallization is observed to occur when there is a rapid growth in the size of these strain-free regions. Recovery and recrystallization could then be two stages of the same process, and it would seem unnecessary to prescribe a separate mechanism, such as strain relief, for the recovery stage.

Acknowledgments

The author would like to express his appreciation to Professor B. E. Warren for his many helpful suggestions during the course of this investigation, and to Mr. Sergei Lorris and Mr. William Clancy for their assistance in obtaining the data.

Ferromagnetic Alloys in the Systems Cu-Mn-In and Cu-Mn-Ga*

F. A. HAMES,† Junior Member and D. S. EPPELSHEIMER,‡ Member, AIME

The ferromagnetic copper-manganese-aluminum and copper-manganese-tin alloys (Heusler alloys) owe their ferromagnetism to the beta phases (body-centered cubic structure) in their respective systems.^{1,2,3} The ternary beta phase regions in these systems are extensions of the beta fields of the binary copper-aluminum and copper-tin systems into the ternary models of the copper-manganese-aluminum and copper-manganese-tin systems respectively.

X ray analysis has indicated the presence of long-range order in the more strongly magnetic alloys.^{3,4,5} The ideal ordered structure is obtained in alloys of compositions Cu_2MnAl and Cu_2MnSn ; the copper atoms occupy positions at cube centers while the aluminum (tin) and manganese atoms alternate at cube corners. This atomic arrangement is illustrated in Fig 1. The compositions Cu_2MnAl and Cu_2MnSn are also those that show maximum magnetic saturation moment.^{3,4,6,7} Departures from these compositions result in a decrease in the degree of order attainable and a decrease in magnetic saturation moment.

In view of the chemical similarities of aluminum, tin, indium, and gallium, and the existence of beta phases in the binary systems copper-indium and copper-gallium, it may be suspected that ternary beta phases exist in the systems copper-manganese-indium and copper-manganese-gallium, and that these are ferromagnetic. The purpose

of this investigation was to determine whether ferromagnetic beta phases exist in the systems copper-manganese-indium and copper-manganese-gallium analogous to the ferromagnetic beta phases in the systems copper-manganese-aluminum and copper-manganese-tin.

Previous Work

At the time this investigation was started no information could be found regarding the constitution of copper-manganese-indium and copper-manganese-gallium alloys, nor of the binary manganese-indium and man-

FIG 2—X ray Diffraction Pattern of Copper-Manganese-Indium Alloy I-1, Quenched from 500°C.

ganese-gallium alloys. The general features of the equilibrium diagrams of the systems copper-indium and copper-gallium are known however, and these are next considered with special reference to the beta phase fields.

SYSTEM COPPER-INDIUM

Weibke and Eggers have worked out a constitution diagram for the copper-indium system on the basis of thermal, microscopic, and X ray studies.⁸ These investigators showed by X ray analysis that the beta phase in this system has the body-centered cubic structure. Powder diffraction photographs of quenched beta alloys taken at room temperature showed extra diffraction lines indicative of a superlattice.

Hume-Rothery and coworkers re-investigated the beta phase area in the copper-indium system,⁹ their beta phase field boundaries being in good agreement with those of Weibke and Eggers. High temperature X ray powder photographs taken by Hume-Rothery and coworkers of alloys in the homogeneous beta area showed only the lines to be expected from a simple body-centered cubic structure. They concluded that the extra lines on the films of Weibke and Eggers are characteristic of quenched alloys, rather than of the actual structure at high temperatures.

SYSTEM COPPER-GALLIUM

Weibke has published a constitution diagram for the copper-gallium system based on thermal, microscopic, and X ray studies.¹⁰ Weibke reported a beta phase having a body-centered cubic structure, but that the beta copper-gallium alloys particularly resemble beta copper-aluminum alloys in that the structure of quenched alloys depends on the cooling velocity.

Hume-Rothery and Raynor¹¹ re-examined the constitution of copper-gallium alloys in the region 18–32 at. pct of gallium and published a diagram which shows a high temperature

Table 1 . . . Composition of Alloys Studied

| Alloy Designation | Weight Pct | | | |
|-------------------|------------|------|------|------|
| | Cu | Mn | In | Ga |
| I-1 | 42.5 | 18.0 | 39.5 | |
| G-1 | 49.5 | 21.6 | | 28.9 |
| G-2 | 62.3 | 13.0 | | 24.7 |
| G-3 | 57.8 | 16.0 | | 26.2 |

beta phase having boundaries that agree well with those of Weibke. Hume-Rothery and Raynor reported that the beta structure is retained by quenching from the homogeneous beta area only in alloys containing 22.5–23.8 at. pct of gallium. Beta alloys lying outside these composition limits decomposed on quenching. The same investigators also reported two modifications of the beta phase which they designated as beta' and beta'', and suggested that a third modification exists below 420°C.

In later papers by Hume-Rothery and coworkers,^{9,12} it appears that they have combined the beta' and beta'' fields in a single field, representative of the beta phase (close-packed hexagonal structure). High temperature X ray powder photographs taken by these investigators showed that the beta phase has a simple body-centered cubic structure. They call attention to the fact that experiments with quenched alloys may give quite misleading results and point to the existence of a non-equilibrium phase having a simple close-packed hexagonal structure in alloys quenched from the homogeneous beta area.

Experimental

Alloys were prepared from copper of 99.99 pct purity; indium of 99.97 pct purity; Eagle-Picher gallium (purity not specified); and vacuum-sublimed or electrolytic manganese, both of 99.96 pct purity. The electrolytic manganese was treated for removal of hydrogen by heating at 500°C for

one hour in a silica tube under a vacuum of 20 microns.¹³

One copper-manganese-indium alloy and three copper-manganese-gallium alloys were prepared and studied. The alloys were analyzed for copper and manganese and indium and gallium contents were obtained by difference. Analyses are listed in Table 1.

Alloy I-1 was prepared by melting indium and copper-manganese master alloy (composition Cu₂Mn) in an aluminum thimble under a vacuum of 17 microns, with the use of a high-frequency induction coil. Alloy G-1 was prepared by melting copper, manganese, and gallium together in an aluminum thimble under helium. Alloys G-2 and G-3 were prepared by remelting portions of alloy G-1 with added copper in evacuated Vitreosil tubes.

The compositions of alloys I-1 and G-1 were intended to correspond to atomic proportions Cu₂MnIn and Cu₂MnGa, respectively. Actual compositions as listed in Table 1 correspond to atomic proportions Cu_{2.00}Mn_{0.952}In_{1.00} and Cu_{1.97}Mn_{1.00}Ga_{1.05}.

Alloy specimens for heat treatment were sealed in evacuated pyrex glass or Vitreosil tubes and heated in an electric pot furnace. Temperatures below 200°C were measured with a mercury thermometer, and temperatures above 200°C with a chromel-alumel thermocouple calibrated against the melting points of lead, zinc, and antimony. Temperature was adjusted by a Variac and was held within 10° of the desired temperature.

Powder diffraction photographs were taken with the Straumanis technique in a cylindrical camera of 57.3 mm diam. Unfiltered iron-K radiation from a Baird Associates X Ray Diffraction Unit was used. Powders were prepared from lump-annealed specimens and the powders were annealed as specified. The powder specimen was mounted in the camera on a glass fiber with the aid of vaseline, and rotated during exposure.

ration intensity of magnetization were measured at room temperatures with a magnetic balance constructed from an old magnetic ore separator. The balance is similar in design to balances used by Fereday,¹⁴ Buehl and Wulff,¹⁵ and Carapella.¹⁶ The force per unit mass exerted on a small specimen placed in an inhomogeneous magnetic field is compared with the force per unit mass exerted on a standard specimen, in this case electrolytic nickel of 99.95 pct purity. The balance was arranged so that the force was exerted vertically and the force was measured with an analytical balance.*

I-1, was magnetic as prepared. Homogenized for three days at 500°C and quenched, this alloy was magnetic, and under the microscope appeared to consist of a single phase. The specimen was badly cracked and preparation of a suitable metallographic specimen was difficult.

Fig 2 shows the X ray diffraction pattern obtained from a powder specimen of alloy I-1 quenched from 500°C, and Table 2 summarizes the diffraction data for this alloy. Reflections were found which correspond to those expected for an ordered body-centered cubic structure with $a_0 = 6.206$ Å. This alloy appears to be structurally analogous to the ferromagnetic beta phases in the systems copper-manganese-aluminum and copper-manganese-tin. Following the analogy, an alloy of composition Cu₂MnIn, when fully ordered, would have an atomic arrange-

FIG 6—Effect of Aging on Saturation Magnetization of
Copper-Manganese-Gallium Alloy G-3.

FIG 7—X ray Diffraction Pattern of Copper-Manganese-Gallium Alloy G-3, Quenched from 750°C.

ment like that shown in Fig 1 with indium atoms in place of aluminum (tin) atoms. This structure is based on space group O_h -Fm3m. Relative intensities were calculated as being proportional to $F^2 p U$, where F is the structure factor, p is the multiplicity factor, and U is the Lorentz-polarization factor. These are listed in Table 2 together with visually estimated intensities for comparison. With the data at hand, nothing quantitative can be said about the degree of order in this alloy. It is certainly not fully ordered as it is deficient in manganese (composition $Cu_{2.00}Mn_{0.952}In_{1.00}$.)

After the present work was practically completed, the authors discovered an article by Valentiner and Pusicha¹⁷ concerning the system aluminum-indium, in which mention was made of a ferromagnetic copper-manganese-indium alloy of composition Cu_2MnIn having the same structure as beta Cu_2MnAl and Cu_2MnSn . In a later brief paper,¹⁸ Professor Valentiner has summarized his findings regarding the copper-manganese-indium system. He states that the composition Cu_2MnIn shows the highest intensity of magnetization. The structure is the same as that of Cu_2MnAl and Cu_2MnSn , with $a_0 = 6.2 \text{ \AA}$. This alloy has a very small hysteresis and coercive force (less than 0.4 oersted). The specific electrical resistivity is about three times as great as that of iron. The alloy is very brittle. The Curie temperature is about 270°C. Thermal treatment has but a very slight effect on the magnetic properties of copper-manganese-indium alloys, in contrast to the behavior of the copper-manganese-aluminum and copper-manganese-tin alloys.

SYSTEM COPPER-MANGANESE-GALLIUM

The copper-manganese-gallium alloy G-1 was not magnetic as prepared, and a series of heat treatments was therefore carried out to determine whether it could be rendered magnetic. Specimens were quenched from temperatures between 500°C and 750°C and aged at 100°C and 200°C for times

ranging up to 110 hr following quenching. Saturation magnetization was measured after quenching and at intervals during aging.

The specimens were only feebly magnetic, as quenched, and the effect of aging on magnetization was very slight. A notable exception was a specimen quenched from 650°C. This had a saturation magnetization about $2\frac{1}{2}$ pct of that of nickel as quenched. Aging at 100°C for 110 hr doubled this value while aging at 200°C reduced this value ten-fold.

All quenched specimens showed two constituents under the microscope. Fig 3 shows a typical microstructure. In view of the feeble magnetism of alloy G-1 and the complexity of interpretation of the microstructure, this alloy was abandoned. The composition of alloy G-1 corresponds to atomic proportions $Cu_{1.97}Mn_{1.000}Ga_{1.05}$. It will be a matter of interest to determine whether an alloy of exact composition Cu_2MnGa ever exists as a single phase, analogous to the beta phases of compositions Cu_2MnAl , Cu_2MnSn , and Cu_2MnIn .

Alloys G-2 and G-3 were prepared by remelting portions of alloy G-1 with added copper. After homogenizing for 15 hr at 750°C the alloys were quenched in water and examined under the microscope. Both alloys showed an acicular (martensitic) structure and there was

no evidence of the presence of more than one constituent. This is illustrated in Fig 4.

Both alloys G-2 and G-3 were magnetic after quenching. Experiments were carried out on alloy G-3 to determine the effect of certain heat treatments on magnetization. A portion of this alloy, when cooled in the furnace, became nonmagnetic and under the microscope had the appearance of Fig 5. A transformation is indicated. This behavior is similar to that of slowly cooled copper-manganese-aluminum and copper-manganese-tin ferromagnetic beta alloys.

Specimens of the quenched G-3 alloy were aged at 100°C and 200°C, and magnetization measured at intervals. The magnetization of the specimen aged at 200°C decreased with aging time, and after 40 hr was very feebly magnetic. The effect of aging at 100°C was also to cause a decrease in magnetization but at a slower rate. This behavior is shown graphically in Fig 6.

X ray diffraction photographs were taken of powder specimens of alloy G-2 and G-3, quenched from 750°C. Similar patterns were obtained for the two alloys. Fig 7 shows the pattern for alloy G-3 and Table 3 lists interplanar spacings and visually estimated line intensities for this pattern.

The diffraction patterns could not be interpreted satisfactorily. In particular, no combination of lines could be found which is reconcilable with lines to be expected from a body-centered cubic structure, simple or ordered. The occurrence of martensitic structures in quenched alloys (Fig 4) suggests strongly that the high temperature equilibrium structure is not retained by quenching. The acicular structure of quenched beta copper-gallium alloys has been noted by Hume-Rothery and Raynor,¹¹ and it is quite possible that this behavior persists in the ternary beta copper-manganese-gallium alloys. Also, Weibke¹⁰ noted the resemblance of beta copper-gallium alloys to beta copper-aluminum alloys which are known to develop martensitic structures on quenching.¹⁹

It is therefore suggested that the quenched alloys G-2 and G-3 consist of a transition phase derived from the beta phase of the system copper-manganese-gallium, the beta phase being stable at high temperatures but not retained by quenching. This description is based on indirect evidence: by analogy with beta copper-gallium and copper-aluminum alloys. It should be possible to clarify the structure of the ferromagnetic copper-manganese-gallium alloys with the aid of high temperature X ray diffraction data.

Summary

A ferromagnetic copper-manganese-indium alloy has been prepared having an ordered body-centered cubic structure, and it is probably structurally analogous to the ferromagnetic beta copper-manganese-aluminum and copper-manganese-tin alloys (Heusler alloys).

Ferromagnetic copper-manganese-gallium alloys have been prepared. An alloy of composition $\text{Cu}_{1.97}\text{Mn}_{1.000}\text{Ga}_{1.05}$ variously heat treated is feebly magnetic and has a two-phase structure. It is questionable whether an alloy of the exact composition Cu_2MnGa ever exists as a single phase analogous to the beta phases of compositions Cu_2MnAl , Cu_2MnSn , and Cu_2MnIn .

With higher copper contents, quenched copper-manganese-gallium alloys are strongly magnetic. Quenched alloys show martensitic structures and are tentatively described as consisting of a transition phase derived from the beta phase of the system copper-manganese-gallium, the beta phase being stable at high temperature but not

retained by quenching. Quenched alloys lose their magnetism on aging. Slowly cooled alloys also lose their magnetism, and this loss is correlated with a transformation which is observable under the microscope.

Acknowledgments

Grateful acknowledgment is made of metal donations from the following companies: The Indium Corporation of America (indium); The Electro Manganese Corporation (electrolytic manganese); The Eagle-Picher Company (gallium); and The National Research Corporation (copper).

Effect of Carbon and Nitrogen on Temper Brittleness

D. C. BUFFUM,* L. D. JAFFE,* Junior Member AIME, and W. P. CLANCY*

Many earlier workers have suggested that the temper brittleness of steel is associated with the presence of carbon or nitrogen.† Nevertheless, no investigations on the effect of removal of these elements upon susceptibility to temper brittleness have been published. It was therefore decided to determine whether temper brittleness would develop in an iron alloy contain-

ing very little carbon and nitrogen. The alloy,‡ in the form of a 10-lb ingot, was prepared by melting purified materials under argon. Its composition, in per cent, was:

| C | Mn | Si | S | P | Ni | Cr | Mo | N | O | H |
|-------|------|-------|-------|-------|------|------|-------|--------|-------|---------|
| 0.003 | 0.80 | 0.020 | 0.005 | 0.002 | 1.49 | 0.61 | 0.002 | 0.0004 | 0.017 | 0.00006 |

This analysis, except for carbon content, is within the specified range for SAE 3140, which has been demonstrated by previous work at this laboratory² to be markedly susceptible to

FIG 1—Toughness vs. testing temperature curves for alloy of S.A.E. 3100 composition with 0.003 pct carbon.

temper brittleness.

Charpy blanks machined from the alloy were heat treated as follows:

°F °C

10 min. at 2100 (1150), water quench
10 min. at 1650 (900), water quench
30 min. at 675 (360), air cool
60 min. at 1250 (675)

Half the blanks were water-quenched from the final temper and half were furnace-cooled. The treatment produced an austenitic grain size of ASTM 3-2 and a microstructure which was entirely ferritic.

The blanks were machined to sub-sized V-notched Charpy specimens 7.5 mm square, 55 mm long, with a 45° V-notch 1 mm deep and having a 1/8 mm radius at its base.* The specimens were tested on a standard (217 ft-lb) impact machine, with the results given in Fig 1.

The transition temperatures of the quenched and slow cooled specimens were -53 and -54°C, respectively, as

shown in Fig 1. Since these temperatures are the same within the limits of experimental error, the results are consistent with the view that temper brittleness cannot develop in the absence of carbon and nitrogen. It may be pointed out, however, that two alternative explanations are possible. First, embrittlement may occur so slowly that furnace cooling provides insufficient time for appreciable embrittlement. Second, embrittlement may occur so rapidly that complete embrit-

tlement develops even on the water-quench from the temper.² In an alloy of the composition used, it is considered unlikely that either of these alternative views is valid.

It is interesting to note that the material used apparently does not quench-age, but the amounts of carbon and nitrogen present are sufficient to cause strain-aging.

Further work is planned on the same composition, as well as on alloys with carbon and nitrogen added separately and together, since an alloy to which carbon and nitrogen are added will still differ from commercial steel in phosphorus content.

Secondary Recrystallization in Copper

M. L. KRONBERG* and F. H. WILSON,† Member AIME

The low temperature recrystallization of very heavily rolled copper produces a fine grained structure with a high degree of preferred orientation. Additional heating to within a few hundred degrees of the melting point may induce an abrupt and pronounced increase in the grain size, with the resulting crystals having new orientations. This behavior at high temperatures is commonly termed "secondary recrystallization."

Several investigations have dealt with the phenomenon and have served to bare many features of the behavior.¹⁻⁴ In general, observations have been made on the sizes and shapes of the grains, and data have been presented showing the existence of an induction period in isothermal experiments.

Although it has been well established that the orientation before the change is statistically (100) [001], the so-called "cubically aligned" texture, there is no such agreement on the orientation after the change. For example, Dahl and Pawlek¹ describe it as being equivalent to an approximately 30° rotation about the [100] axis of the ideal cubic texture which is parallel to the rolling direction, the resulting orientation being near (210)[001]; and Cook and Richards² find an orientation of approximately (110)[112].

Since the completion of most of the work to be reported in this paper, Bowles and Boas³ have published their very illuminating paper on "secondary recrystallization," in which they present convincing evidence for a third orientation and show that their experiments give no evidence for either of the other two orientations. The orientation is described as equivalent to an approximately 30° rotation about a [111] pole of the ideal cubic orientation.

The existence of a variety of reported orientations is not unique for copper, for a similar state of affairs exists for other systems that have been studied—

aluminum, nickel, nickel-iron alloys, and others. It seems therefore that the existence of this variety does not necessarily constitute a contradiction, but rather indicates that different experimental conditions yield different results.

The fundamental nature of the phenomenon has not been elucidated. However, it has been generally recognized that the large grains could be the end product of growth of a few select grains already existing in the sample in minor amounts—too small to allow detection—or that entirely new ones could be formed by a process of nucleation and growth. Existing experimental evidence does not distinguish between these two most apparent possibilities. Nevertheless, the former has been more generally favored largely because our current understanding of the state of an annealed metal has not made it seem reasonable to expect a nucleation event to occur at temperatures above those required for the primary recrystallization.

Observations on the Preparation and Heating of Twin-bearing Cubically Aligned Copper

The starting material used throughout the investigation was a bar of OFHC copper, forged and annealed at 950°C. Visual inspection showed the grain size to be around 0.5 mm, and did not disclose any preferred orientation.

A chemical analysis showed the following composition:

| | |
|----------|------------|
| Cu + Ag— | 99.99 pct |
| S — | 0.005 pct |
| O — | <0.005 pct |

For the preparation of cubically aligned copper, ¾ in. thick slabs were cut from the bar, heavily pickled in concentrated HNO₃ and cold rolled to sheets about 0.012 in. thick. The reduction in thickness was approximately 98.5 pct. Standardized annealing techniques were followed. Samples to be heated were lightly dusted with alumina in order to prevent sticking and then sandwiched between ⅛ in. copper plates. The resulting sandwich was heavily wrapped with copper sheet, and then annealed in air. The protection was such that only very thin films of oxide were formed. That the associated light oxidation of the samples had no specific effect on the recrystallization behavior was shown by the similar results that could be obtained on annealing in highly purified and dried hydrogen.

Two methods were used in bringing samples to temperature: (1) by placing the package directly in the furnace at temperature and (2) by placing the package in the furnace at room temperature, and then slowly increasing the temperature. The corresponding heating rates are illustrated in Fig 1, and will be referred to as "rapid" and "slow," respectively. Unless specified otherwise, all anneals will be of the former type.

Metallographic examination was made on samples prepared by electrolytic polishing and etching as described in the Metals Handbook.*

STRUCTURES FOUND BEFORE "SECONDARY RECRYSTALLIZATION" OCCURS

Annealing the rolled material for 1 hr at 400°C produced a heavily twinned, cubically aligned structure, the grain size being of the order of 0.03

FIG 1—Rates of heating in two annealing techniques used for secondary recrystallization of copper.

mm. The effect of annealing at progressively higher temperatures was to cause an increasing consumption of the twins, and a moderate increase in the size of the grains. With a 1 hr anneal at 850°C the grain size increased to around 0.08 mm. Fig 2 illustrates the microstructure of the resulting material. Only a light etch is needed to reveal the twins, whereas the individual cubic grains as seen in the figure are revealed by a heavier etch. Still heavier etching develops the familiar aligned cubic etch pits characteristic of the material. The effect is illustrated in Fig 3.

Fig 2 also discloses that the grain boundaries are generally curved, and

that there is a wide variation in the angles between the boundaries. These conditions indicate that the equilibrium state of grain growth by boundary migration has not been achieved.

The resolution of the grain boundaries between a grain and its various neighbors varies considerably, some of the boundaries being scarcely visible at all. This observation leads to the conclusion that there is a variation in the extent of mismatch in the relative positioning of the individual crystals—presumably the closer the match, the finer the grain boundary. Apparently the material can be described equally well as a very imperfect single crystal or as a polycrystal having a high de-

gree of preferred orientation.

It has been observed that heavy rolling reductions cause the edges of the strip to tear and thus to form protruding “ears.” When the rolling is completed these “ears” have undergone a different kind of deformation from the bulk of the material, and thus on recrystallization do not have a well developed “cubic” texture. On the other hand, the grain size within such a region after a 400°C anneal is approximately the same as that of the “cubic” grains. Annealing at higher temperatures, however, develops larger grains within the “ears,” and indeed at temperatures of around 800–900°C the size is several fold larger. (Fig 4). Thus it can be concluded that grain growth in cubically aligned copper is very sluggish because of the great similarity in the orientations of the individual grains.

STRUCTURES RESULTING FROM “SECONDARY RECRYSTALLIZATION”

Although a 1 hr anneal at 850°C resulted only in grain growth of the cubic grains, heating samples for longer times, of the order of 2 hr, at 850°C sometimes induced “secondary recrystallization,” thereby verifying the existence of an induction period. In general, in those samples showing the large grains, the treatment had not resulted in a complete absorption of the cubic material. Longer annealing

FIG 2 (left)—Structure of twin-bearing cubically aligned OFHC copper. Starting grain size approx. 0.5 mm, rolled 98.5 pct, annealed 1 hr at 850°C. 75 ×
FIG 3 (right)—Cubic etch pits in cubically aligned copper. 250 ×

times, of the order of 4 hr, were needed in order to complete the absorption, but growth always stopped at the "ears." The foreign orientations existing in these edge fragments could not be absorbed even by annealing for 4 hr at 900°C. Higher temperatures were needed for invasion of these areas and in general many of the grains resisted consumption even after annealing for 4 hr at 1000°C. Thus it is seen that the cubically aligned grains are absorbed much more readily than grains of other orientations.

Examination of numerous samples showing partial consumption of the cubic material revealed no specific tendency for growth to initiate at the "ears." Rather, growth almost always started within the body of the sample and then spread toward the edges. Thus there is a pronounced tendency for growth to start within the cubically aligned grains, rather than among the foreign orientations existing at the edges. Fig 4 shows two illustrations of the transition region between residual cubically aligned grains and those existing at an edge of a sample almost entirely converted to large crystals.

The shape of the boundary between a growing large grain and the residual cubic ones has been observed. It is illustrated in Fig 5. One sees that the boundary is scalloped, being pointed toward the boundaries of the cubic grains. Thus growth is proceeding in accord with the principles of boundary migration.^{5,6}

FIG 5—Advancing boundary of a large grain.

FIG 4—Structure of the transition region between cubically aligned copper and the more random orientations near torn edges.
75 X. Reduced approximately one-third in reproduction.

Experimentation showed that for ultimate temperatures of 900–1000°C the sizes of the large grains are strongly influenced by the heating rate, the more rapid the heating the smaller the grain size. For example, slow heating often produced grains with from 1–8 sq in. in surface area, whereas the rapid heating produced grains with approximately $\frac{1}{16}$ – $\frac{1}{4}$ sq in. Fig 6 illustrates typical samples formed by the two heating methods.

The illustrations show that the individual grains formed during "sec-

ondary recrystallization" have a highly preferred orientation. Two types are formed: those characterized by, (a) prominent twin traces at approximately 45° to the rolling direction, and (b) elongation parallel to the rolling direction and frequently showing no twins at all. The former are formed almost exclusively if the heating rate is rapid through the region of 800–1000°C and the latter form in minor concentrations if the rate is slow in this temperature region, or if rapidly heated samples are held at temperature in the

region of 850–900°C. Examples of the latter type are the “white” grains at the upper and lower left of sample (a) and near the upper center of sample (b) in the figure.

A careful examination of the grains formed by rapid heating to 1000°C shows a tendency for the development of a characteristic shape and a characteristic positioning of the twin boundaries. It is convenient to describe the grains in terms of these fundamental characteristics, and Fig 7 illustrates the idealized shapes in a highly schematic way. The simplest shape (a) is an ellipse with the major axis coinciding with the trace of a twin boundary. Indeed, around 70 real crystals approximating such a shape and composed of a single twin pair have been observed. In a more common variety (b) one of the twins appears as a band dividing the grain about equally. Careful examination of grains with relatively thick bands has shown, however, that it is not the band which divides the grain, but rather one of its boundaries. Some of the grains (c) show additional twins within either or both of the components. Fig 8 (a and b) shows some particularly illustrative grains.

FIG 8—Elongated twinned grains found in samples rapidly heated to 1000°C. Rolling direction vertical. 10 X. Slightly reduced in reproduction.

The repeated appearance of roughly elliptical grains containing a twin boundary near the center and along the major axis suggests that growth develops a twinned crystal as the first unit of growth and continues most rapidly parallel to the twin boundary. If it occurs by the development of a grain already existing in the material, then this starting grain would be a single twin pair. If it occurs by nucleation and growth, then the nucleation would presumably occur at a twin boundary. During the growth, either member of the twin pair could twin on a parallel plane generating another unit of the complementary orientation, and both orientations could give rise to second generation twins on other (111) planes.

There are some observations indicating that growth initiates most readily at the surfaces of the samples and proceeds most rapidly parallel to the surface. Specimens displaying the early stages of growth show some grains extending over $\frac{1}{4}$ in. along the surface, but only a few thousandths of an inch below the surface. Others show grains extending $\frac{1}{2}$ in. along the surface, but meeting other grains growing from the other surface approximately half way.

In brief summary, “secondary recrystallization” occurs after an induction period at temperatures above about 850°C in twin-bearing cubically aligned OFHC copper, the induction period being shorter at higher temperatures. Slow heating through the temperature range of 800–1000°C produces much larger crystals than rapid heating. The latter process produces one kind of orientation, type (a), and the former produces an additional one, type (b), in minor concentrations.

Type (a) always contains a twin boundary at about 45° to the rolling direction, whereas type (b) frequently is twin free. When formed by rapid heating, the type (a) grain is often approximately equally divided by a twin boundary and is elongated in the direction of the boundary.

Growth of the large grains occurs readily in cubically aligned copper but is slowed drastically when grains of other orientation are met at the torn edges. There is no particular tendency for growth to initiate at the torn edges. The contour of the boundary of a growing grain is in accord with the predictions of the principles of grain growth by boundary migration.

CRYSTALLOGRAPHIC ORIENTATIONS RESULTING FROM “SECONDARY RECRYSTALLIZATION”

Orientations of the grains resulting from “secondary recrystallization” were determined using the back-reflection Laue technique of Greninger.⁷ Eleven samples were used. Four were formed by “rapid” anneals for 1 hr at 900°C and seven by “slow” anneals at 950°C. The resulting orientations of both types of grains, (a) and (b), apparently were not affected by the variation in heating rate.

The analysis of the data showed that the position of the octahedral pole common to a twin pair (type (a) grain) is close to the position of one of the octahedral poles of the ideal “cubic” orientation. The location of this pole for 52 grains is plotted in stereographic projection in Fig 9, in which the plane of projection is the plane of the copper strip. The distribution of poles is shown in relation to the 5° radius circles

around the $[111]$ poles of the ideal "cubic" orientation. The plot is to be compared with Fig 10, showing a pole figure of the "cubic" texture plotted from X ray photographs of unconsumed material in one of the samples annealed at 900°C . For comparison, 5° circles are drawn around the $[111]$ poles of the ideal orientation. The great similarity in the two distributions suggests that the orientations of the new grains may be formally related to those of the old by rotations around a $[111]$ pole.

The character of the indicated rotations can be investigated rather simply if one confines the analysis to those poles falling within a densely populated region. For this purpose, the area defined by the 5° circles about the ideal cubic position has been selected. The positions of the corresponding central $[100]$ poles of the selected crystals are plotted in Fig 11 after bringing their $[111]$ poles into the same quadrant, and 5° circles are drawn to cover the most densely populated regions. By plotting the poles of both twins in some cases, a total of 63 orientations on 40 $[111]$ poles is included. It is seen that nearly all the poles are enclosed by the circles, but that there is a spread of a few degrees in the directions of greater and lesser rotation. The corresponding distribution is roughly of the form that would be required for a discrete, or unitary, rotation, that is, one involving an exact angular relationship between each grain and its parent. The poles within the circle would arise from cubic grains whose $[111]$ poles lie within the defined 5° circle, and whose central $[100]$ poles would lie within a 5° circle about the ideal position of those poles. In the pole figure of cubically aligned copper, there is an appreciable concentration extending several degrees outside the 5° circle, and thus with unitary rotation the observed kind of spread would develop. An amount of rotation can be estimated by the angular distance from the center of the plot to the centers of the 5° circles. It is seen that the rotations are opposing ones of approximately 22 and 38° , the individual rotations corresponding to the members of a twin pair.

With one exception, specific directions of rotation are observed. Around the south-east and north-west $[111]$ poles the 22 and 38° rotations are found to be clockwise and counter-clockwise respectively, and for the other two poles the directions are re-

FIG 9—The positions of the $[111]$ poles of 52 large crystals which lie near the $[111]$ poles of $(100)[001]$.

versed. The effect is illustrated in Fig 9. Thus in the formal relationship developed, the pole figure shows a loss of the four-fold axis associated with cubic symmetry, but the planes of symmetry are preserved.

Coincidence Plot for a 22° Rotation

The nature of the relationship between the two highly preferred orientations involved suggests that a discrete mechanism operates in the formation of the "secondary" crystals. It has previously been shown that the primary unit of growth is probably a twin and that this unit forms in cubically aligned copper which has been observed to contain twins. This circumstance suggests that the twinned unit might be derived from a twin pair in the starting material by a mechanism which rotates the unit by a 22° or 38° rotation about the twinning pole. In order to attempt to gain an insight into the nature of the mechanism thereby suggested, it is useful to examine the relationship between the crystallographic orientations, before and after "secondary recrystallization." Referring to Fig 12, the small

filled circles of net A represent the positions of the atoms in a (111) plane of the ideal cubic orientation. The large filled circles then represent the positions of the atoms in a neighboring layer. Net B is derived by a 22° rotation of the latter net (or a 38° rotation in the opposite direction) about an arbitrary point of this net. The positions

of the open circles in the resulting net then represent the positions of the atoms of a (111) plane for the orientation after "recrystallization." This formal construction is not intended to imply that the orientation change actually occurs by means of the indicated rotational shear operation. Rather, it serves only to illustrate the relative positions of the atoms in a (111) plane before and after "secondary recrystallization."

However, examination of the figure reveals several striking features. It is seen that $\frac{1}{4}$ of the atoms of the new orientation are in coincidence with atoms of the old orientation, and the positions of these coincidence atoms define a unique equilateral net which is a multiple of the primitive net. Moreover, the remaining atoms can be brought onto the sites of the new net by a very simple movement of the order of $\frac{1}{3}$ of an interatomic distance.

In order to effect a three dimensional change in orientation, formally speaking, it is necessary to consider neighboring layers. The corresponding coincidence sites for such a layer are shown by small annular rings in net A. Fig 13 shows the completed re-orientation in detail for two layers, and in one section for three layers. Coincidence sites in the second layer are defined by triangles in this figure. The remainder of the structure is derived by a repeated stacking of such groups of three.

Although it appears that the formal operations have produced a 22° rotation of the structure, such is not the case. Actually, study of the plots shows

FIG 12—Coincidence plot showing relation between positions of atoms in an octahedral plane before and after a 22° rotation.

the new orientation to be a twin of the starting orientation, rotated by 22° . Thus in the formal conversion of a twinned cubic crystal to the newly oriented twin, each part can be described as being related to its parent as a twin rotated 22° , or as its own orientation rotated 38° in the opposite direction.

Examination of the figure which shows the re-orientation for three layers reveals several interesting geometrical features. One sees that the coincidence positions uniquely define a multiple face-centered cubic lattice. All other original sites can be brought to their new positions by relatively short displacements.

A fundamental characteristic of the cluster of atoms composed of a coincidence atom plus its nearest neighbors is readily discerned. An atom in a cubic closest packed structure is surrounded by twelve nearest neighbors, six "around the waist" in any given $\{111\}$ plane, three in the parallel plane above and three in the plane below—the latter six forming an octahedron about the central atom. For the case of twins, the packing of the three layers involving the composition plane and its contiguous neighbors corresponds to hexagonal closest packing. Thus, for a coincidence atom lying in the composition plane the atoms in the two sets of three nearest neighbors in adjacent planes define a triangular prism. Considering either case, in order to effect the formal orientation change under discussion, the six "waist" atoms all move in one direction, whereas the re-

FIG 14—The positions of the central cube poles of 30 large crystals which are derived by rotation about $\{001\}$.

maining two groups of three move in the opposite direction.

There are no obvious clues to a possible origin of the type (b) crystals which form most readily on slow heating. However, they exist with a very high degree of preferred orientation and there is a definite geometrical relationship between the atomic positions

before and after "secondary recrystallizations." Fig 14 is a pole figure showing that the orientation can be related to that of the cubic by a $\pm 19^\circ$ rotation about a $[100]$ axis parallel to the rolling direction. It is significant to note that the degree of preferred orientation is apparently considerably greater than that of the "cubic" material. Fig 15 illustrates the relative positions of the atoms before and after "recrystallization."

Observations on the Preparation and Annealing of Twin-free Cubically Aligned Copper

In order to test whether the occurrence of "secondary recrystallization" is dependent upon the presence of twins in the cubically aligned material, experiments were performed on apparently twin-free samples. It is known that the effect of a progressively diminishing grain size of the material prior to the heavy rolling reduction is the development of cubic material containing correspondingly diminishing amounts of twins.¹⁶ Experiments in the current investigation have shown that, for starting grain sizes of the order of 0.01–0.1 mm, cubic material can be

FIG 13—Coincidence plot showing relationship for two and three octahedral planes before and after a 22° rotation.

FIG 15—Coincidence plot showing relation between positions of atoms in a cube plane before and after a 19° rotation.

produced in which twins have not been detected by microscopic methods.

Starting with 0.5 mm grain size stock, samples of the finer grain size were produced by repeated cold forging and 300°C annealing treatments. Heavy cold rolling reductions and subsequent anneals were performed as described for the 0.5 mm material.

Fig 16 illustrates the kinds of samples obtained by rapid annealing to 1050°C. It is seen that all grains touch the edges of the sheet suggesting that growth has initiated at these boundaries. Careful examination of around 50 samples of the kind illustrated has shown that all the grains have this characteristic. Study of the microstructures of the sheared and torn edges of sheets annealed 1 hr at 850°C, a treatment which develops the structure existing just prior to "secondary recrystallization," revealed the presence of twinned cubically aligned grains along with other grains of varying orientations. By pickling the sheared edges of cold-rolled samples, regions where such grains might develop were removed and it was possible to obtain material apparently free of twins which did not undergo "secondary recrystallization" even during 6 hr anneals at 1050°C. Thus, twin-free cubically aligned copper does not undergo "secondary recrystallization" under the conditions of experimentation.

Fig 17 illustrates the microstructure of the twin-free material after a 6 hr anneal at 1050°C, and is to be compared with Fig 2, showing the microstructure of twin-bearing material after annealing at 850°C for 1 hr. Comparison shows that the grains persist in shapes characteristic of a nonequilibrium state of growth, displaying highly curved boundaries and

varying angles between boundaries. The deviations from equilibrium shapes appear to be even more pronounced in the twin-free material. In this connection, it has been observed that the processing which develops the formation of twin-free material yields a markedly higher degree of preferred orientation than the processing which forms the twin-bearing material. Thus it would be expected that the former material would be the more sluggish in approaching the equilibrium state.

With regard to the sheets showing edge growth, an extensive study of the orientations of the large grains has not been made because of the lack of knowledge of the orientations existing at the cut and torn edges. However, the same kinds of orientations as were found in the twin-bearing material were also found in such samples, but

with somewhat more spread in orientation. Several generations of twins were sometimes found in these grains. Also the type (b) rotations about a [100] pole are now found to occur about poles parallel to both the rolling and cross-rolling directions, and the relative abundance of these orientations is greater than for the grains arising in cubic material containing twins in the body of the sheet. Some additional orientations are occasionally encountered, but they have not been determined to date.

Fig 18 illustrates the shapes of grains grown by rapid annealing at 1000°C for 1 hr in a sample with edges sheared after the rolling reduction. It shows that growth of several crystals proceeded from the shorter edges at an approximately constant rate, thus meeting in the center of the sample. The large grains are all of the (a) and (b) types, as initially described.

Annealing at lower temperatures of the order of 850–900°C, a region in which the rates of growth are relatively slow, allows the development of characteristic shapes. Fig 19 illustrates the phenomenon, samples (a) and (b) having all edges sheared, and (c) and (d) having sheared edges parallel only to the cross-rolling direction. Again, all grains are of the (a) or (b) type in these samples, but some contain additional generations of twins. Unconsumed cubic material can be seen in the illustration. The existence of the characteristic shapes simply means that some planes are developed more readily than others. Previous investigators have ob-

FIG 16—Growth from edges, annealed 1 hr at 1050°C.
Actual size.

served and described such typical shapes.^{1-4,8}

It is important to note that elaborate lineage-like structures have been observed in the large grains. There has been no opportunity to study the nature of these structures, but it seems probable that they will afford additional clues to the dynamics of "secondary recrystallization."

The results of these experiments do not help particularly in determining whether the large grains grow in this kind of material from favorably oriented ones already existing at the edges, or by nucleation and growth of new ones in these regions. Nevertheless, the positive result that "secondary recrystallization" does not occur in twin-free cubically aligned copper, but does in twin-bearing material to form twinned units having orientations so discretely and simply related to the parent cubic orientation is the strongest kind of experimental evidence in favor of the concept of nucleation of new orientations at a twin boundary in the cubically aligned material.

On this basis, therefore, it would seem feasible to try to understand why a reorientation might occur at a twin boundary. The packing of layers in the face-centered cubic lattice follows the sequence: ABCABCABCABC . . . , corresponding to cubic closest packing whereas the sequence for a twinned crystal is: ABCABCACBA . . . , in which there is a region of three layers corresponding to hexagonal closest packing: . . . BCB . . . Since

copper does not crystallize in the hexagonal closest packed structure it can be concluded that the associated mode of packing is higher in energy content than that associated with cubic closest packing. There would, therefore, be an inherent tendency for the atoms to rearrange so as to eliminate the fault.

Annealing Lightly Deformed Twin-free Cubically Aligned Copper

There is much current interest in the question of whether stacking faults are produced in face-centered cubic metals during deformation. For over twenty years, Mathewson has

FIG 17—Structure of twin-free cubically aligned OFHC copper.

held the view that annealing twins probably originate in copper during primary recrystallization from twins, or twin faults as he has more recently described them, arising within slip bands, during cold work,^{9,10} and has presented experimental evidence showing that twins begin to form within slip bands during the annealing of worked copper. More recently Barrett has pointed out from structural considerations that twin faults might have nearly a 40 pct chance of forming during slip.¹¹ Thus, if twin faults can be induced in twin-free cubically aligned copper by cold work, it might be anticipated that primary recrystallization should produce twinned crystals of the same kind and orientation as are observed to form during "secondary recrystallization" in twin-bearing material. As a corollary, the formation of these kinds of crystals could be taken as evidence for the formation of the faults during deformation. This interesting possibility has been subjected to a preliminary investigation by three techniques: peening, stretching, rolling.

Twin-free cubically aligned material was prepared from starting stock having a grain size of approximately 0.05 mm. Heavy rolling reductions were performed as already described, the edges of the resulting cold worked sheets were all sheared and pickled and

the samples were then annealed for 1 hr at 1050°C. The microstructure of the kind of material thus formed has been illustrated by Fig 17.

A light ball peening produces copious deformation lines emanating from the peened spot and making approximately 45° angles with respect to the rolling direction, as shown by Fig 20. Recrystallization at temperatures as low as 600°C induces growth of twinned crystals in the regions of these markings, having twin directions at approximately 45° to the rolling direction and possessing orientations the same as those described for "secondary recrystallization." Orientations of type (b) are also found. Annealing at higher temperatures causes these grains formed by "primary recrystallization" to consume the remainder of the sample by grain growth. Fig 21 illustrates typical crystals formed during a 900°C anneal.

Annealing of samples containing deformation lines produced by tensile stretchings of the order of 5–10 pct yields the same kinds of results. Thus it is seen that both types of experiments are confirmatory and, in addition, show that the corresponding "primary recrystallization" occurs at temperatures several hundreds of degrees below those required for "secondary recrystallization" of unworked

twin-bearing cubically aligned copper.

Light rolling reductions of the order of 1–5 pct yield similar effects as illustrated by Fig 22, except that in most samples the [111] rotations appear to be shifted from 22° toward a region around 30°, and the [100] rotations are shifted toward a region around 15° and now occur about the [100] pole that is normal to the sheet. The [111] poles of rotation and the central [100] poles of 18 large grains which grew on annealing lightly rolled twin-free cubically aligned copper are plotted in Fig 23. Presumably, the very close correspondence of the [111] poles to their "cubic" positions is simply a reflection of the very high degree of preferred orientation existing in the parent material.

The significance of this apparent change in the amount of rotation has not been evaluated. Perhaps the deformation process has caused the indicated additional rotation at the site of nucleation. On the other hand, coincidence plots very similar to those presented for the 22 and 38° rotations about [111] can be drawn for 28 and 32°, as shown by Fig 24, and a similar kind of plot can be constructed for [100] at 16°. Thus there is an alternative possibility that the reorientation of the rolled material proceeds according to the geometry of these new coincidence plots.

In this connection it is to be noted that in Fig 11 the spread is somewhat asymmetric, being greater in a clockwise direction. Thus, it is possible that a few of the orientations might be better described in terms of the 28 and 32° plots. An analysis based on considerably more data would be needed in order to evaluate properly this possibility.

Exploratory experiments on the recrystallization of more heavily rolled samples have revealed the very interesting finding that there is no pronounced change in the recrystallization orientation for deformations as high as approximately 35 pct, the limit of reduction that has been tried. It is interesting to note, in this connection, that Baldwin¹² has determined the orientation of 45 large grains produced by a 540°C anneal of cubically aligned copper that had been reduced 22 pct in thickness by rolling. He found a very high degree of preferred orientation which was described as:

| Rolling Plane | Rolling Direction |
|---------------|--|
| (113) | Between [110] and [301] 21° from [301] |
| (113) | Between [301] and [211] 10° from [301] |

Examination of the data shows, however, that the orientation can also be described about as well by an approximately 30° rotation about [111].

On the other hand, the grain size de-

creases continuously as a function of increasing deformation, being of the order of $\frac{1}{2}$ in. or more for a 5 pct reduction and approximately $\frac{1}{32}$ in. for a 35 pct reduction. At the same time, the density of twins increases and the components become increasingly thinner, giving rise to a fine lamellar structure. It can be observed that growth in undeformed twin-free material (Fig 16, 18, and 19) produces a minimum

number of twins, and therefore the suggestion arises that perhaps the formation of twins during growth in the deformed material might be associated with twin faults produced during the deformation.

The importance of the observation that the orientations of the grains resulting from the recrystallization of the rolled samples are essentially insensitive to the degree of rolling cannot be overemphasized, for it indicates the action of a fundamental, discrete mechanism of deformation and recrystallization throughout the range of deformation studied. An extensive study of the effects of deformation on the recrystallization orientations and structures is currently being prosecuted, and will be the basis of a separate, detailed publication.

Considerations Concerning A Possible Mechanism

The considerable evidence in favor of a nucleation hypothesis warrants an investigation of a possible mechanism for "secondary recrystallization." Indeed, the final acceptance or rejection of such an idea may well depend on the outcome of a detailed analysis of the energetics of such a process. The experimental data and the geometrical relationships derived therefrom are of a suitable form to allow such an investigation. If it can be proven that nucleation cannot occur, then one is left with the apparent conclusion that reorientation occurs by the highly selective growth of constituents present in amounts too small to be detected. As a beginning, it seems that the following

FIG 22—Structure after light rolling and annealing cubically aligned copper. 20 X.

FIG 23—The positions of the octahedral poles of rotation and the central cube poles of 18 large crystals arising during annealing of lightly rolled cubically aligned copper. Centers of the $\pm 5^\circ$ circles correspond to the 30° rotations about [111].

kinds of information should be given attention.

The lowest energy state of an assemblage of atoms in the solid state is a single crystal, and thus the polycrystalline cubically aligned material containing twins is naturally proceeding in the direction of this ideal state when it converts into huge single crystals. Grain boundaries are removed and therefore would be the most probable source of the driving energy required for the change. On the other hand, there is a change in orientation altering the geometrical distribution of atoms exposed at the surface of the specimen and, if this lowers the surface tension, the corresponding decrease in energy would likewise contribute to the driving force. The fact that the conversion occurs only if twin boundaries are present indicates that the energy associated with the stacking fault existing at a twin boundary is probably involved in the activation energy, in part at least. Experiments indicating that growth initiates at a surface, where the atoms have the greatest freedom of movement and are correspondingly more energetic, can be interpreted to mean that the associated surface energy likewise probably contributes to the activation energy. Other likely contributions could come from the localized statistical fluctuations in the distribution of thermal energy among the various atoms, and the distortional energy of imperfections such as vacant sites, foreign atoms, and others.

A reasonable picture, therefore, would have the most favored site of nucleation be the region of intersection between a grain boundary, a twin boundary and the surface. A necessary condition to the atomic reorganization occurring during nucleation would be the disappearance of the grain boundary region involved. A disordered area would therefore vanish and the corresponding imperfections would be discharged at the surface. Experimental observations indicate that the twin boundary would be maintained, but would be reoriented.

It is important to point out that a structurally perfect twinned crystal would not be expected to undergo recrystallization, even though the region of the boundary is a place of higher energy than the remainder of the interior of the crystal, for this energy is locked up for a perfect crystal. Thus it is necessary to evaluate the interaction of structural imperfections, such as vacant sites or the disorganization

associated with a grain boundary, with this faulted region. The balance of forces normally maintaining the atoms in their faulted positions would be upset by the entry of imperfections into the boundary region, and might therefore promote the initiation of an atomic rearrangement in accord with the inherent tendency to de-twin or remove the fault. Indeed, inspection of Fig 12 and 13 shows that the nearest three atoms to a coincidence site in the plane above and in the plane below it actually travel in the directions of de-twinning sites in the formal picture, but achieve the equilibrium positions corresponding to the observed reorientation by moving only somewhat more than one-half the distance to a normal de-twinning site. Thus in this picture the reorientation might be described as the end product of an abortive attempt to de-twin.

It is interesting to note that the r.m.s. value of the amplitude of the thermal vibration of the atoms at the temperatures of the re-arrangement is roughly 0.3\AA , which corresponds to approximately $\frac{1}{3}$ the total distance of formal travel between sites. Statistical fluctuations are considerable and become more pronounced with increasing temperatures. Thus, it would be desirable to evaluate the probability that an atom, or perhaps a few atoms, in cooperation with an imperfection such as a vacant site, might spontaneously execute oscillations favoring the initiation of the rearrangement.

Presumably, a critical number of atoms would have to reorient in accord with the formal cooperative movements indicated by the coincidence plots of Fig 12 and 13 in order to form a stable nucleus. Once this critical size is reached, the remaining atoms in the crystal involved in the nucleation would reorient rapidly by cooperative movements. Further increase in size would be achieved by boundary migration, and presumably would proceed readily because of the favorable orientation relationship.

It seems reasonable that the induction period observed for isothermal recrystallization might, in part at least, be essentially a reflection of the improbability of the nucleation event. Accordingly, few nuclei would form, and huge grains would consequently be developed. The observation that the grain size decreases with increased heating rate might be interpreted as follows. The probability that a nucleus will form at any given temperature de-

pends on the time the sample is held at that temperature. Thus, on slow heating one nucleus might form at a relatively low temperature and consume the entire sample before another nucleation event could occur. On rapid heating, there would not be as great a probability for nucleation to occur at so low a temperature. Rather, initial nucleation would occur more probably at a higher temperature. Since the frequency of nucleation will increase with temperature as a result of the increased amplitude of thermal vibration the overall result would be the formation of many grains.

The significance of the experimental observation of specific directions of rotation about the individual [111] poles has not been evaluated, but is apparently an important clue to an understanding of the structural nature of the reorientation phenomenon.

In the very important case of the recrystallization of the lightly deformed samples of cubic material, there is no difficulty in understanding the nature of the driving force. It is the residual energy of cold work. Although its structural nature is not too well understood, it is quite possible that a deeper insight might result from continued studies of recrystallization utilizing the concepts of atomic rearrangement as revealed in the studies of "secondary recrystallization."

General Application of Coincidence Plots to Secondary Recrystallization

None of the orientations observed during the current investigation has corresponded with those described by either Dahl and Pawlek¹ or Cook and Richards.² However, the orientation study of the latter team was on material prepared by a rolling reduction of 85 pct, and it is known that such a reduction is insufficient to promote the kind of "secondary recrystallization" studied in the current investigation.

Bowles and Boas³ have reported rotations of approximately 30° about [111] on the basis of a study of 11 large grains produced in their experiments. Examination of the method of analysis employed in the evaluation of their data shows that the 30° figure results from an averaging process of all observed rotations. It seems that re-evaluation of the data might show it

to fit the 22 and 38° regions reported in the current study.

One element in common with nearly all the reported observations of new orientations produced by "secondary recrystallization" in cubically aligned metals and alloys is that old and new orientations are related by rotations about [111] and [100] axes. It would seem feasible to attempt to evaluate the significance of the variety of recorded observations utilizing the variety of possible coincidence plots, although it is to be emphasized that very carefully acquired and analyzed data will be needed. For [111], there are plots corresponding to 28, 22, 18, 15, 13, $11\frac{1}{2}$ °, etc., but there are no experiments indicating rotations other than the two discussed. For those values less than about 15°, the density of coincidence sites is relatively low and the corresponding plots can probably be ignored. For [100], there are plots corresponding to 37, 28, $22\frac{1}{2}$, 19, 16, 14, $12\frac{1}{2}$ °, etc. A commonly reported rotation for both copper and 50:50 nickel-iron alloys is approximately 30°,⁴ and there is one report¹³ of 37–38° for a 30:70 nickel-iron alloy, a coincidence plot for which is shown in Fig 25.

Some Implications of the Concept of Coincidence Plots

In applying the concepts of atomic rearrangement suggested by the experiments on "secondary recrystallization" to the experiments on lightly deformed cubically aligned copper, the deformation was considered as a means for inducing faults locally comparable in structure to twin boundaries. Nevertheless, the reorientation on annealing is fundamentally primary recrystallization and suggests that this approach may be a good tool for the study of both deformation and primary recrystallization. If extensive orientational relationships of the nature described by coincidence plots are found between deformed and recrystallized grains, they will provide strong evidence in support of the suggested atomic rearrangements; and detailed studies of recrystallization orientations accordingly should make it possible to learn more about the fine structure of deformed metal. The fruitfulness of this field of investigation is indicated by some observations which appear to be consistent with the present concept. Further research will be necessary to evaluate them.

FIG 24—Coincidence plot showing relation between positions of atoms in an octahedral plane before and after a 28° rotation.

Although the structure of aluminum is based on the face centered cubic lattice it is well known that annealing twins are rarely formed by this metal. Thus, it can be predicted that a modified picture of the deformation and recrystallization processes, as developed for copper, should result from similar studies on cubically aligned aluminum. Exploratory experiments have shown that twin-free cubically aligned "high-purity" aluminum does not undergo "secondary recrystallization" on annealing in air at 650°C for 24 hr. On the other hand, recrystallization of lightly rolled samples produces the same kinds of orientations as observed for twin-bearing copper after "secondary recrystallization," with both types of orientations, (a) and (b), being found. Twinned crystals are almost entirely absent, and the rotations about [111] are predominantly of the 38° type.

In this connection, it is interesting to note that Barrett¹⁷ has observed clusters of orientations of new grains produced by the recrystallization of deformed single crystals of aluminum, compressed so as to avoid the formation of deformation bands. The orientations of these clusters can be related with considerable success to the deformation orientations by approximately 38° rotations about the [111] poles.

It was pointed out by Cook and Richards¹⁴ that components of the (100)[112] rolling deformation texture of brass are related to components of the so-called (113)[112] recrystallization texture by a 30° rotation about a

[111] pole near the rolling direction. It is possible to reproduce the pole figure, referred to as (113)[112] quite well by a 22° rotation in one direction and a 38° rotation in the other around the same [111] poles of a single component of the deformation texture. This would, of course, also be true of any of the other metals having the same textures. Rotations may occur also in wires which have a [111] fiber axis and recrystallize to the same fiber texture, as copper and aluminum are reported to do—although the rotation of each crystal would be definite in amount and the random distribution around the axis would arise from the randomness of distribution in the deformation structure. Moreover, triangular coincidence plots of the basal plane of hexagonal close packed metals would be similar to those illustrated for the octahedral planes of the face centered cubic lattice, and similar rotations might be expected. Thus, the retention of the [00.1] axis normal to the plane of the sheet during recrystallization of heavily rolled hexagonal close packed metals is comparable to retention of the [111] fiber axis in wires of face centered cubic metals. Likewise, worked material of random orientation could retain the randomness on recrystallization if each grain undergoes a rotation during the recrystallization. Although the "cubic" texture, having no complements, is considerably simpler than the deformation texture from which it arises, there is a component of deformation texture which is related to "cubic" by a 38° rotation about [111].

FIG 25—Coincidence plot showing relation between positions of atoms in a cube plane before and after a 37° rotation.

The conversion of the so-called (113)[112] low temperature recrystallization texture of brass to (110)[112] at higher temperatures¹⁵ may be a form of "secondary recrystallization" without the development of very large grains. This reversion to the deformation texture could be accomplished by a reversal of the rotations occurring during primary recrystallization.

Dunn has observed clusters of orientations of recrystallized grains formed on annealing lightly deformed iron-silicon crystals,¹⁸⁻¹⁹ and it would be pertinent to determine whether these new orientations can be related to the deformation orientations by means of coincidence plot relations. One might anticipate coincidence relationships on (110) planes, since they are the most densely packed ones in the body centered cubic lattice.

Summary

A formal relationship between pairs of orientations, which can explain extensive apparent rotations of a structure in terms of short, cooperative atomic movements, has evolved from a study of the orientations of the large grains that can be produced during the "secondary recrystallization" of twin-bearing cubically aligned copper. Experimental evidence indicates that the large grains are formed by a process of nucleation and growth of new orientations, with nucleation apparently initiating at twin boundaries. Two types of orientations are found. Each can be related formally to the ideal cubic orientation by rotations about [111] and [100] poles, respectively. The former always contains twins at approximately 45° to the rolling direction. There are simple relationships between the relative positions of the atoms

before and after "secondary recrystallization," which indicate that the reorientation probably occurs by a cooperative movement of atoms.

Twin-free cubically aligned copper, when lightly deformed by peening or tensile elongation, recrystallizes to form grains of the same kinds and orientations as are produced by "secondary recrystallization" of unworked twin-bearing cubically aligned copper. This result supports the hypothesis that twin faults form during the deformation, and participate in the recrystallization of the worked material to form annealing twins.*

Some speculative comments are made concerning a possible mechanism of "secondary recrystallization," pointing out the need for a theoretical analysis, and emphasizing the apparent necessity of considering imperfections in searching for the driving and activation forces. The driving force is probably mainly the energy associated with the disorganization existing at a grain boundary, but the differential in surface energy between the orientations before and after reorientation must be considered in addition. The activation energy is probably associated with a combination of the energies corresponding to the stacking fault existing at a twin boundary, imperfections such as vacant sites, the localized fluctuations of thermal energy amongst the various atoms, and the relatively loose binding of surface atoms.

A detailed account is given of the observations made on the prepara-

* By private communication, Dr. Robert Maddin of the Hammond Laboratory of Yale University informs us of some particularly timely results of his current work on the tensile elongation and subsequent annealing of single crystals of alpha brass. After recrystallization, twinned crystals are found whose orientations can be related to the parent orientation by opposing rotations of approximately 22 and 38° about a [111] pole.

tion and annealing of cubically aligned copper, and a description is given of the sizes, shapes and orientations of grains formed by "secondary recrystallization."

Some implications of the results of the "secondary recrystallization" studies are discussed as they might be related to recrystallization phenomena in general.

Acknowledgments

Acknowledgment is made to the American Brass Co. for permission to publish; to Mr. John R. Freeman, Jr., Technical Manager, whose interest and support made the work possible; and to Mr. E. W. Palmer, in charge of the Copper Research Laboratory, for sponsoring the work and for his critical advice and encouragement. The staffs of the laboratories of the Company deserve much credit for assistance throughout the project.

Before the paper was written, various aspects of the experimental results were discussed with Professors P. Debye, J. D. H. Donnay, and C. H. Mathewson. We wish to thank these gentlemen for their kindly and stimulating consideration.

Kinetics of the Reactions of Zirconium with O_2 , N_2 and H_2

EARL A. GULBRANSEN* and KENNETH F. ANDREW*

Introduction

The gas-metal reactions of zirconium are very interesting. The metal is extremely stable at room temperature to reactions with the several gases present in air and the metal will stay bright indefinitely. However, at temperatures of several hundred degrees higher the metal reacts readily with oxygen, nitrogen and hydrogen. This behavior, in addition to the fact that zirconium is one of the higher melting point metals which might have high temperature applications under the proper conditions, resulted in the work reported in this communication.

There are several factors which indicate that zirconium might have good oxidation resistance at elevated temperatures. These are: (1) the high melting point of approximately 1860°C, (2) the high melting point of the oxide of approximately 2675°C, (3) the high degree of thermodynamic stability of the oxide to chemical reaction and the low decomposition pressure of the oxide and (4) the possible formation of a continuous oxide film since the volume ratio of oxide to metal is greater than unity. The unfavorable factors are: (1) the metal reacts to form nitrides, hydrides and carbides, (2) the oxide is soluble at elevated temperatures in the metal and (3) the oxide ZrO_2 undergoes crystal structure transformations at high temperature.

The oxidation resistance of this metal is not only a question of the rate of film formation but is complicated by the fact that the oxide and other reaction products dissolve in the metal which in turn will affect the physical and mechanical properties of the metal.

The protection of the metal to nitride formation must be considered separately from the oxide problem. One unfavorable factor is that the volume ratio of the nitride to the metal is about unity. This indicates that a discontinuous film might be

formed. This paper will present measurements on the rates of reaction of the metal with O_2 , H_2 and N_2 over a wide temperature and pressure range. The reaction in high vacuum and the stability of the several compounds formed will be presented. The results are correlated with fundamental rate theory and with the physical and chemical structure of the metal and film.

Literature

Although many papers have been published on the chemical reactions of zirconium with various gases, comparatively few are concerned with the protective nature of the metal and its reactions at normal pressures. The studies in the pressure range below 0.01 mm of Hg gas pressure are largely of interest in the nature of the adsorption of gases by hot filaments in high vacuum apparatus. The reactions of zirconium in this pressure range have been reviewed by Fast⁸ and by Raynor.²⁷ In spite of certain differences of opinion as to the maximum adsorption temperatures for various gases, the low pressure range is qualitatively understood. Some of these papers will be mentioned briefly here.

1. LOW PRESSURE

Ehrke and Slack⁷ find that oxygen reacts above 885°C and hydrogen above 760°C. Nitrogen does not react up to a temperature of 1527°C. Fast⁹ on the other hand observes that oxygen is absorbed above 700°C and nitrogen at temperatures exceeding 1000°C.

Hydrogen is absorbed from 300° to 400°C and liberated between 500° and 800°C. It is readsorbed at 862°C and released above 862°C.

Hukagawa and Nambo²² find a rather complicated picture for the absorption of oxygen. A rapid initial absorption is found between 180° to 230°C. Further oxygen is not taken up until a temperature of 450°C is reached. The optimum temperature for complete absorption is 650° to 700°C. Nitrogen is found to be completely adsorbed at 600°C. However some of the gas is evolved at higher temperatures. Their data on the absorption of hydrogen indicate some of the gas is removed at 550°C.

Guldner and Wooten¹⁷ in a study of the low pressure reactions of zirconium with various gases observed that the reaction with oxygen occurs at temperatures above 400°C and that the oxide is formed. The reactions with carbon monoxide and carbon dioxide occur rapidly at temperatures of about 800°C with the oxide and carbide being formed. Zirconium reacts at temperatures of 400°C slowly and at 800°C rapidly to form the nitride and with hydrogen and water at 300°C to form the hydride and a mixture of the oxide and hydride respectively.

2. NORMAL PRESSURE

DeBoer and Fast³ in a study of the electrolysis of oxygen in zirconium find that the metal absorbs up to 40 at. pct of oxygen without forming a new phase. The solubility of nitrogen in the lattice has been studied by de Boer and Fast⁴ and Fast¹⁰ and is found to be considerable. At higher temperatures the oxide dissolves in the lattice at an appreciable rate according to Fast¹⁰ and the zirconium surface becomes active.

De Boer and Fast⁴ and Hägg¹⁸ have studied the solubility of hydrogen and find that at room temperature the solubility corresponds to $ZrH_{1.95}$. Desorption occurs on lowering the pressure. Hydrogen is stated to be more soluble in the β -form and the

paper.

FIG 1—Equilibrium calculations on Zr reactions.

transition between the α and β forms occurs at 865°C.

Hall, Martin and Rees¹⁹ have studied the solubility of hydrogen in zirconium and Zr-O solid solutions at temperatures up to 1000°C and at pressures of 1 to 760 mm of Hg. The hydrogen desorbed on lowering the pressure.

3. CRYSTAL STRUCTURE

The crystal structures of the oxide films formed on zirconium at temperatures from 300° to 600°C using the electron diffraction method have been studied by Hickman and Gulbransen.²¹ The monoclinic form of ZrO_2 was observed over the temperature range. ZrO_2 is reported to exist in at least three crystalline modifications: monoclinic,²⁰ cubic⁵ and tetragonal²⁸ from X ray diffraction studies. Kelley and co-workers²³ from a specific heat study of the oxide ZrO_2 have shown the existence of an (α) and a (β) form with a transition at 1205°C.

Zirconium forms a nitride ZrN having a cubic lattice of the sodium chloride type.² The reaction with hydrogen has been studied by Hägg.¹⁸ Several phases are observed. Hydrogen is adsorbed up to 5 pct in the hexagonal close packed lattice without an appreciable change in lattice parameters. The lattice constants of the solid solutions of oxygen and nitrogen have been given by Fast.⁸

4. STABILITY

The stability of the several oxides of zirconium has been studied by Cohn and Tolksdorf.⁵ They found the monoclinic modification to be stable to 1000°C and the tetragonal modification above 1000°C. The latter may be cooled

to room temperature. After long heating above 1900°C a trigonal modification was found to form. When cooled a transition occurs at 625°C.

5. EQUILIBRIUM CALCULATIONS ON THE REACTION OF ZIRCONIUM WITH SEVERAL GASES

Zirconium reacts with most of the common gases to form stable compounds with the exception of the inert gases. The chemical equilibrium of these reactions may be evaluated for reactions in which the end products are ZrO_2 , ZrN or ZrC . Data are not available on the reaction with hydrogen.

The following reactions of zirconium with O_2 , H_2O , CO_2 , CO and N_2 can be evaluated from thermodynamic data:

1. $Zr(s) + O_2(g) \rightleftharpoons ZrO_2(s)$
2. $2 Zr(s) + CO_2(g) \rightleftharpoons ZrO_2(s) + ZrC(s)$
3. $3 Zr(s) + 2 CO(g) \rightleftharpoons ZrO_2(s) + 2 ZrC(s)$
4. $Zr(s) + \frac{1}{2} N_2(g) \rightleftharpoons ZrN(s)$
5. $Zr(s) + 2 CO_2(g) \rightleftharpoons ZrO_2(s) + 2 CO(g)$
6. $Zr(s) + 2 H_2O(g) \rightleftharpoons ZrO_2(s) + 2 H_2(g)$

The letters (s) and (g) refer to the solid and gaseous states respectively.

The free energy of formation of ZrO_2 (α) and ZrO_2 (β) is calculated from the data given by Thompson³¹ and using the recent data of the Pacific Experiment Station of the Bureau of Mines²³ on the entropy of ZrO_2 (α) and the heat content of ZrO_2 (α) and ZrO_2 (β). The free energy of formation of ZrC is calculated from an equation given by Kelley.²³ This equation is open to some question and may involve a maximum error of ± 2 in the logarithm of the pressures calculated for the reactions

in which ZrC is involved. The results of the calculations are shown in Fig 1. The logarithm of the gas pressure or pressure ratios are plotted against the temperature in °C for the several reactions.

The results show the following: (1) ZrO_2 , ZrN and ZrC are stable at all temperatures shown in the graph and zirconium from a thermodynamic point of view will remove O_2 , N_2 , CO and CO_2 at the lowest pressures used in modern vacuum technology, (2) the reactions of water and carbon dioxide to form the oxide and hydrogen and carbon monoxide respectively are possible below 1100°C in vacua of the order of 10^{-7} mm of Hg.

Apparatus

BALANCE

The microbalance with its auxiliary apparatus is similar to that previously described.^{12,13} The sensitivity of the balance is 0.86 divisions (0.001 cm) per microgram and the weight change can be estimated to 0.3×10^{-6} g. The balance zero point is constant and the instrument is insensitive to pressure and to small changes in the temperature of the surroundings.

VACUUM SYSTEM

The vacuum system has been changed from that previously described.¹² The length of the glass tubing connecting the several parts of the apparatus has been decreased and the diameter increased to a minimum of one inch. In addition, a high speed single jet mercury diffusion pump of the Illinois design has been added to increase the pumping speed at the outlet of the pumps by a factor of ten. The Illinois pump is backed by a two jet Princeton type of mercury diffusion pump and a Cenco Hyvac fore pump. No grease, wax, cement or metal seals are used in the system.

FURNACE TUBES

Previous to this work we have used pyrex, Vycor and quartz tubing for the construction of the furnace vessel. For higher temperatures and better vacuum conditions we have recently found synthetic mullite or zircon to be very valuable materials for the construction of furnace vessels. These materials are vacuum tight when properly made and can be sealed directly to pyrex. This feature allows double walled furnace

vessels to be constructed in which the outer tube serves as a protecting vacuum.

McLeod gauge pressures of 10^{-6} mm or lower can be achieved with these vessels at temperatures of 1175°C and perhaps higher. Leak rate measurements with the McLeod gauge on these furnace tubes show values as low as 1.4×10^{-9} mm liters per sec. after pumping over night at 900°C . We do not infer that such readings represent conditions in the furnace vessel itself since a cold trap is used on the system.

The determination of the pressure in the furnace tube is a difficult problem and any apparatus for such a task must be incorporated in the tube itself. This problem will be discussed in a later communication. For chemical and metallurgical purposes the chemical reactivity of the furnace atmosphere is of more importance than the absolute value of the pressure. This can be measured by observing the reaction rate of an active metal such as zirconium in the furnace tube itself.

GAS PURIFICATION

The purification of the oxygen and hydrogen are the same as previously described.¹² The nitrogen is purified by passing the tank gas over hot copper turnings at 400°C and removing water vapor by passing over $\text{Ba}(\text{ClO}_4)_2$. The gas is next passed over palladium asbestos at 400°C and then through another column of $\text{Ba}(\text{ClO}_4)_2$ and ascarite. It is finally passed over a liquid nitrogen trap at 0.1 atmosphere pressure.

SAMPLES

The specimens of zirconium are cut from a five mil sheet of the metal obtained from the Foote Mineral Co. No accurate analytical data are available on the material. However, the supplier states that it contains approximately 3.0 pct hafnium and about 0.04 pct iron. We are indebted to Mr. W. C. Lilliendahl of our Bloomfield Works for furnishing additional information on the presence of carbon, nitrogen and oxygen in zirconium samples. Several samples of 0.05 in. drawn wire have shown the following analysis: carbon 0.01–0.05 pct; nitrogen 0.01 pct; and oxygen 0.02–0.04 pct.

The specimens weigh 0.6840 g and have a surface area of about 15 cm^2 . Most of the samples were abraded starting with No. 1 grit and finishing with 4/0 paper. The last stage of the

abrading is carried out under purified kerosene.

Results and Discussion

HIGH VACUUM REACTION

A consideration of the high vacuum reactions of the metal under investigation is essential if a film free metal is desired at the start of the experiment. For most metals this can be achieved by heating the metal to the reaction temperature in a vacuum of the order of 10^{-6} mm of Hg and then reducing the film initially present with pure hydrogen.

The problem of preparing and keeping an active metal such as zirconium in a film free condition is practically impossible. Zirconium not only acts as a getter but the oxide ZrO_2 is not reduced by hydrogen or other reducing gases. Since the oxide is soluble in the metal at high temperatures, the oxide film may be removed by heating. However, on cooling, a film will again form in the vacuum. This procedure results also in the addition of oxide and other impurities to the metal.

Since the oxides are not reducible we have adopted the use of abraded specimens. Every effort is made to keep the films formed during abrasion to a minimum. On heating the specimen in vacuum to the reaction temperature an additional film forms. With many metals this film is only several atomic layers thick. However, zirconium forms an unprotective film and the film forms continuously in the best vacuums that we have been able to obtain.

It is of interest to show the extent of the vacuum reaction of zirconium in a furnace tube made from zircon or mullite. The furnace tube consists of two concentric tubes closed at one end and sealed at the other end to pyrex.

FIG 2—Reaction Zr in vacua-zircon furnace tube 900°C .

The space between the concentric tubes is evacuated. Fig 2 shows the results of heating a zirconium specimen. The weight gain is given in scale divisions (1 division = 1.2 micrograms). Two curves are shown for a temperature of 900°C and for a McLeod gauge pressure of 1×10^{-6} mm of Hg or lower. The weight gain of a sample of zirconium suspended in the furnace tube is plotted against the time in minutes. The first curve shows the reaction rate after one hour of pumping time. A reaction rate of 0.2 divisions per min. is observed. This corresponds to 0.016 micrograms per cm^2 per min. or about 1 Å of ZrO_2 per min. assuming a surface roughness ratio of unity. The second curve shows the reaction rate after 15 hr of pumping. A reaction rate of 0.04 divisions per min. is observed which corresponds to 0.0032 micrograms per cm^2 per min. or 0.2 Å per min. The calculations on thickness are based on the assumption that the film is composed largely of ZrO_2 .

We are interested also in the nature of the reaction at temperatures below 425°C and for practical pumping times of up to one hour. These are the conditions that we use in our rate studies. Experiments indicate that the maximum film formation observed is of the order of 0.70 micrograms per cm^2 for one hour of reaction at 425°C . If this is assumed to be ZrO_2 , a maximum thickness of 43 Å may be formed. In most of our measurements the vacuum formed film will be a fraction of this value.

REACTION WITH OXYGEN

The reaction is studied as a function of the time, temperature, pressure and surface treatment. The results are presented in Fig 3, 4, 5, 6 and 7. The weight gain in micrograms per cm^2 is plotted against the time in minutes.

FIG 3—Reaction Zr with O₂ 7.6 cm. Effect of temperature 200–425°.

Assuming the ratio of real area to measured area to be unity ($P = 1$) and the oxide film to be ZrO₂,²¹ the thickness of the oxide film in Angstroms is 61.5 times the weight gain in micrograms per cm². Unless specifically mentioned the samples are abraded.

Time

Several experiments are made at 7.6 cm pressure and at 375°C to check the method and the reproducibility of the surface preparation. The results on the oxygen reaction can be duplicated within several percent. One run is extended for 7 hr but no additional information is obtained over the 2 hr experiments.

The shapes of the oxidation curves are similar to those observed for other metals.¹⁵ A fast reaction rate is observed in the early stages of the reaction which gradually decreases as the film thickens. In this sense the oxide film may be said to have protective properties.

Time and Temperature

Fig 3 shows the effect of temperature on the reaction for the range of 200° to 425°C. At the right of the curves is shown the weight gain corresponding to a thickness of 1000Å. A comparison of the 200°C curve with the 425°C curve after 2 hr of reaction shows a film thickness of 150Å at 200°C and a thickness of 5000Å at 425°C.

Time and Temperature Equations

Three equations have been used to explain the time variation of the oxidation rate. The parabolic rate law was

first derived by Pilling and Bedworth²⁶ on the basis of diffusion of oxygen through the oxide lattice. It has been derived more recently by Wagner and Grünewald³³ and by Mott.²⁴ The equation is

$$W^2 = Kt + C$$

Here W is the weight gain, t is the time and K and C are constants. Mott²⁵ has recently modified the parabolic law to account for the presence of a potential due to oxygen ions on the surface. The field resulting from this potential is greatest for thin films and becomes small for thick films.

The logarithmic rate law has been derived by Tammann and Köster.³⁰ This equation states that

$$t = \beta (e^{W/\alpha} - 1)$$

Here α and β are constants. The physical basis for this rate law has not been well established although Wagner³⁴ has recently derived the law from physical considerations.

The linear rate law is given by the equation

$$W = Kt + C$$

This equation states that the reaction rate is independent of film thickness and the limiting factor in the reaction rate is not a simple diffusion mechanism.

FIG 4—Reaction Zr with O₂ 7.6 cm. Parabolic rate constant vs. $1/T$.

Dunn⁶ first applied the Arrhenius equation to the temperature coefficient of oxidation rate measurements. The Arrhenius equation as applied here states that

$$K = Ae^{Q/RT}$$

Here K is the parabolic reaction rate constant, Q the activation energy and A is a constant.

Mott²⁴ has considered the physical interpretation of Q for the case where ions and electrons are diffusing through the oxide to react with oxygen at the gas interface.

One of the authors¹⁶ has applied the transition state theory of chemical reactions and diffusion processes as developed by Eyring and coworkers¹¹ to the oxidation reaction. The parabolic rate law constant K is given by the following equation:

$$K = \frac{2kT}{h} \lambda^2 e^{\Delta S^*/R} e^{-E/RT}$$

Here ΔS^* is the entropy of activation and E the energy of activation. λ is the interatomic distance between diffusional states, k is Boltzman's constant and h is Planck's constant. This equation is useful since both ΔS^* and E can be calculated. ΔS^* is the probability or steric factor of the particular barrier limiting the reaction.

Time and Temperature Correlation

The applicability of the parabolic and logarithmic rate laws can be tested by plotting the square of the weight gain against time in the former case and the weight gain against the logarithm of the time in the latter case. A straight line would show that the law is obeyed.

Parabolic plots are made of the data. Although some deviations are observed from a straight line during the initial stages of the reaction, there appears a trend to approach a straight line for the longer periods of the reaction.

Plots of the weight gain against the logarithm of the time show smooth curves of increasing slope. The logarithmic rate law does not apply for this reaction over the complete time and temperature range studied.

The linear rate law is not found to fit the data as can be seen by an examination of Fig 3.

It is necessary to conclude that none of the simple rate laws suggested adequately explains the data. The modification of the parabolic rate law as suggested by Mott is useful since it predicts the sign of the deviation as well as the general shape. However, the theory has not been developed in sufficient detail to apply to the data.

Temperature Dependence

The temperature coefficient of the reaction rate is a very useful quantity to evaluate. If the reaction rate can be related to a mechanism an energy of activation may be calculated for the process. If the theory or mechanism is unknown it is possible to show the thickness or time dependence of the temperature coefficient. Assuming that one mechanism has a constant temperature coefficient it may be possible to show whether one or more than one mechanism is responsible for the reaction. We will use both points of view in the discussion that follows.

1. *Energy and Entropy of Activation.* Fig 4 shows the parabolic rate law constant K plotted against $\frac{1}{T}$. The temperature range is from 200°–425°C. The limiting slopes at long times are used where the data deviate in the earlier stages of the reaction from the straight line.

The energy of activation of the rate determining process is calculated from the plot. A value of 18,200 cal per mol is found. The temperature independent factor $e^{\Delta S^*/R}$ is calculated from the

parabolic rate law constant as expressed by the transition state theory. The equations for the parabolic rate law constant K and the diffusion constant D_0 are as follows

$$K = \frac{2kT}{h} \lambda^2 e^{\Delta S^*/R} e^{-E/RT}$$

$$D_0 = \frac{K}{2e^{-E/RT}}$$

The significance of the terms has been previously discussed. The parabolic rate law constants vary from $0.0391 \times 10^{-14} \text{ cm}^2 \text{ per sec}$ at 200°C to $22.15 \times 10^{-14} \text{ cm}^2 \text{ per sec}$ at 425°C. In terms of Angstroms of film thickness, the above rates correspond to 2 Å per sec at 200°C to 50 Å per sec at 425°C.

Table 1 shows the values for the parabolic rate law constants and diffusion constants and the entropies, energies and free energies of activation of the rate determining process. The K values are connected to thickness by the use of the density of the oxide and the stoichiometric ratio of oxygen in the oxide. A surface roughness ratio P of 1 is assumed.

The energy of activation 18,200 cal per mol is lower than that observed for several other metals previously studied. The entropies of activation are negative and are close to those observed for the oxidation reactions on iron and aluminum. ΔS^* is a measure of the (frequency factor) or the probability of an ion with a definite energy getting through the lattice. For most metals ΔS^* is negative although tungsten and molybdenum show positive

values. The free energy of activation is made up of the energy of activation E and the term $T\Delta S^*$. The sign and magnitude of the term $T\Delta S^*$ thus determines whether the effective barrier ΔF^* is increased or decreased by the steric factor. The values of ΔF^* for the oxidation of zirconium vary from 29,850 to 35,800 cal per mol. These are somewhat lower than those observed for other metals at 400°C, for example, the ΔF^* for the oxidation of zirconium is 35,200 cal per mol while the following values are obtained for iron, tungsten, molybdenum and aluminum respectively: 39,150, 37,700, 36,260 and 39,900 cal per mol.

2. *Temperature Coefficient as a Function of Film Thickness:* The data shown in Fig 3 are plotted on a large scale and a smooth curve drawn through the points. The slopes of these curves $\frac{dW}{dt}$ are determined for film thicknesses of 10, 20, 30, 40, 50 and 60 micrograms per cm^2 by Lagrange's formula for determining slopes at a given point. These slopes are tabulated in Table 2 at the same film thickness as a function of the temperature. Fig 5 shows the slopes plotted on a logarithmic graph as a function of $\frac{1}{T}$. A series of straight lines of approximately the same slope are observed. This result indicates an approximately constant temperature coefficient over a wide thickness range. This suggests that one mechanism may be responsible for the reaction.

FIG 5—Oxidation rate vs. temperature at film thickness of 10–60-g per cm².

FIG 6—Reaction Zr with O₂ 375°C. Effect of pressure.

Pressure Effect

The effect of pressure on the reaction at 375°C is shown in Table 3 and in Fig 6. The pressure is varied by a factor of 100 from 7.6 cm to 0.076 cm of oxygen. The effect is largest for the thin film range and decreases with increasing film thickness. No simple relationship with the pressure has been determined.

Effect of Abrasion

Fig 7 shows a comparison of the reac-

tion of an abraded sample and an unabraded sample. The abraded sample oxidizes more rapidly than the unabraded sample. The effect may be related to one or more of the following factors: (1) increased surface area, (2) removal of initial oxide film, and (3) change in the size and state of the surface crystals.

REACTION WITH NITROGEN

In this section the reactions of zirconium with purified lamp grade of nitrogen are studied in detail as a

Table 3 . . . Summary of Data Pressure Effect

| Pressure Atmospheres | $\frac{dW}{dt}$ (micrograms per cm ² per min) $T = 375^\circ\text{C}$ | | | | |
|----------------------|---|------|------|------|------|
| | At the Following Thicknesses (Micrograms per cm ²) | | | | |
| | 0 | 10 | 20 | 30 | 40 |
| 0.1 | 15.9 | 5.35 | 1.1 | 0.46 | 0.24 |
| 0.01 | 14.1 | 3.33 | 1.02 | 0.35 | 0.17 |
| 0.001 | 8.6 | 1.36 | 0.82 | 0.31 | 0.20 |

function of time, temperature and pressure and a comparison of two gas sources is used to show the strong effect of impurities. The results are shown in Fig 8–11 and discussed in the following subsections. In all of the figures the weight gain in micrograms per cm² is plotted against the time and where necessary the temperature is given at the top of the graph.

1. *Purity of Nitrogen:* A study of the reaction of nitrogen with zirconium presented the problem of obtaining a sufficiently pure gas to make the reaction with impurities a small part of the nitrogen reaction. To show this effect we can compare the results of the reaction using purified commercial nitrogen and purified lamp grade of nitrogen. The time course of the reaction of the purified commercial nitrogen at 350°C is identical with the reaction using the purified lamp grade of nitrogen at 700°C.

Mass spectrometer analysis of the gases showed the presence of 0.3 pct oxygen in the commercial gas source before purification. The lamp grade of nitrogen shows 0.01 pct. The gas analyses are not complete since hydrogen is not determined at low concentrations by our mass spectrometer.

It is of interest to note that colored films are formed using the purified commercial nitrogen while no films are observed in the experiments at the higher temperatures using the purified lamp grade of nitrogen. Electron diffraction studies show the outer layers of the colored films to be the monoclinic form of ZrO₂ while no diffraction patterns were obtainable with the higher temperature experiments using lamp grade of nitrogen. We do not conclude that no oxide or hydride is formed with the purified lamp grade of nitrogen but rather that the reaction rate is so slow that one has to use a higher temperature to observe an appreciable reaction. The temperatures used in the nitride study are in general above the decomposition temperature of the hydride. At temperatures above 500°C both the

nitride and oxide appear to be soluble in the metal and colored films would not be expected to be observed.

The stability of the nitride to vacua of the order of 10^{-6} mm of Hg has been tested experimentally. The reaction products formed with purified nitrogen at 750°C are stable to temperatures of at least 900°C. However, if the reaction products formed with purified commercial nitrogen at 425°C are heated, part of the product decomposes at 490°C. This may indicate the presence of a nitride of low stability or a hydride. The decomposition of the hydride occurs at about this temperature.

These experiments show: (1) that impurities of oxygen and hydrogen are very important in determining the rate of reaction and (2) that purified lamp grade of nitrogen is a rather pure source of nitrogen.

2. *Time and Temperature:* The time behavior of the nitride reaction for several temperatures from 400° to 825°C is shown in Fig 8. In all of the experiments the reaction rate decreases as the film thickens. The effect of temperature on the reaction rate is quite uniform.

The shape of the weight gain curves indicates that a parabolic rate law may agree empirically with the data. Fig 9 shows a plot of the weight gain squared against the time for the nitriding reaction at 750°C. The agreement is very good even for very small amounts of reaction. The agreement with the parabolic law at other temperatures is tested and except for the 400° and 500°C experiments is found to be good. At the lower temperatures deviations are observed for the initial stages of the reaction.

Although the data may obey the parabolic rate law the mechanism of the reaction may be quite different from the oxidation reaction since the nitride is soluble in the metal at these temperatures.

If we consider that the diffusion of ionic species through the surface film and surface interface reactions is not limiting the reaction it is possible to apply the results of diffusion theory to the reaction.

Van Liempt³² has considered the problem of the degassing of metals and he has by the aid of an approximation method obtained a solution to the problem. His equation is

$$Q/Q_0 = \frac{8}{d} \sqrt{\frac{Dt}{\pi}}$$

Here Q is the quantity of gas evolved

FIG 7—Reaction Zr with O_2 350°C. Effect of abrasion.

FIG 8—Reaction Zr with pure N_2 —7.6 cm. Effect of temperature.

or taken up at any time t , Q_0 is the original quantity of gas in the metal and D is the diffusion coefficient. This expression can be reduced to the parabolic law,

$$W/W_0 = K\sqrt{t}$$

In the van Liempt expression the only term that depends upon the temperature is D . Since the data fit the parabolic rate law it is of interest to evaluate the temperature dependence and relate this to the energy of activation E for the diffusion process.

Table 4 shows the values of the parabolic rate law constants for the temperature range of 400° to 825°C. Fig 10 shows a logarithmic plot of the parabolic rate law constant against $\frac{1}{T}$. A

straight line is found for the temperature range of 600° to 825°C. Below 600°C the data fall away from a straight line. An energy of activation of 39,200 cal per mol is calculated.

3. *Pressure:* Fig 11 shows the effect of pressure on the time course of reaction with purified lamp grade nitrogen at a temperature of 750°C. The rate of

Table 4 . . . Reaction Zirconium with Nitrogen 7.6 Cm

| Parabolic Rate Law Constants | | | |

| 825 | 1098 | 0.9107 | 9.60×10^{-12} |

reaction is nearly independent of the pressure in the range of 7.6 cm to 0.15 cm pressure. This evidence indicates that mechanism of reaction is very different from what is observed in the reaction with hydrogen which is presented in Fig 14 and discussed in the section *Reaction with Hydrogen* of this paper. In the case of hydrogen it is shown that the reaction rate is proportional to the square root of the pressure at a given temperature.

Barrer¹ has summarized several systematic studies of the permeation of hydrogen through metals. Two possible

FIG 9—Reaction Zr with pure N_2 —7.6 cm. Parabolic plot.

FIG 10—Reaction Zr with pure N_2 — $\log K$ vs. $\frac{1}{T}$.

FIG 13—Reaction r with H_2 . Effect of temperature.

FIG 14—Reaction Zr with H_2 300°C. Effect of pressure.

FIG 15—Reaction Zr with H_2 300°C. Initial reaction rate vs. $P^{1/2}$.

rate-pressure relationships have been found:

(1) Activated diffusion without dis-

$$\text{sociation } \frac{dW}{dt} = -kpe^{-b/T}$$

(2) Activated diffusion with dis-

$$\text{sociation } \frac{dW}{dt} = -kp^{1/2}e^{-b/T}$$

Here $\frac{dW}{dt}$ refers to the rate of reaction, p the pressure, t the time, T the temperature and k and b are constants. This expression predicts for the diffusion of atoms in the crystal of zirconium at constant temperature an expression of the type $\frac{dW}{dt} = Ap^{1/2}$.

It is rather surprising that the reaction does not follow one of the rate-pressure relationships. This evidence indicates that the reaction is not occurring on a bare metal surface but rather through a film of the nitride, the nitride in turn dissolving in the metal. Upon evacuation the nitride continues to dissolve but no further film formation is possible. After a certain time bare metal will be exposed and this is the condition in which we find the metal after completion of the experiment. The thickness of the nitride film is governed by the rate of reaction which is a reciprocal function of the thickness and the rate of solution of the nitride. The square root relationship of pressure is not expected to govern a reaction in which a film is present since the nitride is diffusing under a constant concentration gradient.

REACTION WITH HYDROGEN

The reaction is studied as a function of time, temperature and pressure. The stability of the reaction product is studied as a function of the temperature under high vacuum conditions. Fig 12–

16 show the results. The hydrogen is prepared by diffusion through a palladium tube after a preliminary purification. A maximum pressure of 2.6 cm of hydrogen is used in the experiments since greater pressures required rather long preparation times.

Fig 12 shows a preliminary study of the reaction as a function of temperature for a pressure of 2.2 cm of hydrogen. The reaction appears to start at a temperature of 235°C and the rate of reaction increases rapidly with the temperature. A visual examination of the film showed no evidence of a surface film. It is assumed that the hydrogen is dissolving in the metal to form a compound or stable complex. On evacuating the hydrogen from the specimen shown in Fig 12 no decomposition is noticed. This evidence supports the point of view that the hydrogen is forming a compound or complex.

1. *Time and Temperature:* It is of interest to examine the time behavior of the reaction rate. Typical curves are shown in Fig 13 for temperatures of 250° to 300°C. The reaction rate falls off with time. An analysis of the change of slope with time shows that there is no great difference in the way the rate is changing with time for the three curves in spite of the great difference in the amount of hydrogen taken up during the reaction.

The 300°C curve after two hours of reaction shows a hydrogen uptake corresponding to the formula $ZrH_{0.216}$. Hall and co-workers¹⁹ have found a saturation value of $ZrH_{1.95}$ for 20°C. No attempt is made to determine the saturation value.

If the rate determining process in the uptake of hydrogen is the diffusion of hydrogen into the metal, it is possible

to account qualitatively for the decrease in reaction rate as due to a change in the diffusion constant D or to a change in the concentration gradient.

2. *Temperature:* A study of the reaction with hydrogen as a function of temperature is necessary if the details of the reaction mechanism are to be worked out. However, the reaction is very sensitive to the pretreatment and to the presence of surface films. In addition, the reaction is very sensitive to temperature, especially in the temperature range of 275° to 300°C. Very little reaction occurs at 250°C while at 300°C a very rapid reaction rate is observed. The temperature coefficient has not been determined for this reaction.

3. *Pressure:* The effect of pressure on the permeability of metals to hydrogen has been discussed by Barrer¹ and summarized in the section on *Reaction with Nitrogen* of this paper. Two possible rate-pressure relationships were proposed: (1) Activated diffusion without dissociation, and (2) activated diffusion with dissociation. Mechanism (2) is expected to govern the diffusion of hydrogen in metals since the openings in the metal structure are not large enough to allow molecules to diffuse directly.

The reaction rate may then be expressed at a constant temperature as follows:

$$\frac{dW}{dt} = Ap^{1/2}$$

Fig 14 shows the effect of pressure on the time course of the reaction for a temperature of 300°C. The pressure is varied from 2.6 to 0.06 cm. The results show that pressure has a large effect on the reaction.

To test the application of the square root law Fig 15 shows a plot of the initial reaction rate $\frac{dW}{dt}$ as a function of $p^{1/2}$. Good agreement is observed. This correlation shows that the diffusion of hydrogen into the metal is mainly by atoms of hydrogen.

It may be noticed that the curve bends at low pressure and is not linear with $p^{1/2}$ in this range. This effect has been discussed by Smithells and Ransley²⁹ for the permeation of hydrogen through metals. The rate should include a term which is a function of the fraction of surface covered θ .

4. *Stability:* Fig 16 shows the stability of the hydrogen complex with zir-

conium as a function of temperature in a vacuum of 10^{-6} mm of Hg. H_2 is added to zirconium at $250^\circ C$ and 2.5 cm pressure. After evacuation the temperature is gradually raised. The temperature is given at the top of the graph. At a temperature of $436^\circ C$ the hydrogen is given off. All of the hydrogen is removed as is shown in the figure. Above $700^\circ C$ the specimen is reacting with its environment and gaining weight. We are not sure whether the specimen is readsorbing hydrogen and other gases given off by the furnace. The addition of hydrogen to a low pressure appears to increase this reaction.

Conclusion

The kinetics of the reactions of ductile zirconium with oxygen, nitrogen and hydrogen are studied as a function of time, temperature, pressure, surface preparation and stability of the particular film. The vacuum microbalance method is used for all of the measurements.

The oxidation reaction showed an appreciable rate at $200^\circ C$. No simple rate law is found to fit the data over a wide temperature range. However, the modification of the parabolic rate law suggested by Mott predicts the general shape of the time curve. An analysis of the parabolic rate law plots for long periods of reaction time shows straight lines. Using the transition state theory of gas-metal reactions an energy of activation of 18,200 cal per mol and an entropy of activation of -25.6 cal per mol per $^\circ C$ are calculated. These are compared to similar calculations on other metals.

A study of the temperature dependence of the oxidation rate as a function of film thickness shows a constant relationship. This fact suggests that one mechanism is controlling the rate over a wide thickness range. No evidence was found for an unstable oxide.

The nitride reaction is of special interest. The reaction is found to be very sensitive to traces of oxygen and hydrogen in the reacting gas. The rate of reaction of zirconium with nitrogen is much slower than the reactions with oxygen and hydrogen. The data agree well with the predictions of the parabolic rate law although reaction films are not observed on the metal. An energy of activation of 39,200 cal is calculated from the temperature co-efficient of the parabolic rate law constants.

FIG 16—Stability of Zr hydride 250° – $1000^\circ C$.

The nitride reaction is insensitive to pressure and the reaction does not follow any simple pressure function. A theory of the reaction is presented in which the limiting factor is the diffusion of the nitride into the metal under the conditions of a constant concentration at the surface.

The stability of the nitride is tested and the nitride is found to be stable to a temperature of at least $900^\circ C$.

The hydride reaction obeys the square root of pressure law. In this case, a film is not formed and it appears that hydrogen diffuses into the zirconium lattice as atoms. The time behavior of the reaction deviates from a linear law. This deviation may be due to changes in the concentration gradient in the metal or to a change in the diffusion constant. The hydride is stable in vacua up to a temperature of about $440^\circ C$.

Discontinuous Crack Propagation

L. D. JAFFE,* Junior Member, AIME, E. L. REED,* and H. C. MANN*

It has been generally believed that fracture originates at a point and, if the stress is sufficient, propagates across the material from this point. Evidence to the contrary is given in Fig 1. This micrograph shows an area close to the fracture of a steel containing

| C | Mn | Si | Cr | Mo | V |
|------|------|------|------|------|------|
| 0.28 | 0.74 | 0.20 | 1.00 | 0.49 | 0.12 |

The material had been quenched from 1675°F and tempered at 1150°F as a round about 10 in. in diam, and had a static tensile strength of 132,000 psi and a static yield strength of 105,000 psi. The steel was broken in 3000 cycles of reversed bending at a nominal max. fiber stress of 110,000 psi at a speed of 10,000 rpm. It was in the form of a standard R.R. Moore specimen with 45° V-notch, 0.015 in. radius and 0.220 in. diam at base of notch. The fractured edge in Fig 1 is part of the central portion of the specimen which broke during the final sudden fracture.

Attention is directed to the short cracks which appear as dark lines within the specimen. Similar cracks were found in another specimen of the material, broken in 1,798,000 cycles at a nominal stress of 40,000 psi. The cracks were found in several areas close to the path of the final sudden fracture. This final fracture appeared microscopically to be wholly brittle and transcrystalline. Closer to the surface of the specimens, near the path of progressive fracture, which presumably advanced gradually during many cycles, there was microscopic evidence of some local deformation, but no microcracks. Neither were microcracks observed in areas distant from the main fracture path.

The following explanation is offered: In the sudden fracture of the specimen, a crack propagates along a crystallographic plane, with little or no plastic deformation of the adjacent material, until it reaches a grain boundary or a particle of carbide or inclusion which stops its advance. (The particle or boundary may be outside the plane of polish and not visible in the micrograph.) A stress concentration occurs about the end of the stopped crack. One or more new cracks are likely to start in the zone of this stress concentration. They may lie in the same grain as the first crack or in an adjacent

FIG 1—Microcracks near fracture of fatigue test specimen.
× 500. Vilella etch.

grain. New cracks may occasionally start in a nearby but not adjacent grain whose orientation with respect to the stress leads to more ready fracture than does that of the grain between. Once started, these cracks propagate along crystallographic planes in their grains and the process repeats. This leads to discontinuous, branching chains of microcracks.

As the process continues, microcracks probably tend to link up by fracture of intermediate material under the influence of increasing stress concentration. Occasionally, too, there may be a series of nearby grains of similar orientation so that there is a certain continuity of fracture across them. In either case the effective size of a crack is increased, resulting in greater stress concentration at its ends and a greater likelihood of further increase of size of the continuously-fractured region. When one continuous crack crosses the entire specimen, macroscopic fracture has occurred. The fractured edge of the specimen in Fig 1 represents a

series of microcracks which became continuous across the entire specimen. The short, dark-appearing cracks in the figure did not become continuous over a large area. The row of microscopic stress concentrations at their ends may link up with those of the "main crack" outside the plane of polish.

The above explanation does not imply that microcracks develop at the same rate in all portions of the specimen. They will develop most rapidly where the macroscopic tensile stress and macroscopic stress concentration are greatest. Viewed on a scale large compared to the grains, the fracture would appear to progress continuously across the specimen.

Although Fig 1 shows a specimen broken in a fatigue test, it is believed that the microcracks discussed do not depend on the repetitive nature of the stressing used, since they are in the region where "sudden" fracture occurred, presumably in a single stress cycle. The whole process of microcrack propagation outlined above is thought to have occurred during this single cycle.

It is believed that discontinuous crack propagation may be universal in brittle transgranular fracture of crystalline solids. Further experiments are under way.

specimen was found in perfect alignment with the classical conjugate slip lines and hence it may be concluded that both effects were caused by the same family of octahedral planes.

In order to observe critically the direction of slip on the cross-slip plane, a crystal was prepared as in the previous manner but without any flat surfaces. It was then extended an amount sufficient to produce a large number of slip lines.

In any metallic single crystal, slip lines are visible because the linear translation of the glide planes displaces the surface. There are, however, two positions (180 degrees apart) on the circumference of a cylindrical crystal at which this displacement is parallel to a surface plane and hence slip lines would not be visible. These positions lie in planes containing the specimen axis and the slip direction.

By observing the presence or absence of cross-slip in planes parallel to the plane containing the specimen axis

and each of the three possible slip directions in turn, the plane of observation in which cross-slip could no longer be observed would identify the direction of slip. The technique becomes critical if the three observation planes are suitably placed about the periphery of the cylindrical specimen. Accordingly, careful microscopic observations were made at all positions on the circumference of the crystal. The position where cross-slip could not be observed coincided with the position where primary slip lines could no longer be seen. Furthermore, since cross-slip could be seen at all other positions, two of the three possible slip directions were eliminated. Hence it may be concluded that both the primary and cross-slip planes possess the same slip direction.

Summarizing this situation, the slip systems involved in the plastic extension of the face-centered cubic alpha brass are: 1. The (primary) system required by the classical Taylor and Elam analysis. 2. A system exhibiting

the octahedral plane which contains the same slip direction as the first octahedral plane, now constituting the active direction as in the other system. 3. The conjugate system required by the classical Taylor and Elam analysis. 4. A system exhibiting the octahedral plane which contains the same slip direction as the plane normally acting in conjugate slip, now constituting the active direction as in the case of the conjugate system.

The slip produced by System 2 was originally termed "cross-slip" because its trace as observed in the first experiments cut across the trace of the primary slip and the early evidence of other cross markings now traceable to the conjugate slip system (acting prematurely) was not conclusive.

It should be noted that the same "cross-slip" plane is associated with both primary slip and conjugate slip but the direction differs in accordance with the associated plane. Therefore, three slip planes and two directions

of slip have been observed in these experiments.

X-ray Results

No measurable amount of asterism could be noted in the Laue spots during the deformation corresponding to shears through 0.463. At the beginning of classical conjugate slipping, a large amount of asterism could be observed. In some cases, the streaks encompassed as much as seven degrees.

After the crystal had been elongated 12.8 pct corresponding to a shear of 0.257, Debye rings amounting to at least 20 degrees of arc could be seen in the back-reflection photograms corresponding to areas such as those shown in Fig 8, whereas they could not be observed in photograms representing areas of the type shown in Fig 9. This effect became more pronounced throughout the specimen during the later stages of the deformational

process. At the beginning of classical conjugate slip, the fragmentation rings, sometimes as great as 180 degrees of arc, could be noted wherever there was a dense concentration of cross-slip (Fig 12) but was noticeably absent for areas of the type shown in Fig 13.

The lattice rotations for the various extensions of the specimen are plotted in Fig 15. These rotations follow, generally, the theoretically predicted course. It may be noted, however, that in the initial stages of deformation, the reorientations observed from the X ray data exceeded the calculated; they agreed in the vicinity of the symmetry curve and, in the final stages, the observed reorientations lagged behind the theoretical.

It may be well to point out that for the first five extensions, λ and χ values (λ is the angle between the specimen axis and the slip direction, and χ is the angle between the specimen axis and the primary slip plane) were observed from a series of photo-

grams made only at the center of the specimen, whereas, the λ and χ values for the last seven extensions were averaged from photograms made at the ends and center.

Stress-strain Results

The initial stress-strain curve for the specimen with a constant rate of loading of 100 lb per min. is plotted in Fig 16. Correspondingly, stress-strain curves for several series of consecutive loadings of the crystal to the yield point, generally with the same rate of loading, are plotted in Fig 17, 18, 19 (a larger shear and a ten-fold increase in the rate of loading) and 20. It may be noted that no noticeable rise in proportional limit results from this type of extension. However, by plotting the first loading of each group superimposed upon one another, Fig 21 is obtained, in which it is evident that strain hardening

FIG 9—Lack of cross-slip and density of primary slip lines on a surface diametrically opposite to the one shown in Fig 8. Stress axis is vertical. Shear is 0.257. $\times 1000$

FIG 11—Displacement of the third set of markings by primary slip clusters of different widths. Data obtained from Fig 10.

has occurred. Moreover, the plot of the critical resolved shear stress for each of these curves against the prior shear, Fig 22, is in good agreement with the strain hardening curve for brass of the same composition as reported by von Göler and Sachs.⁶ Whereas the von Göler and Sachs curve, Fig 23, indicates that, shear strengthening begins at a value of shear of about 0.18, the present curve shows that hardening begins at a value located between shears of 0.174 and 0.257. Beyond these points there is apparently a sharper rise in the present curve than in the one reported by von Göler and Sachs.

Discussion of Results

The methods by which the different parts of a metallic single crystal reorient during deformation and at the same time adjust themselves to the constraints of adjacent matrix material and the specimen grip ends have been

the subject of many investigations. These investigations have postulated in the main a bend-gliding mechanism (*Biegeleitung*)⁷ and a crystal fragmentation⁸ followed by the rotation of minute crystallites. Asterism has been cited as evidence of both these mechanisms. However, the absence of asterism and the presence of collateral slip on hitherto unpredicted systems in a strained crystal oriented wholly within the hypothetical single slip region suggest that the above postulated mechanisms can be considerably modified, perhaps in the direction of simplification.

Consider, for example, the constraints imposed by the material adjacent to a latent glide plane. Once slip has occurred along this plane forming a visible slip line at the surface, the crystal has already reoriented. The actual reorientation can be considered as formative during the gliding and completed once the slip line has appeared. Consequently, in order for reorientation to occur, the gliding

plane must be in a state of flexure (of the type reported by Polanyi⁷), caused by the stresses due to the unslipped adjacent material. This bending causes compression of the gliding plane on the concave side and tension on the convex side and is assumed to be directed about an axis in the plane of slip at right angles to the direction of slip ($\langle 112 \rangle$). A set of octahedral planes favorably situated to reduce these stresses would be the conjugate slip planes which cut across the primary planes at a wide angle (70 degrees) and it is not surprising to observe their participation in the process long before the advent of classical conjugate slip. Bending moments arising from the action of these intersecting octahedral planes would be opposite in the rotational sense although not entirely symmetrical since the $\langle 112 \rangle$ axes in question do not lie in the same plane. In order to produce glide plane curvature without plastic action, the potential glide plane would have to be bent elastically in the modified sense of elastic shear and flexure outside the range of perfect elastic behavior, that is, by an anelastic process or an initial elastic stage of flexural gliding. However, instead of full flexural glide, relief could take place by action of the conjugate slip planes just prior to slip on the primary glide plane carrying the highest conventionally resolved shear stress. It might be predicted, therefore, not only that a set of secondary markings would always be associated with the primary slip lines but that this set would also be displaced by the primary lines. This was found to be the case with the present specimens in which the markings in question have been described as the third set, and with other

crystals investigated in the Hammond Laboratory.

The cross-slip plane was identified as the one having a common slip direction with the major slip plane. Since it has also been found that the slip direction is the same for both the cross-slip plane and the major slip plane, shear may now be pictured as occurring simultaneously along a pair of planes forming steplike folds, with the cross-slip plane corresponding to the short leg of the fold. Whether this

can be clarified in the mechanics of stress action in a perfect crystal with regard for inhomogeneities at the stepped ends of the lamellae, or must be explained in terms of dislocations or other abnormalities in the crystal must be determined by further study.

In the initial stages of the deformation process, back-reflection Laue photographs were made with the X ray beam incident in the central region of the crystalline rod where the major deformation had occurred as shown

by the much larger number of slip lines in this area. Consequently, the lattice reorientation observed from the X ray data exceeded the reorientation as calculated from the initial and final gauge lengths representing the over-all elongation of the specimen. In the vicinity of the symmetry curve where the theoretical and observed reorientations agreed, slip had taken place throughout the crystal and the X ray data represented an average of exposures made at different points of

FIG 19 (right half)—Strain—in/in $\times 10^{-6}$.

FIG 22—Shear strengthening curve for specimen investigated.

the specimen and thus gave a more truly representative macro-history of the lattice reorientation.

In the later stages, the observed reorientations lagged behind the theoretical ones. This lag has previously been reported by von Göler and Sachs.⁶ An explanation of this latter behavior might stem from a consideration of the additional amount of glide on the cross-slip planes as compared with the small amount during the early stages of deformation. Cross-slip first occurred either simultaneously or in close association with primary slip since neither the primary nor the cross-slip lines were displaced. During the later stages of deformation, however, additional glide occurred on the cross-slip planes as noted by their displacement of primary lines. In this way, the theoretical reorientation did not represent the true reorientation since it gave no account of glide on the cross-slip planes.

Although consecutive loadings to the yield point show no strain hardening, shear strengthening can be observed after the separate extensions. One possible explanation for this behavior might be sought in the hypothesis that recovery rates are greater while deformation is proceeding than after deformation has stopped.

Summary

The observations reported seem to suggest that plastic deformation in single crystals of alpha brass of

approximately 70-30 composition begins by gliding on octahedral planes possessing cross-slip folds. This stage of the deformation process is not accompanied by measurable strain hardening. To cause slip to proceed along planes segmented into folds would conceivably require a greater stress than along other planes and, consequently, slip is diverted to undisturbed areas. Hence there would be no over-all measurable strain-hardening. When all available unslipped areas are eliminated, it would seem that greater stress would be required to cause further glide in previously slipped areas. This stage of the deformation process appears to be the beginning of shear strengthening and would be accompanied by the occurrence of further glide on the cross-slip and primary slip planes. Since shear strengthening begins to occur at about the point where additional glide has also occurred on the cross-slip planes as well as on the primary planes and since this stage of the deformation process is accompanied by notable fragmentation wherever there is a large amount of prominent cross-slip it would seem that shear strengthening may be caused primarily by the necessity of forcing glide along planes segmented into folds. With additional deformation which increases fragmentation, the stress rises sharply until the classical stage of conjugate slip begins. Cross-slip also occurs during conjugate slip and on the same slip plane that operated before true conjugate slip began.

The Effects of Molybdenum and Commercial Ranges of Phosphorus upon the Toughness of 0.40 Pct Carbon Chromium Steels

M. BAEYERTZ,* Member AIME, W. F. CRAIG, JR.* and J. P. SHEEHAN*

This paper deals with molybdenum modifications of 5140 steel that have the same hardenability but a better tolerance for phosphorus than the AISI-SAE 5140 grade. Lack of toughness in steels with higher than normal phosphorus contents is well known to metallurgists. This problem is troublesome even within normal phosphorus ranges, if the heat treatment or the design of the part or the service is critical. Under such unfavorable conditions and also in the case of phosphorus contents toward the upper side of the commercial range, the use of molybdenum to replace a part of the chromium in 5140 steel provides a factor of safety.

The toughness of steel is variously exhibited in different mechanical tests; broadly the term is applied to the capacity of the steel to deform prior to fracture. Defined in this way, toughness is considered to be an inherent quality that depends upon the composition and structure of the steel, and also upon its temperature during deformation and fracture in the test. In the present state of our knowledge, the type of mechanical test needs to be included in any discussion of toughness, because the revelation of this quality in steel depends on the stress state and rate of stressing imposed by the test.

In comparing the toughness of one steel with another by laboratory testing, it has long been customary to use notched tests that impose severe constraint to deformation, and then to test over a range of temperatures to obtain the so-called transition. At temperatures above the transition, the steel fails after considerable deformation and absorption of energy. Below the transition, less energy is absorbed as the steel fails largely by cleavage. The transition range itself is characterized by a more or less abrupt change

in energy absorption and type of fracture. The conventional V-notch Charpy impact test has been used exclusively in the work covered by this report. For the steels under study, rather sharp transitions are obtained with this test, at testing temperatures that are easily obtained in the laboratory. The position of the transition on the testing temperature scale provides a rather sensitive index of the toughness of the steel, when the steels under study are similar in character as they are in this work.

Turning to the metallurgical reasons for the greater toughness of one steel as compared to another, the authors propose to limit the discussion to the small field under study. Only one structural state is considered, tempered martensite of a hardness of about 28 Rockwell C or 269 Brinell. The study deals first with the loss of toughness in AISI-SAE 5140 steel caused by increasing the phosphorus content from about 0.020 to 0.040 pct. A second part of the work deals with counteracting this loss in toughness by replacing a part of the chromium by molybdenum. A series of molybdenum modifications was studied, in each of which the chromium was reduced sufficiently to duplicate the hardenability of 5140 steel.

Phosphorus affects the toughness of steel in two ways. An inherent lack of toughness of phosphorus-bearing ferrite as compared to low phosphorus ferrite has often been noted. Jolivet and Vidal¹

have shown that phosphorus has the same effect in tempered martensite in chromium steels. The other well known effect of phosphorus is to make steel susceptible to temper embrittlement. Temper brittleness is a loss in toughness brought about by tempering steel within a limited temperature interval somewhat below the A_1 temperature. In most of the standard AISI-SAE alloy steels, this temperature interval is approximately 850–1100°F. Either of these types of loss in toughness is easily followed by the shift in the transition temperature obtained with the notched-bar impact test. The data to be presented show the beneficial effect of substituting molybdenum for a part of the chromium in 5140 steel with either moderate (0.020 pct) or high (0.040 pct) phosphorus contents. Both the inherent lack of toughness of phosphorus-bearing steel and temper brittleness are counteracted by this use of molybdenum.

The work of Jolivet and Vidal mentioned above shows the detrimental effect of phosphorus on the toughness of tempered martensite in the absence of temper embrittlement, as well as the temper brittleness caused by phosphorus. They used two steels, essentially 0.25 pct C-1.4 pct Cr, with 0.044 and 0.012 pct P, respectively. The nonembrittled state was obtained by quenching in oil from 1610°F, then tempering for one hour at 1200°F and quenching in water. In this state the transition temperature range of the low phosphorus steel in the notched-bar impact test was below that of the steel with 0.044 pct P. An additional treatment of 24 hr at 975°F (that is, in the embrittling range) caused both steels to lose toughness, but the high phosphorus steel showed the greater embrittlement.

Recently Hollomon² has published a comprehensive survey and bibliography of the literature on temper brittleness, to which the reader is re-

paper.

ferred for a general review of the subject. Carbon, nitrogen, phosphorus, oxygen, and various alloying elements as well have been blamed for the embrittlement. Other pertinent papers have appeared subsequently. Cohen, Hurlich, and Jacobsen³ and McLean and Northcott⁴ have studied metallographic etchants for revealing the temper brittle state. Pellini and Quenau⁵ have obtained data which they interpret as indicating carbon to be the cause of temper brittleness. Their conclusion is based on the observation of isothermal development of brittleness at temperatures below the A_1 temperature but above that of the iron-nitrogen eutectoid. In the light of data to be presented later in this paper, it may be noted that their steel that developed brittleness at this high temperature contained 0.029 pct P, an amount which might be suspected as the cause of the embrittlement.

The inception of the case against phosphorus, as a factor in temper brittleness, dates from World War I. However, in this early work and to some extent in later investigations conclusions are based on tests made only at room temperature. Andrew⁶ reported that steels with phosphorus in the lower part of a range of 0.01 to 0.058 pct did not exhibit temper brittleness, while in the upper part of this phosphorus range the difference in impact strength between water quenched and slowly cooled specimens was as much as 50 pct.

Ashdown⁷ stated that temper brittleness was observed in large chromium-nickel steel forgings with phosphorus contents of 0.03 to 0.04 pct while he also observed its absence in aircraft crankshaft forgings of the same steel except with phosphorus below 0.02 pct.

Data presented by Andrew⁶ and also by Green⁸ show the influence of phosphorus in a series of 0.35 pct C-3.5 pct Ni steels alike in composition and treatment but with variable phosphorus content. The 0.018 and 0.039 pct P steels had susceptibility ratios of one; in those with 0.058 pct and higher phosphorus contents the ratio rose consistently with the phosphorus content. The susceptibility ratio is the impact value of the unembrittled steel divided by that of the same steel in the embrittled state. The ratio applies to a single testing temperature, usually room temperature.

Greaves and Jones⁹ obtained similar data using Cr, Ni and Cr-Ni steels with about 0.3 pct C, from which they concluded that phosphorus up to 0.04

pct has little influence on temper embrittlement but that higher phosphorus has a marked effect in raising the susceptibility ratio.

Reporting work on various plain carbon and alloy steels, Mauer, Wilms and Kiessler¹⁰ and also Bischof and Bottger¹¹ have added to the observations of the deleterious effect of phosphorus.

Bennek¹² studied the role of phosphorus in temper brittleness using susceptibility ratios, and in some instances supplemented these with determinations of the impact transition curves. Phosphorus contents ranged from less than 0.01 to 0.11 pct. Manganese, Ni, Cr, Cr-Ni and Cr-Ni-Mo steels were employed. Carbon contents were between 0.25 and 0.30 pct. Prolonged heating either above or below the critical range lessened the intensity of embrittlement developed on subsequent heat treatment; presumably phosphorus diffused from regions of high phosphorus segregation during the anneal. The low phosphorus steels exhibited little or no temper brittleness provided that the alloy content was restricted to 1.5 pct Mn, Ni, or Cr; however, a steel with 3.58 pct Ni, 0.92 pct Cr and only 0.012 pct P showed a marked shift in transition temperature on furnace cooling compared to water quenching after tempering. This apparent influence of hardenability on susceptibility to temper brittleness seems of importance, although, for fully hardened specimens, a reason is not obvious.

The greater tendency to embrittlement in steels containing both chromium and nickel, as compared to either alone, had often been observed by investigators of temper brittleness. Recently Hollomon² has shown a rather consistent relationship between the susceptibility ratio (specimens broken at -40°F) and the combined hardenability contributed by manganese, nickel, and chromium in a series of twenty-one 0.30 pct C, Cr-Ni-Mo steels. Manganese varied from 0.76 to 1.52 pct, nickel from a trace to 3.41 pct and chromium from 0.45 to 2.57 pct. Phosphorus was hardly variable as the entire range for the series was 0.009 to 0.014 pct.

Plan of Investigation

In the present work, a straight chromium grade was chosen to avoid the confusion of a number of alloying elements. Heats of 5140 steel were made

with phosphorus contents varying between 0.020 and 0.036 pct. The lower side of the phosphorus range was selected in an attempt to duplicate a usual residual for open hearth steels. The upper side was chosen to fall within the AISI-SAE specification for the grade. Then, because molybdenum has been the element most widely used for reducing or delaying the onset of temper brittleness, another series of modified 5140 steels was studied in which a part of the chromium was replaced by molybdenum, keeping the hardenability essentially constant. Phosphorus was varied as in the 5140 series.

It might be argued that reduction in chromium content would assist in reducing the susceptibility to temper brittleness but, in adding molybdenum, either the hardenability of the steel or the basic 5140 composition must be altered. In view of the apparent relation between hardenability and temper brittleness noted by many investigators and also from the standpoint of providing a steel with the same hardenability as 5140 but with a good tolerance for phosphorus, the substitution of molybdenum for part of the chromium seemed the best procedure, and the one of greatest commercial significance. If molybdenum were added to the 5140 base analysis without reduction in chromium, the 4140 grade of considerably higher hardenability would be approached.

In both the 5140 steels and the molybdenum modifications aluminum was used to produce fine grained steels, which would be comparable with a large part of the commercial production of 5140. Another reason for adding aluminum was to remove both oxygen and nitrogen from the metal phase and thus materially reduce the possibility of a contribution to temper brittleness by these elements.

The tempering treatments were illustrative of common commercial cycles. In considering the choice of a tempering cycle, it is desirable to have reference specimens in an unembrittled state of the same hardness as the embrittled specimens. In isothermal studies this has been done by tempering all specimens between the A_1 temperature and the embrittling range and then quenching in oil or water. Subsequent isothermal treatment in the embrittling range does not change the hardness materially, and the quenched specimens without subsequent isothermal treatment provide a nonembrittled norm.

While isothermal tempering of small

FIG 1—Hardenability band of 5140 and molybdenum-chromium steels with variable phosphorus.
Standard Jominy test, quenching temperature 1550°F.

specimens is attractive for the study of the embrittling reaction, it does not simulate commercial practice in the tempering of machine parts in which loss of toughness would be of practical importance. For the purpose of this work it seemed preferable to temper above the embrittling range and to obtain progressive embrittlement by cooling at various rates through the temper brittle range. A tempering temperature of 1150°F and a range of cooling rates wide enough to simulate those generally encountered in commercial heat treatment were chosen. Specimens quenched in water from the tempering temperature provided a non-embrittled norm for the evaluation of temper brittleness, and also for determination of the effect of the replacement of chromium by molybdenum on toughness in the nonembrittled state.

Another consideration in selecting the tempering treatment was the variable amounts of chromium and molybdenum in the steels, and the influence of these elements on the tempering rate. Their effect on tempered hardness is least at high tempering temperatures such as 1150°F chosen for this study. That the tempering treatments selected were fairly suc-

cessful in obtaining uniform hardness is shown by a maximum range in Rockwell C values of 25 to 31 for both the 5140 and the molybdenum-chromium steels. The molybdenum-chromium steels tended to be slightly higher in hardness than the 5140 steels at each cooling rate, and the hardness of both series decreased slightly with slower rates of cooling from the tempering temperature.

The transition range of the notched-bar test was used as a measure of toughness.

Preparation of the Steels

In order to have comparable steels, 500 lb laboratory induction furnace heats were made, using Armco iron from a single open hearth heat as the charge. Uniform furnace practice was maintained. The steel was deoxidized with 1½ lb of aluminum per ton in the furnace. The analyses of the steels are given in Table 1.

As phosphorus is one of the elements most apt to segregate in steel ingots, it was desired that the experimental data would approach those which might be obtained with the same phosphorus

contents in commercially produced steels. With this in mind, one ingot of 460 lb weight with hot top was poured from each heat and only the top half of each ingot was used in the study of temper brittleness.

The top halves of the ingots were forged to ½ by 2½ in. bars for the impact tests and 1¼ in. round bars for the Jominy tests. All stock was normalized from 1550°F and stress relieved at 1200°F prior to machining the specimens.

Determination of Hardenability

The standard Jominy test was used for the determination of hardenability. The Jominy bars were quenched from 1550°F. The hardenability band for the 5140 steels with variable phosphorus and for the molybdenum modifications is shown in Fig 1. The 5140 steels vary little in hardenability, but the band is unavoidably somewhat wider at the lower hardness levels as a result of the effect of molybdenum.

The austenite grain sizes of the various steels were ASTM No. 8 to 9, as determined by polishing a section from each Jominy test bar.

FIG 2—Impact transition curves for 5140 steel with variable phosphorus. Specimens quenched in oil from 1550°F, tempered for one hour at 1150°F and cooled at the rates indicated in the legend.

Determination of the Transition Ranges

Longitudinal Charpy specimens with a 45° V-notch of 0.010 in. root radius¹³ were used. They were machined in groups of four from the central portion of the ½ × 2½ in. bars.

The specimens, 0.016 in. oversize, were heat treated before grinding to size and notching. The base of the notch was perpendicular to the longitudinal direction of the bars, and extended between the specimen surfaces representing the top and bottom, 2½ in. wide surfaces of the bars. The notches were roughed out with a high speed steel milling cutter, and finished with a carefully ground and checked carbide tipped fly cutter. The radii of the notches were 0.010 in. and were held to a tolerance of ±0.001 in. by

checking every sixth specimen at 50 diam with an optical comparator.

The heat treatment consisted of quenching in oil from 1550°F, tempering for one hour at 1150°F and cooling at different rates from this temperature to 700°F. The cooling rates used were approximately ¼, 3, and 20°F per min., and water quenching. The 3 and 20°F per min. rates were nominal averages of the actual rates between 1150 and 700°F. The ¼°F per min.

rate was maintained with a program controller. All specimens were cooled in air from 700°F.

Specimens of each steel with each treatment were broken over a sufficient range of temperature to determine the transition range. A Sonntag Universal impact testing machine of 120 ft-lb capacity and a striking velocity of 17 ft per sec was used. The capacity was raised to 240 ft-lb when impact values over 90 ft-lb were expected. The data

FIG 3—Impact transition curves for molybdenum-chromium steels with 0.021 to 0.025 pct phosphorus. Specimens quenched in oil from 1550°F, tempered for one hour at 1150°F and cooled at the rates indicated in the legend.

are assembled in Fig 2, 3, and 4, in which the impact values have been plotted against testing temperatures in the conventional way. The points shown in the figures signify individual impact values, not averages. All of the data represent completely fractured specimens.

Rockwell C hardness values obtained on the impact specimens of the various

steels with each cooling rate are listed in Table 2.

Effect of Phosphorus in 5140 Steel

Fig 2 illustrates the changes in toughness that attended an increase in phosphorus from 0.020 to 0.036 pct in

5140 steel. Even in the specimens that were quenched in water after tempering, a rise in the transition temperature range with increase in phosphorus content is to be noted. This agrees with the previously noted observations of Jolivet and Vidal. As it seems unlikely that quenching in water allows sufficient time for embrittlement during cooling of an impact specimen, this effect of

FIG 4—Impact transition curves for molybdenum-chromium steels with 0.037 to 0.041 pct phosphorus. Specimens quenched in oil from 1550°F, tempered for one hour at 1150°F and cooled at the rates indicated in the legend.

phosphorus might be attributed either to inherent brittleness of the phosphorus-bearing ferrite phase in tempered martensite or to embrittlement during the period of tempering at 1150°F. While this question was not answered unequivocally, enough work was done to show that the result is essentially the same in tempering periods of one and three hours at 1150°F. Specimens from the three 5140 steels were heat treated in the same way as the water quenched specimens of Fig 2 except that the tempering period was extended to three hours. The impact transition curves for both the one- and three-hour treatments are shown in Fig 5. Only slight differences in transition were produced in each steel by the additional two hours at 1150°F. These data strongly suggest that the increase of phosphorus from 0.020 to 0.036 pct has raised the transition of 5140 steel, even in the probable absence of temper brittleness.

In Fig 2, temper brittleness becomes apparent with cooling rates less than that of the water quench. To aid in visualizing the influence of phosphorus (and later the combined effects of phosphorus and replacement of chromium by molybdenum), it seems desirable to have a numerical value for the transition temperature. The difficulty is the definition of a transition

temperature as a single temperature in the transition range. Such a definition is still a moot question among metallurgists. The most sensitive values for purposes of comparison would lie on the steepest portion of the energy curve, and, with this in mind, it appears possible to define the transition temperature arbitrarily for the data under consideration.

Inspection of Fig 2, 3, and 4 will indicate that the value of 45 ft-lb falls near the middle of the steepest portion of all the transition curves, and represents the relative placement of the transition ranges with respect to testing temperature. The transition temperatures read from the curves at 45 ft-lb are assembled in Table 3. The authors hold no brief for the value of

FIG 5—Comparison of transition curves of 5140 steel with variable phosphorus after one and three hours at 1150°F. Specimens quenched in oil from 1550°F, tempered for one and three hours at 1150°F and quenched in water.

45 ft-lb except to represent this particular set of data. All of the experimental points have been shown in Fig 2, 3, and 4, so that the reader may select his own criterion, should he not agree with the authors'.

Using the transition temperatures listed in Table 3, Fig 6 was prepared to illustrate the influence of an increase in phosphorus in 5140 steel. The ordinate is transition temperature, beginning arbitrarily at -150°F . Thus the transition temperatures indicated by the upper ends of the bars are significant, but not their length. It might be thought desirable to reduce this axis to the increase in transition temperature of the embrittled as compared to the nonembrittled state. This was avoided for two reasons. It would not show the relation of transition temperature in the water quenched state to the phosphorus content. Secondly, the rise in transition temperature brought about by an embrittling treatment may be only a qualitative measure of the degree of embrittlement, unless the transition temperatures of two steels being compared are essentially the same in the nonembrittled

state. At present there is no reason to suppose that the same rise in transition temperature, if it occurs in quite different temperature ranges, represents an equal change in toughness.

In Fig 6 the transition temperatures of the 0.020 and 0.025 pct P steels are essentially alike in the nonembrittled state, but show an increasing divergence as the cooling rate through the embrittling range is reduced. The divergence is small at a cooling rate of 20°F per min., but is larger with the slower cooling rates. The rise in transition temperature over the entire series of cooling rates is less for the 0.020 pct P steel than for the steel with 0.025 pct P. In the same figure, the transition temperature of the 0.036 pct P steel in the nonembrittled state is 40°F higher than that of the steels with lower phosphorus contents, but the rise in transition temperatures over the series of cooling rates is 220°F as compared to 135°F for the steel with 0.020 pct P and 170°F for the steel with 0.025 pct P. These observations indicate that phosphorus is a major cause of temper brittleness.

Effect of Phosphorus in Molybdenum-chromium Steels with Hardenability Similar to 5140 Steel

Fig 3 and 4 illustrate the extent to which the replacement of chromium by molybdenum in 5140 steel counteracts the loss in toughness caused by phosphorus.

In Fig 3 the steels have a phosphorus level of 0.021 to 0.025 pct; in Fig 4, 0.037 to 0.041 pct. With each steel the transition temperature rises progressively as the cooling rate is reduced from water quenching to $\frac{1}{4}^{\circ}\text{F}$ per min. Taken together with the data on 5140 steels in Fig 2, the impact transition curves of the molybdenum-chromium steels indicate that the replacement of chromium by molybdenum reduces the embrittlement caused by phosphorus to an extent dependent upon the phosphorus level and the amount of the replacement. To effect a similar reduction in embrittlement, the higher phosphorus steels require a greater addition of molybdenum than the steels with moderate phosphorus contents.

From the transition temperatures

listed in Table 3, Fig 7 has been prepared to show the combined effects of an increase in phosphorus and the replacement by molybdenum of a part of the chromium in 5140 steel. For the purposes of this comparison, average values of the transition temperatures were taken for heats 2316 and 2321, and for heats 2336 and 2337. The trends of transition temperature with both phosphorus and molybdenum are progressive throughout the data; only the transition temperature for the water quenched specimens of the 0.11 pct Mo steel with moderate phosphorus falls out of line. In the water quenched 0.020 to 0.025 pct P series (with the exception of the 0.11 pct Mo steel) replacement of chromium by molybdenum lowers the transition temperature slightly, amounting to about a 40°F shift for 0.16 pct Mo. In the 0.036 to 0.041 pct P series, the decrease in transition temperature for the same molybdenum content is less, amounting to about a 20°F shift in transition temperature. In each steel, the transition temperature in the nonembrittled state is raised by increasing the phosphorus content from the moderate to the higher level.

Turning to the evidence for temper brittleness shown in Fig 7, temper embrittlement is minimized by molybdenum but not entirely eliminated in any of the steels under study. In general, phosphorus increases the manifestation of temper brittleness, and the replacement of chromium by molybdenum lowers the transition temperature for each phosphorus level and cooling rate under consideration. In the range of 0.020 to 0.025 pct P, the beneficial effect of molybdenum is evident at all cooling rates (except the water quenched series of the 0.11 pct Mo steel). In the 0.036 to 0.041 pct P range the difference between no molybdenum and 0.11 pct is considerable, but the difference between 0.11 and 0.16 Mo is evident only in the cooling rates of 3 and of 1/4°F per min.

Discussion of Results

One effect of phosphorus is to cause a brittleness of tempered martensite which appears to be essentially the inherent brittleness of phosphorus-bearing ferrite so often noted by metallurgists. Confirmation of this was obtained in the present study of 5140 steels with 0.020, 0.025, and 0.036 pct P. The structural condition of the steel was martensite tempered for one and

FIG 6—Effect on transition temperature of an increase of phosphorus in 5140 steel. Transition temperatures taken from Table 3.

for three hours at 1150°F, followed by quenching in water. While the difference in tempering period had little effect on the transition temperature at each phosphorus level, a definite loss of toughness accompanied raising of the phosphorus from 0.025 to 0.036 pct. If this is caused by temper brittleness, nearly maximum temper embrittlement must have developed during the one-hour period of 1150°F. Such rapid development of temper brittleness seems improbable in view of the slow isothermal embrittlement in this temperature range shown by Pellini and Queneau for their high phosphorus steel. Thus it seems reasonable to conclude that phosphorus reduced the toughness of the tempered martensite, in the absence of temper brittleness. As deformation in tempered martensite occurs by slip in the ferrite phase, this loss of toughness is assumed to be the already well-known brittleness of phosphorus-bearing ferrite.

The inherent brittleness of phosphorus-bearing martensite described above appears to be counteracted to a slight extent by the replacement of chromium by molybdenum in 5140 steel, as illustrated by Fig 7. With the higher phosphorus level, the use of 0.11 and 0.16 pct Mo in this way lowered the transition temperature about 20°F. With the lower phosphorus level, the steel with 0.11 pct Mo appears to be

out of line as mentioned earlier; however, a recession of the transition to lower temperatures may be noted in the 0, 0.04, and 0.16 pct Mo series. The use of 0.16 pct Mo lowered the transition temperatures about 40°F as compared to 5140 steel.

The data obtained in this study substantiate the evidence presented by numerous investigators that phosphorus can cause temper brittleness in tempered martensite. Temper brittleness was observed to depend on phosphorus content in 5140 steel and also to a degree in the molybdenum modifications of this grade. Using the transition temperature as a measure of the degree of embrittlement, the susceptibility to temper brittleness in the molybdenum-chromium steels decreases as more of the chromium is replaced by molybdenum.

In the 5140 grade chosen for study, it has been demonstrated that a good tolerance for phosphorus can be obtained by the use of molybdenum to replace a portion of the chromium without essential alteration of the hardenability of the steel. The desirable amount of such replacement would depend upon the phosphorus level to be expected and the tempering cycle to which the steel is to be subjected. In commercial alloy steels made by the basic open hearth or electric process, the ladle analyses for phosphorus are

FIG 7—Combined effect on transition temperature of phosphorus and replacement by molybdenum of part of the chromium in 5140 steel. Transition temperatures taken from Table 3.

usually well below the maximum limits permitted by current AISI-SAE specifications. Because of segregation, however, substantially higher levels of phosphorus are frequently encountered, especially in material from the upper central portion of the ingots. It is in such material that the beneficial effect of replacing chromium by molybdenum would be greatest. The extent to which loss of toughness due to phosphorus segregation can be overcome is demonstrated by the 0.16 pct Mo-Cr steel with 0.041 pct P which had a lower transition temperature than the 5140 steel with 0.020 pct P when given an embrittling treatment, namely, cooling at $\frac{1}{4}$ °F per min. after tempering at 1150°F.

The work reported here has dealt entirely with 5140 steel and molybdenum modifications of essentially the same hardenability. Similar work is already under way on the effect of replacing a part of the manganese by molybdenum in 1340 steel, in an effort to evaluate further possibilities in the development of steels with good tolerance for phosphorus.

Conclusions

1. Phosphorus reduces the toughness of tempered martensite even in the absence of temper brittleness. In 5140 steel this loss in toughness can be partially compensated by replacement of part of the chromium by molybdenum with no essential change in the hardenability of the steel.

2. Confirmation has been obtained of the conclusion of a number of earlier investigators that phosphorus accentuates temper embrittlement of martensite. (Structures other than tempered martensite were not included in this work.)

3. The replacement by molybdenum of part of the chromium in 5140 steel materially reduces its susceptibility to loss of toughness by temper embrittlement.

4. A study of 5140 steels and molybdenum modifications of similar hardenability has shown that replacement of part of the chromium by molybdenum can be used to improve the toughness at phosphorus levels encountered in commercial steels.

FIG 1—Electrical resistance as a function of aging time at constant aging temperatures in water quenched and directly quenched specimens of an aluminum-copper alloy.

copper alloys quenched into cold water and aged at 200°C while specimens aged after quenching into boiling water or oil at 153°C showed precipitation throughout the grains. They correlated these structural observations with hardness-time curves for various aging temperatures and concluded that the rapid hardening of specimens quenched into water resulted from accelerated precipitation in regions plastically deformed by quenching. Other investigations¹¹⁻¹⁸ have confirmed that severe quenching promotes age hardening compared to cooling at slower rates from the solution treatment.

Experimental Procedure and Results

The alloys were received as hard-rolled sheet 0.066 in. thick. They had the following compositions:

| | Aluminum-copper, pct | Aluminum-silicon, pct |
|---------------|----------------------|-----------------------|
| Cu | 4.13 | 0.004 |
| Si | 0.002 | 0.97 |
| Fe | 0.003 | 0.005 |
| Mg | 0.001 | 0.001 |
| Al (by diff.) | 95.86 | 99.02 |

Specimens for hardness tests were cut from the sheet stock; they measured $\frac{1}{2}$ by $\frac{5}{8}$ in. (aluminum-copper) and $\frac{3}{8}$ by $\frac{5}{8}$ in. (aluminum-silicon). Specimens for electrical resistance measurements were prepared by wire drawing.

The aluminum-copper wire measured 0.0392 ± 0.0002 in. in diam and the aluminum-silicon wire 0.0385 ± 0.0003 in. For heat treating, the wires were cut into equal lengths of about $3\frac{1}{2}$ in.

The solution heat treating and artificial aging operations were carried out in salt or oil baths heated by electrical resistance units. The temperature was automatically controlled to $\pm 2^\circ\text{C}$ for solution treating and to $\pm 1^\circ\text{C}$ for aging. At and above 200°C a special heat treating salt mixture was used; at 125° and 70°C a light mineral oil proved suitable.

FIG 2—Electrical resistance as a function of aging time at constant aging temperatures in water quenched and directly quenched specimens of an aluminum-silicon alloy.

The solvus temperature is approximately 515°C for aluminum containing 4.13 pct copper¹⁹ and 525°C for aluminum containing 0.97 pct silicon.²⁰ The aluminum-copper alloys were solution treated at 524°C and the aluminum-silicon alloys at 535°C for a period of 6 hr. In preliminary experiments the hardness of water quenched aluminum-copper samples became approximately constant after 3 to 4 hr of solution treatment at 521°C. No undissolved second phase could be found by metallographic examination. Specimens treated for 10–12 hr showed marked grain growth.

After 6 hr of solution treatment one wire and one rectangular specimen were transferred rapidly to the aging bath. These will be referred to as directly quenched specimens. Another wire and rectangular specimen were

quenched in water at $20^{\circ} \pm 1^{\circ}\text{C}$ and were then placed in the aging bath. The directly quenched specimens aged at 70°C were quenched into water at that temperature and transferred to an oil bath for aging. Aging treatments of less than 20 min. were timed to within a few seconds and similar precision was maintained for longer aging times. The specimens were staggered so that only one rectangular and one wire sample were ready for testing at a time.

The specimens were quenched from the aging furnace in water at 20°C. Each wire was removed from the water bath after 10–15 sec and its electrical resistance measured. The hardness was then determined on the rectangular specimen. This small delay did not appreciably affect the hardness. For specimens aged less than 5 min., the

schedule was modified so as to allow almost immediate determination of resistance and hardness.

Electrical resistances were measured on a Kelvin double bridge using an effective specimen length of 2.376 in. The resistances were determined in microhms and are so reported here. Care was exercised not to deform or mar the wires, and any variations in tension applied by the holder were negligibly small.

The Rockwell F scale could be used with good reproducibility on the aluminum-copper samples, but was unsatisfactory for the aluminum-silicon alloys. All hardness values were therefore determined by superficial hardness tester on the Rockwell 15-T scale. Hardness readings on the same specimen of aluminum-copper alloy agreed within two or three points, but the

FIG 3—Hardness as a function of aging time at constant aging temperatures in water quenched and directly quenched specimens of an aluminum-copper alloy.

spread obtained with the aluminum-silicon specimens was large. Five, and occasionally six, separate readings were taken on each specimen in a standardized geometrical pattern. Only the averages of these readings are reported.

Both alloys were aged at 70, 125, 200, 250, 300, 350, 400 and 450°C. Fig 1-5 report all observed values graphically.

Discussion of Results

SOURCES OF ERROR

Measurements of hardness and resistance were made at room temperature on separate samples for each aging temperature and time. Aside from experimental advantages, this procedure made it possible to compare all data directly without reducing them to a common temperature. It should be kept in mind that each point plotted in Fig. 1-5 represents a different specimen.

The data obtained for aging temperatures above 300°C fit simple curves well. The observed values become less regular for aging below 300°C and are somewhat erratic at 125° and 70°C.

The resistance and hardness of samples in the water-quenched condition before aging were also determined. While the hardness values showed good agreement, the resistance values were spread over a considerable range, probably owing in large measure to variations in the quenching action. It is known^{18,21} that the quenching rate affects the properties of aluminum alloys in the water quenched condition much more than after aging.

GENERAL FEATURES OF AGING CURVES

The aging curves (Fig 1-5) show the effects of aging temperature, type of quench and alloy composition on the aging process. Before discussing these factors individually, some general features of the curves will be considered.

The first statement is general; the comments under (2) to (5) refer only to aging at 200°C and above, while the curves for 70° and 125°C are discussed under (6) and (7).

1. The changes in hardness and in electrical resistance are not directly comparable even for the same time and temperature of aging. Aside from the different nature of hardness and electrical resistance, in this investigation the two properties were measured on specimens of different size and shape. The resulting different quenching strains complicate any comparison by an additional variable.

2. The electrical resistance reaches steady values after sufficiently long aging. These values vary with the aging temperature, but are nearly equal at any temperature for water quenched and directly quenched samples. This applies to both alloys.

3. The resistance of the aluminum-copper alloy decreases sooner after a water quench than after a direct quench. At 250° and 300°C the de-

FIG 4—Hardness as a function of aging time at constant aging temperatures in water quenched and directly quenched specimens of an aluminum-silicon alloy.

crease in resistance slows down more in the water quenched than in the directly quenched specimens toward the end of the aging period so that the curves cross.

4. The resistance of water-quenched aluminum-silicon alloys decreases very rapidly at temperatures above about 250°C; a large fraction of the total

decrease occurs in the first minute of aging. The decrease in resistance of directly quenched aluminum-silicon alloys begins slowly and requires considerable time for its completion.

5. The alloys harden more rapidly after a water quench than after a direct quench. The maximum hardness of the water quenched specimens exceeds

that of the directly quenched specimens in most cases. The difference in the rate of hardening and in the maximum hardness reached tends to be larger in the aluminum-silicon than in the aluminum-copper system.

6. The difference in quenching interval between water quenching and direct quenching decreases as the aging temperature is lowered, but even at 70°C the two quenching treatments do not lead to identical results in all respects. Regardless of the type of quench the resistance of aluminum-copper alloys aged at 125° and 70°C decreases slowly, possibly after a small initial rise. During the aging times used the resistance of the aluminum-silicon alloys undergoes no change as the result of aging at 125° and 70°C.

7. The hardness of aluminum-copper alloys increases slowly with aging at 125° and 70°C. At the latter temperature the directly quenched samples lead by a small margin over the water quenched samples. This fact is consistent with the observation of Gayler¹⁶ who found that quenching into boiling water promoted the age hardening at 130°C of an aluminum alloy containing 4 pct copper more effectively than quenching into cold water. The behavior of the hardness of the aluminum-silicon alloys aged at 125° and 70°C is particularly interesting; the directly quenched samples show no change during the longest periods of aging employed while the water quenched samples increase steadily in hardness.

THE EFFECT OF AGING TEMPERATURE

Fig 6 and 7 show the total changes in resistance of the aluminum-silicon alloys against the aging temperature for different times. The plotted points are taken from the curves in Fig 2 and 5. Resistance-temperature curves for aluminum-copper alloys show the same pattern as the aluminum-silicon alloys although in a less pronounced manner. For each aging period the decrease in resistance reaches a maximum at some intermediate temperature. As the aging period is lengthened the maxima become more marked. They also shift to lower temperatures because the depletion of solute from the solid solution causes the reaction to reach a maximum at lower temperatures where a sufficient degree of supersaturation can be expected.

The hardness-temperature curves were simple only for water-quenched aluminum-silicon alloys (Fig 8). The

FIG 5—Electrical resistance and hardness as functions of aging time in water quenched and directly quenched specimens of an aluminum-copper alloy and an aluminum-silicon alloy aged at 70°C.

hardness peak was attained at lower temperatures as the aging period was lengthened. Hardness curves for aluminum-copper and directly quenched aluminum-silicon alloys did not show such a simple pattern.

Chevenard, Portevin and Waché⁸ found a maximum hardness value at 200°C for a water-quenched aluminum alloy containing 0.63 pct silicon and 0.13 pct iron aged 8 hr. This value is in good agreement with the corresponding result of the present investigation. In experiments of Jetter and Mehl¹⁴ with aluminum-silicon alloys a maximum of initial dilation against temperature of aging seemed to be approached at 236°C which was the upper temperature limit of their observations.

The temperatures for maximum total change in resistance (Fig 6 and 7) are not necessarily identical with the temperatures for maximum rates of resistance changes. In fact there is no satisfactory method of defining these rates in a manner which would allow an absolute comparison between different aging temperatures. The terminal solubility of copper and silicon in

aluminum increases with temperature and the resulting resistance of the saturated solution increases also. The change in resistance is therefore smaller the higher the aging temperatures.

A comparison on the basis of the completion of a specified fraction of the aging reaction is not a comparison in absolute terms. It implies that the aging curves have or should have similar shapes. For complex reactions in the solid state this assumption is not warranted. Nevertheless such arbitrary measures of the rate as the time required for half the total reaction are of some value and have been used for finding activation energies.

ACTIVATION ENERGIES

The rate of the aging process may be expressed by the equation

$$r = c \exp - \frac{Q}{RT}$$

In this equation the reaction rate r must be measured by some arbitrary standard such as the reciprocal of the time required for one-half of the total change in resistance or the reciprocal of the time required to reach maximum hardness. Q is the activation energy for

the over-all process, T is the temperature and R and c are constants.

The activation energy may be found from a plot of the logarithm of the rate against the reciprocal of the absolute temperature. Such curves were straight in the temperature range of 200–250°C, and in some instances up to 300°C. At higher temperatures some of the curves became erratic, but in most cases they bent back toward the abscissa. This behavior is to be expected from the eventual reversal of the aging rate with increasing temperature.

The activation energies determined from the straight portions of the curves are listed in Table 1. In every instance the activation energy was larger for the water-quenched than the directly quenched alloy. The faster aging rate of the water-quenched samples therefore must have been due to differences in the value of the factor c .

Guy, Barrett and Mehl¹⁷ found that the activation energy for precipitation in the copper-beryllium system is less than the activation energy for diffusion of beryllium in copper. A similar relation had been noted by Jetter and Mehl¹⁴ in their investigation of alu-

FIG 6—Electrical resistance of water quenched specimens of an aluminum-silicon alloy as a function of temperature at constant aging times.

Table 1 . . . Activation Energies (in Calories)

| Alloy | Based on Resistance | | Based on Hardness | |
|--------------------------|---------------------|---------------|-------------------|---------------|
| | Water Quench | Direct Quench | Water Quench | Direct Quench |
| Aluminum-copper | 30,500 | 24,100 | 34,200 | 25,100 |
| Aluminum-silicon | 24,300 | 15,900 | 24,100 | 22,900 |

minum-silicon alloys. In the investigation reported here this relation between activation energies of diffusion and of aging was confirmed.

THE EFFECT OF QUENCHING

As stated in the description of experimental procedure, the directly quenched samples aged at 70° and 125°C were quenched into media which were different from those used with all other directly quenched specimens. While the latter were transferred from the solution bath into the salt bath and remained there for aging, the specimens aged at 125°C were quenched into a bath of oil in which they were aged and the specimens aged at 70°C were quenched into water at that temperature and aged in oil. This difference in quenching procedure is one reason why the quenching stresses cannot be considered as continuous or simple functions of the aging temperature.

The sequence of molten salt (200°C and over), oil (125°C) and water (70°C), however, parallels the increase in quenching severity resulting from the decrease in temperature. A correlation of all runs on the basis of decreasing temperature is therefore reasonable.

While the final values of the resistance of water quenched and directly quenched samples are alike for any aging temperature, the rates at which these values are approached are generally more rapid after water quenching than after quenching directly to the aging temperature. This accelerating action of water quenching is particularly pronounced in the medium temperature range of aging. The water quench also accelerates the rate of hardening and with some minor exceptions raises the maximum hardness obtainable.

The accelerating effect of the water quench may be owing to one or both of two causes. In the first place, the number of available nuclei is larger at room temperature than at elevated temperatures according to Becker's analysis of nucleation.⁴ This is a simple effect of temperature. Secondly, rapid cooling by quenching into water produces thermal stresses and the resulting strains create favorable regions for the progress of age hardening. This effect results from the rapid change in temperature.

The number of nuclei is larger at

room temperature than at elevated aging temperatures because the critical radius for a stable nucleus decreases as the temperature is decreased. The greater undercooling and the greater degree of supersaturation with a receding solvus cooperate toward this decrease in critical nucleus size. In order to be effective in subsequent aging at elevated temperatures, however, the nuclei must remain in existence. They must, therefore, grow at room temperature or during heating so that they will not be below the critical size characteristic of the higher temperature.

If it is assumed that even a fraction of the nuclei existing at room temperature survives on heating, a difficulty arises from the generally accepted explanation of the phenomenon of retrogression or restoration. According to this explanation the property changes of an alloy aged at room temperature revert partially in the direction of the unaged state because on heating active aggregates go again into solution. Since the nuclei resulting from a short period at room temperature are smaller than the aggregates resulting from long-time aging at this temperature, they can be expected to resist the effects of higher temperature less strongly.

A difference exists between room-temperature age hardening and room-temperature nucleation: the matrix surrounding the hardening aggregates

FIG 7—Electrical resistance of directly quenched specimens of an aluminum-silicon alloy as a function of temperature at constant aging times.

approaches closer to the equilibrium state than does the matrix which surrounds the nuclei existing at room-temperature. The supersaturated matrix may have a stabilizing effect on the nuclei which is absent in the matrix after aging. Whether such a stabilizing effect is sufficiently strong to protect small nuclei at a temperature where retrogression would occur is open to question. It can be stated with certainty only that the effect of room temperature on nucleation favors the aging of quenched alloys to whatever extent nuclei survive upon reheating.

An alternative or additional explanation of the acceleration of aging caused by water quenching is based on the effect of strains on the age hardening process. Plastically deformed regions are regions of instability. Their high energy favors any rearrangement which tends toward a more stable condition. In addition to explaining the increase in the rate of aging, strains can also explain the greater total hardness obtained by water quenching than by direct quenching. Following an argument of Fink and Smith,¹⁰ the increase in hardness results from the presence of zones of preferential aging throughout the grains; the spread in time between aging at the grain boundaries and in the bodies of the grains is thus reduced and this causes a more concentrated aging effect and greater

hardness. It should be emphasized, however, that a corresponding argument can be based on the nucleation effect of low temperatures.

It may be argued that the effects of strains are removed on reheating to elevated aging temperatures. Hartnagel¹² concluded from his work that relief of quenching stresses takes place and this is also to be expected from the work of Kempf and Van Horn²² on residual stresses in aluminum alloys. Regardless of the relief of residual stresses during aging, the plastic strains due to the thermal shock of quenching create regions of instability in which the aging process takes place preferentially. In fact, the process by which the effects of plastic deformation are relieved in age hardening is probably closely related to the aging process.

THE EFFECT OF ALLOY COMPOSITION

When the aging curves of the two alloys are compared, several differences become apparent. Except for aging at 125° and 70°C, the electrical resistance of water quenched aluminum-silicon specimens decreases more rapidly than that of the water quenched aluminum-copper specimens. The rates of hardening behave correspondingly, although to a less marked degree. At the two lowest aging temperatures the water

quenched aluminum-silicon alloy aged less rapidly than the aluminum-copper alloy, especially when considered in terms of the first appreciable aging effect.

The directly quenched samples of both alloys changed in resistance and in hardness at comparable rates at most temperatures but the directly quenched aluminum-silicon alloys showed almost no effect of aging at 125° and 70°C.

With minor exceptions the accelerating effect of water quenching is thus more marked for the aluminum-silicon than for the aluminum-copper alloy. This observation must be interpreted in the light of the fact that the age hardening mechanism is simpler in the aluminum-silicon than in the aluminum-copper system.

Summary and Conclusions

Two alloys of aluminum were aged at various temperatures after quenching from the solution treatment directly to the aging temperatures and also after first quenching into water. The progress of the aging reaction was followed by electrical resistance and by hardness measurements.

The absolute amount of change in electrical resistance as a function of the aging temperature went through a maximum. This was true for both

FIG 8—Hardness of water quenched specimens of an aluminum-silicon alloy as a function of temperature at constant aging times.

alloys and regardless of the type of quench, given a certain minimum time of aging. The change of hardness behaved similarly although some of the curves were of complicated shape. It may also be concluded that the age hardening rates went through maxima at intermediate temperatures, although no absolute basis exists for comparing these rates at different temperatures.

At most temperatures water quenching greatly accelerated the rate of aging compared to directly quenched samples. This accelerating effect is the result of strains caused by the thermal shock of quenching assisted to an unknown extent by the effect which exposure to room temperature has on nucleation.

At most temperatures the water-quenched aluminum-silicon alloy aged more rapidly than the aluminum-copper alloy, while the directly quenched alloys aged at comparable rates. At the two lowest aging temperatures, however, the water quenched aluminum-silicon alloy aged less rapidly than the aluminum-copper alloy and the directly quenched aluminum-silicon alloy showed almost no effect of aging. At most temperatures, the accelerating effect of water quenching over direct

quenching is larger for aluminum-silicon than for aluminum-copper alloys.

Acknowledgments

Low Pressure Distillation of Zinc from Al-Zn Alloy*

MAX J. SPENDLOVE† and HILLARY W. ST. CLAIR,† Junior Member AIME

Introduction

The problem frequently arises, particularly in refining metals or smelting scrap metals, of separating metals in the metallic state. Many metals may be separated by taking advantage of their difference in vapor pressure. Such separations can be made at atmospheric pressure, but the separations are much more selective and can be carried out at considerably lower temperatures if the distillation is done at pressures of a few millimeters or less in an evacuated enclosure. Until recently, this has not been considered feasible as a metallurgical operation, but the recent improvements that have been made in vacuum technology have broadened the applicability of vacuum processes and have prompted re-examination of low-pressure distillation of metals as a practicable process. The distillation of zinc from lead is one separation that has already been reduced to practice.¹

This paper is the first of a series of studies being made on separation of nonferrous metals by distillation at low pressures. Although these experiments were confined to the separation of zinc from aluminum, the significance of the results is by no means confined to these two metals. The purpose has been to investigate a metallurgical technique rather than merely to devise a means of separating specific metals.

The experimental work on distillation of zinc from zinc-aluminum alloys at reduced pressure grew out of earlier work on distillation at atmospheric pressure.² The earlier work indicated that it would not be practicable to decrease the zinc in the alloy much below 10 pct owing to the high temperature required. Therefore attention was turned to distillation at low pressures, at which lower temperatures are required. After preliminary tests were made in a small, evacuated tube furnace, a larger furnace having a capacity

of 100 to 150 lb of metal per charge was constructed. Distillation tests were first made on pure zinc and then on aluminum-zinc alloys of various composition. Particular attention was given to the limit to which zinc could be reduced in the residual metal. Data were also taken on the rate of evaporation, and heat balances were made for both the crucible and the condenser.

Distillation Furnace

The vacuum-distillation unit is illustrated schematically in Fig 1. The major components are the induction furnace, the condenser, the vacuum system, and the power-conversion unit. Power is supplied to the induction furnace from a 50-kw 3000-cycle motor-driven alternator. The pressure in the furnace is reduced by a vacuum pump having a nominal pumping speed of 10 liters per sec. When in operation, the metal vapors travel upward from the furnace to the water-cooled condenser where they are collected in amounts of 50 to 100 lb. The condenser is removed with aid of an electric hoist. When the system is under vacuum, the condenser is made self-sealing by a rubber gasket between the smooth-faced, water-cooled flanges at the top of the furnace and the bottom of the condenser. The pressure of the atmosphere is more than sufficient to insure sealing. At the conclusion of an experiment, the residual

metal can be removed from the furnace by removing the condenser and tilting the furnace with the electric hoist. The metal was cast into the molds carried on a mold truck. A photograph of the furnace and auxiliary equipment is shown in Fig 2.

The details of the vacuum furnace are illustrated in Fig 3. The furnace proper is made vacuum-tight with rubber gaskets placed at each end of a fused quartz cylinder. A clamping plate at the bottom and a ring at the top are made to squeeze the rubber between the metal and the end of the quartz tube. A large graphite crucible placed inside the quartz cylinder is thermally insulated and physically supported by refractory insulating bricks. A thermocouple in a quartz protection tube is located at the bottom of the crucible; the leads pass through a rubber seal in the bottom plate. The supporting structure for the furnace is an angle iron frame with transite board sides.

The condenser is made in the form of a water jacketed cylinder with an opening to the vacuum line at the top. The bottom has a projecting skirt inside the machined flange to provide additional cooling for the rubber gasket. Condenser sleeves are made in the form of two semicylindrical pieces of sheet metal that fit snugly inside the cooling jacket. The split sleeve facilitates removal of the condensate.

Measurement of Temperature and Pressure

The metal temperature was measured by a platinum-platinum rhodium thermocouple inserted in a well extending up into the bottom of the graphite crucible. During rapid evaporation there is a wide difference in temperature between the surface and the main body of metal in the crucible because of the large amount of heat that must be conducted to the surface to supply the heat of evaporation. The heat of

evaporation amounts to about 200,000 cal per lb of zinc. The temperature gradient required for conducting heat to the surface, neglecting the effect of stirring of the melt due to induced currents in the metal, will be of the order of 10 to 30°C per cm. Therefore, during rapid evaporation, the temperature of the main body of the melt as measured by the thermocouple at the bottom of the crucible may be as much as 100°C higher than the surface temperature. Nevertheless, the temperature of the metal is quite sensitive to changes in the temperature at the surface and gives a fairly accurate representation of relative temperature changes at the surface even though the actual recorded temperatures are considerably higher.

The pressure in the system was measured by a McLeod gauge and by a thermocouple gauge connected to the recording potentiometer. The vacuum indicated by the potential across the thermocouple gauge was checked frequently by the McLeod gauge. Dust filters and cold traps, cooled with dry ice, were placed between the vacuum gauge manifold and the vacuum line. A Pirani gauge was used for leak detection. A small jet of helium was passed over the walls where leaks might occur. When the stream of helium impinged against the leak, the Pirani gauge would indicate a sudden rise in pressure.

The pressure indicated by the vacuum gauge is the partial pressure of the residual gas in the system. There

is no way of directly measuring the partial pressure of the zinc vapor. During evaporation the partial pressure of the residual gas in the region between the metal and the condenser is much lower than is indicated by the vacuum gauge because the zinc vapor tends to sweep the residual gases toward the condenser. In other words, the zinc vapor acts as a diffusion pump, removing gases from the crucible and discharging them at the condenser. Therefore, during rapid evaporation the vapor above the metal is virtually all zinc vapor. The pressure of the residual gases indicated by the vacuum gauges applies only to the condenser and the lines to the vacuum pump.

Experimental Procedure

Weighed amounts of zinc or zinc and aluminum were melted together in the carbon crucible preceding the test. After the metals were thoroughly melted and blended, a sample was taken for chemical analysis. The condenser and baffle were put in place and the metal was allowed to freeze before the system was evacuated. If this precaution was not taken, the rapid evolution of gas from the molten metal during initial stages of evacuation sometimes caused spattering of the alloy into the condenser. After the system was evacuated, the metal was remelted, and the power was increased to the desired level. The flow of cooling water to the condenser was regulated during the test to keep the temperature of the water leaving the condenser less than about 90°C. The flow of water was measured by a rotameter. At the conclusion of a test the condenser was removed from the furnace and allowed to cool. Samples were taken from the condensate and the residual metal for chemical analysis and the condensate and residual metal were weighed.

Experiments 1 to 6 were made with charges of pure zinc. The purpose of these tests was to remedy any operating difficulties before introducing the aluminum and to obtain data on pure zinc for comparison with those to be obtained on zinc-aluminum alloys.

After the preliminary tests, cylindrical sleeves were placed in the condensing chamber to permit easy removal of the condensate. These sleeves were painted before each test with a thin paste of lampblack and water to prevent the condensate from adhering to the sleeve. The paste was allowed

to dry before placing the sleeves in the furnace.

Radiation baffles were placed between the crucible and condenser to prevent direct radiation of heat to the condenser and to equalize the distribution of condensate. Three types of baffles were tried as shown in Fig 4. The baffles were constructed of iron and painted before each experiment with lampblack to protect the iron from the hot zinc vapor.

Experiment 1 was run without the radiation baffle. The deposit was clean and fairly dense but showed evidence of refluxing. The condensate from experiment 3, with a single-deck baffle in place, was cleaner, denser, and showed no evidence of refluxing. Improvements in the condensing sleeve were worked out in experiments 3 and 4. In these experiments the single-deck baffle directed most of the vapors to the lower portion of the condenser, thereby constricting the path of the vapor as the deposit grew out from the walls. In experiment 5 the baffle was inverted to direct the flow of vapor higher into the condenser. This change overcorrected the distribution, resulting in excessive condensation at the top of the condenser and clogging the exit to the vacuum line. In experiment 6, a two-deck baffle was made and placed within the condenser as shown in Fig 4. This baffle gave a fairly uniform deposit. Although baffles were useful in this furnace, it is doubtful that they are absolutely necessary. The same effects doubtless could be reached by properly proportioning the diameters of the upper part of the crucible and the condenser.

The metal temperature provides a good indication of what is happening in the distillation furnace. As the temperature reaches the melting point, an arrest is indicated on the temperature chart. The temperature climbs steeply until it reaches the point at which evaporation begins; then, as the heat supplied is gradually offset by the heat required for evaporation, the temperature levels and remains nearly constant for the remainder of the test. The beginning of distillation is also marked by a sudden rise in the temperature of the cooling water from the condenser as heat is transferred to the condenser by the zinc vapor. A typical temperature curve for the metal temperature is shown in Fig 5, together with a corresponding curve showing the variation of temperature of the cooling water from the condenser. It will be ob-

served that the temperature rises linearly after melting, as shown by section *AB*. The beginning of evaporation is indicated by *C*, the point at which the temperature curve begins to break away from *AB*. It will also be observed that the temperature of the cooling water starts to rise at the melting point and then begins to rise abruptly as the temperature reaches *C*. The rate of evaporation in each experiment was calculated, using point *C* as a starting point.

Distillation Tests on Pure Zinc

Six tests were made on distillation of pure zinc (99.99 pct Zn); the data for these tests are summarized in Table 1.

Evaporation began when the metal temperature reached about 470°C. The maximum metal temperature during evaporation was determined chiefly by the power input; for an input of 10 kw, the temperature leveled at about 500°C and for 30 kw at about 550°C. The metal temperature was also influenced by the distance

between the evaporation and condensing surfaces and by an obstruction to the flow of vapor to the condenser. This effect is shown by the temperature curves for tests 3, 4, 5, and 6 shown in Fig 6. Tests 3 and 4 were run with the single-deck baffle. This baffle constricted the flow of the vapor as it left the crucible and directed it toward the walls of the condenser. Most of the zinc condensed as large clusters of

crystals in the lower part of the condenser. In test 5 the baffle was inverted as shown in Fig 4, thereby constricting the flow even more than in tests 3 and 4 and directing the vapor to the top of the condenser. This caused the temperature to rise to 540°. The double-deck baffle used in test 6 offered much less impedance to the vapor flow and caused more uniform distribution of the deposit. This ex-

plains the low average metal temperature during test 6. The temperature first leveled slightly above 470°; during the early part of the test the vapor traveled only a very short distance before it was condensed. As the zinc gradually condensed higher on the walls of the condenser where cooling was more effective, the temperature of the metal gradually rose to 500°C, the same as for test 3.

Referring to Table 1, it will be noted that the rate of evaporation is related more directly to the power input than to the metal temperature. This is not surprising since the rate of evaporation is determined by the rate at which heat is conducted to the surface of the metal; the metal temperature automatically adjusts itself to bring the two in balance. The relationship between rate of evaporation and metal temperature will be discussed again later.

Distillation Tests on Zinc-aluminum

Six distillation tests were made on zinc-aluminum alloy containing about 80 pct zinc. The alloy was made up of commercially pure aluminum (99.89 pct Al) and pure zinc. The zinc and the aluminum were melted and heated

until the aluminum was dissolved. The melt was then skimmed thoroughly before the condenser was placed on top of the furnace. In the first series of tests, only 60 to 80 pct of the zinc was distilled. Tests were made with the power input adjusted to 10, 20, 30 kw, respectively. Temperature of the metal, pressure of the system, and temperature of the cooling water of the condenser were all recorded automatically on a strip-chart potentiometer. A photograph of the chart for test 9 is shown in Fig 7. The chart is calibrated to read the furnace temperature directly in hundreds of degrees centigrade. The pressure and water temperature are recorded on the same chart in arbitrary units. Several actual values for the water temperature and pressure are shown on the chart. The horizontal lines indicate ten minute intervals.

In this test it will be observed that the metal temperature, which had been raised to about 700°C to dissolve the aluminum, dropped abruptly as soon as the vacuum pump was started. The rapid cooling of the metal is a result of rapid evaporation. When the power was turned on the metal gave off dissolved gases and the pressure in the system rose from 80 to 130 microns, then gradually decreased to about 90 microns as the metal was degassed.

The water-temperature variations

were a result of manual adjustment of the flow of cooling water. It was intended that the water should remain at 80°C but the valve adjustment was too coarse to permit accurate control during this test.

The undulations in the metal temperature are interesting. They were always observed when the temperature of the metal was in the liquidus-solidus range. They are explained as follows: As evaporation continues, the zinc in the melt is decreased until the metal temperature is equal to or perhaps less than the liquidus temperature. Then the solid phase crystallizes out; and since it is lighter than the melt, it floats on top. This forms a protective layer on the surface and decreases the rate of evaporation, allowing the temperature to rise until the solid phase is redissolved. Then the same sequence starts all over again, producing a series of undulations in the temperature. It will be noted that simultaneous variations occur in the pressure, indicating that gas evolution increases and decreases with the temperature throughout the test.

The temperature of the melt gradually increases as the proportion of zinc decreases. The vapor pressure of zinc in zinc-aluminum alloys shows a positive deviation from Raoult's law; that is, the vapor pressure is greater than that calculated by multiplying the vapor pressure of zinc by the molal fraction of zinc in the melt. The vapor pressure of zinc-aluminum alloys was measured by Schneider and Stoll³ at 650 to 800°C. They found that their data were in good agreement with Hildebrand's⁴ equation for activity of a solute, in which the coefficient β equals 0.50 or

FIG 7—Potentiometer chart for test 9 showing metal temperature, pressure in system, and temperature of water from condenser.

FIG 8—Temperature-composition curves for constant partial pressure of zinc over zinc-aluminum melts.

$$\log \lambda_{Zn} = \log \frac{p}{x_{Zn}p_0} = 0.50 (x_{Al})^2$$

where p_0 is the vapor pressure of zinc; x_{Zn} and x_{Al} are the respective molal fractions. From this equation and the vapor pressure of pure zinc it is possible to calculate the vapor pressure of molten zinc-aluminum alloys at any temperature and composition.

Evaporation of pure zinc begins when the vapor pressure reaches about 0.5 mm as indicated by the metal temperature. This would mean that evaporation begins at about 470°C for pure zinc, 560° for 10 pct Zn, 690° for 1 pct Zn, and 800° for 0.1 pct Zn.

If we carry this assumption farther it might be expected that the temperature of the surface of the metal would vary in such a way as to maintain a constant vapor pressure with changing composition. In that case, the temperature at constant power input would vary as in Fig 8, in which are shown the isobaric temperature curves for zinc-aluminum melts having partial pressures of 0.5 mm and 1.0 mm of mercury. However, it was observed, as shown by the temperature curves in Fig 9, that the temperature actually increased more than would be indicated by the isobaric curves of Fig 8. For example, the temperature of test 8 at a power input of 10 kw should have increased 15 to 20°C, according to the change in composition of the residual metal, but the observed increase in temperature shown in Fig 9 was 70°C. The discrepancy for the other two tests at higher heating rates is even greater. As we have already pointed out, the metal temperature may differ appreciably from the surface temperature

during rapid evaporation; but even after taking this into account, it is apparent that the isobaric temperature curves do not provide an adequate guide for predicting the rise in metal temperature.

Another factor to be considered is the nonuniformity of composition arising from rapid evaporation of the zinc at the surface. Zinc will tend to evaporate faster than aluminum can diffuse away from the surface, thereby causing a surface enrichment in aluminum. Accordingly, the observed temperature rise could be explained if the actual surface concentration of zinc in test 8 were between 10 and 20 pct zinc instead of 70 pct as given by the average composition. Likewise, an even greater concentration of aluminum at the surface would be expected at the higher heating rates in tests 11 and 14. The temperature rise in test 14 would indicate only about 2 pct zinc at the surface at the end of the test.

FIG 9—Variation of metal temperature during distillation of zinc from zinc-aluminum melts.

Extent of Removal of Zinc from Aluminum

A series of three tests was run in which the zinc in the alloy was reduced in successive steps. The progressive rise in metal temperature during these tests is shown in Fig 10. The power input to the furnace during the three tests was held at 10 kw. During the first test the metal temperature rose to 512° and remained constant to the end of the test; about 60 pct of the zinc was evaporated, leaving residue containing 34.5 pct zinc. In the second test, about 35 pct more of the zinc was distilled. The metal temperature during this time rose from 512 to 620°. During the final test the temperature rose continuously to more than 900°C and the zinc in the metal was reduced to 0.21 pct.

Comparative tests were made on alloys prepared from aluminum and from aluminum scrap to determine the effect of impurities and other metals

FIG 10—Metal temperature during three successive distillation tests on which zinc was reduced from 60 to 0.2 pct.

present in the scrap in minor amounts. The scrap aluminum came from melted aircraft scrap from the Naval Air Station at Norfolk, Virginia. It was designated by the symbol, "NAS-NOR." A representative analysis is given as follows:

| Analysis of NAS-NOR Alloy in Percent | |
|--------------------------------------|-------|
| Aluminum | 93.88 |
| Zinc | 1.09 |
| Iron | 0.91 |
| Silicon | 0.31 |
| Copper | 3.81 |

Tests 21A and 21B (Fig 11) were run with 2S aluminum and tests 22A and 22B, with NAS-NOR alloy. The original alloy for each test was made up to about 60 pct zinc. Each test was interrupted after 3 hr and a sample was taken of the residual metal. Then evaporation was continued for another 3 hr, during which the zinc in the residual metal was decreased to less than 1 pct. There was no appreciable difference in the metal temperatures during the first 3-hr period but during the last 2 hr the metal containing the impurities was about 30° hotter. The over-all rates of evaporation were very nearly the same, although more zinc was distilled in the first half of the test with scrap aluminum. All in all, there was no significant difference in the general behavior of the two alloys during distillation.

The important data for all the tests

on zinc-aluminum alloys are summarized in Table 2.

Nature of Condensate

The lower section of the condensate consists of large, dendritic clusters of crystals projecting outward from the walls and in a direction opposite that of the vapor flow. The deposit in the upper part of the condenser is thinner, more compact, and the crystals are much finer. This is illustrated by the photograph in Fig. 12. The form of the crystals in the crystal aggregates is greatly influenced by the rate of condensation and the partial pressure of the permanent gas in the system. At low evaporation rates and low pressures, the condensate is composed largely of fine, loosely compacted, needle-shaped crystals. At higher rates of condensation, the crystal aggregates become more massive and compact and at very high rates the deposit becomes compact and the surface becomes smooth and rounded as though the zinc were deposited in the molten state. The same effects are observed when the pressure is increased, except that the surface takes on a dull appearance instead of the bright, metallic surface produced at low pressures. The dull appearance may result in part from some surface oxidation at higher pressures.

The principal impurities found in the condensate were aluminum, iron, and cadmium. The iron is usually less than 0.02 pct; it was probably introduced as a result of contact with the condenser walls. The cadmium was introduced as a minor impurity in the zinc. It was present only in trace amounts. Aluminum is the only impurity that is inherently important. The vapor pressure of aluminum is only about 10^{-9} times that of zinc at 500°C, but when an alloy of aluminum and zinc is distilled the temperature increases and the partial pressure of the zinc decreases thereby increasing the proportion of aluminum in the vapor. For example, the aluminum in the vapor from a 10 pct zinc alloy at 600° is less than 10^{-4} pct. At 900° the vapor pressures of zinc and aluminum are 700 mm and 1.3×10^{-3} mm, respectively. The vapor pressure of zinc over a 0.1-pct zinc alloy is calculated as 0.91 mm, so that the condensate from such an alloy would contain aluminum and zinc in the proportions to give a deposit containing 0.14 pct aluminum.

The average analyses of the condensates obtained in these tests range from less than 0.01 to about 0.5 pct aluminum. The analyses of the condensates and residual metal for tests 15, 21, and 22, the three series in which the zinc in the residual metal was

reduced below 1 pct, are listed as shown below. The analyses for tests 21B and 22B show that the aluminum in the condensate increases markedly as the zinc is depleted in the residual metal. Furthermore, the aluminum content

| Test Number | 15 | 15A | 15B | 21A | 21B | 22A | 22B |
|-----------------------------|------|------|------|------|------|------|------|
| Residual metal, pct Zn..... | 34.5 | 3.8 | 0.21 | 19.4 | 0.96 | 25.5 | 0.98 |
| Condensate, pct Al..... | 0.20 | 0.10 | | 0.04 | 0.34 | 0.05 | 0.56 |

of the condensate greatly exceeds that which can be explained on the basis of evaporation of aluminum, indicating that the aluminum in the condensate is largely a result of spattering.

Spattering seems to occur chiefly during degassing of the molten metal. As the dissolved gas is expelled it carries with it a fine spray of metal formed when the bubbles break at the surface. Spattering from this cause can be reduced considerably by heating the metal very slowly during the time gases are being released. By following such a procedure, it was possible to reduce the aluminum in the condensate to less than 0.01 pct. However, when the zinc in the residual metal is reduced to a few tenths percent, some spattering seems to occur even when there is no evidence of gas evolution. This might be explained on the basis of the concentration of aluminum at the surface during a rapid evaporation. Normally vapor is formed only at the surface because the vapor pressure of the zinc is so low that the hydrostatic pressure even slightly below the surface is too great to permit the formation of bubbles. But as the surface layer becomes depleted in zinc, the temperature will rise to a point where the vapor pressure in the metal immediately under the surface layer will suffice to offset the slight hydrostatic pressure thereby allowing bubbles of zinc vapor to form just below surface. The breaking of these very small bubbles will cause a fine spray of metal some of which may be mechanically entrained in the zinc vapor and carried to the condenser. These droplets must be very minute to be carried by the attenuated zinc vapor, so it is likely that they would be extremely difficult to separate from the vapor. Therefore the condensate probably will contain several tenths of 1 pct aluminum when the zinc in the residual metal is reduced below 1 pct, even though elaborate precautions are taken to avoid contamination by spattering.

Heat Requirements

After distillation has reached a constant rate, the heat requirements consist of the heat of vaporization at the distilling temperature and the

heat necessary to supply losses by radiation and conduction. The heat required for vaporization is transferred by the vapor to the condenser and absorbed by the condenser cooling water. The remainder of the heat input is lost by radiation and conduction from the walls of the furnace and is approximately equivalent to the heat required merely to maintain the furnace temperature.

Tables 3 and 4 give the heat balances for the furnace and the condenser, respectively, for the six tests on distillation of pure zinc. Table 3 was determined by balancing the electrical power input to the furnace, after correcting for the losses in the electrical circuit, against heat removed by radiation and evaporation. The heat losses of the furnace by radiation and conduction were measured by a preliminary test in which the power requirements were determined for maintaining the furnace at various

temperatures when no distillation was taking place.

Evaporation of Metals at Low Pressure

Evaporation of liquids at low pressure is in many respects quite different from evaporation at atmospheric pressure. At low pressures the atmosphere above the liquid is made up almost entirely of molecules of vapor from the liquid. Vapor forms only at the surface and not in the body of the liquid such as occurs when volatile liquids boil at atmospheric pressure. Evaporation takes place at a rapid rate at low temperatures because the diffusion of vapor molecules away from the surface is not retarded by the presence of other gas molecules. The acceleration of evaporation by reduction in pressure is frequently explained

Table 3 . . . Heat Balance for Distillation Furnace

FIG 12—Zinc condensate showing large dendritic clusters found near bottom of deposit and dense fine grained deposit from upper wall.

as a result of the reduction in boiling point. This explanation applies as long as the total pressure remains appreciably greater than the partial pressure of the liquid, the boiling point being defined as the temperature at which the vapor pressure of the liquid is equal to the pressure of the permanent gas in the system. However, at very low pressures the rate of evaporation is limited not by the gas molecules but by the vapor molecules themselves. Under such circumstances the vapor pressure immediately above the liquid exceeds the partial pressure of the permanent gas and the boiling point no longer has any meaning.

The rate at which molecules of vapor leave the surface of the liquid is given by the effusion formula:

$$\omega_0 = p_0 \sqrt{\frac{M}{2\pi RT}} \quad [1]$$

where ω = rate of evaporation in grams per sq cm per sec.;

p_0 = vapor pressure of liquid in dynes per sq cm

M = molecular weight

R = gas constant in ergs per mol per °C

T = temperature °K

Expressing the rate of evaporation in grams per minute, the rate of evaporation of zinc is given by

$$\omega = 28.29 \frac{p_0}{T^{1/2}} \text{ g per sq cm per min.} \quad [2]$$

This equation gives the rate at which zinc would be evaporated into a vacuum or when evaporation is taking place at a comparatively slow rate. However, at high rates of evaporation the molecules of zinc leaving the surface interfere with each other and some of them return to the liquid. The effusion formula [1] may also be used to express the rate at which zinc is being recondensed on the surface:

$$\omega' = p \sqrt{\frac{M}{2\pi RT}} \quad [3]$$

where p now equals the partial pressure of the zinc vapor in contact with the surface. Therefore the net rate of evaporation is given by the difference between ω_0 and ω' or

$$\omega = (p_0 - p) \sqrt{\frac{M}{2\pi RT}} \quad [4]$$

For zinc, this becomes

$$\omega = \frac{28.29}{T^{1/2}} (p_0 - p) \quad [5]$$

When the rate of evaporation reaches a steady state the net rate of evapora-

tion as given by Eq 5 will be equivalent to the rate at which heat is transferred to the surface. The heat required to evaporate 1 g of zinc is 439 cal per g at 500°C. The temperature gradient required to conduct heat to the surface for evaporating at the rate of 1 g per sq cm per min. is equal to 53°C per cm. Therefore, the surface temperature at high rates of evaporation is a good deal lower than the temperature of the main body of metal.

The net rate of evaporation must also be equal to the rate at which vapor is diffused away from the surface. The rate of diffusion is determined by the pressure gradient of the zinc vapor between the evaporating and condensing surfaces. This explains why the temperature of the metal during evaporation is so responsive to obstructions between the crucible and condenser or changes in the distance between the evaporating and condensing surfaces. Any increase in the length of path of the vapor flow or in the pressure of the zinc at the condenser surface produces a corresponding increase in p , the pressure of the zinc at the evaporating surface. This requires a corresponding increase in the vapor pressure, p_0 , and the metal temperature as defined by Eq 5.

Another interesting effect to be considered in connection with the flow of zinc vapor to the condenser is the adiabatic cooling it undergoes. The temperature of the vapor in expanding from pressure p_1 at the crucible to pressure p_2 at the condenser decreases in the ratio

$$\frac{T_1}{T_2} = \left(\frac{p_1}{p_2}\right)^{\gamma} \quad [6]$$

The pressure of the zinc vapor at the evaporating surface is considerably less than the vapor pressure of zinc at the surface temperature or its temperature is above the dew point. However, as it is cooled adiabatically, the vapor becomes saturated so that even before it reaches the condenser, the temperature may be below the saturation temperature so that the condensation takes place from a supercooled vapor. For example, if the pressure of zinc vapor at the surface is 0.20 mm when the surface temperature is 500°C, the vapor at this point is only 20 pct saturated. However, when the vapor has expanded to a pressure of 0.15 mm the temperature will have dropped to the melting point, at which the vapor pressure of zinc is only 0.12 mm, and so the vapor is supersaturated with respect to liquid zinc. If the initial

pressure were a little lower the vapor would become saturated at a temperature below the melting point and would be supersaturated with respect to solid zinc.

This provides an explanation of the marked change in appearance that is found in the condensate at different rates of evaporation. At low rates the condensation takes place from a vapor that is supercooled with respect to the solid phase so the vapor condenses directly as a crystalline solid. At higher rates of evaporation, the vapor condenses from a vapor that is supercooled with respect to the liquid phase, so the vapor condenses momentarily as a liquid, chilling immediately to a solid. This deposit is more dense and compact and explains the rounded surfaces that give the appearance of having been melted.

These interesting aspects of low-pressure distillation of metal are discussed briefly to give a qualitative picture of the interrelation of the various factors that determine the rate of evaporation and the nature of the condensate. A more detailed study is being made of these phenomena which will be given a more extensive discussion in a later paper.

Acknowledgment

This investigation has been made by the Metals Recovery and Refining Section at the Eastern Experiment Station of the Bureau of Mines, College Park, Maryland. Acknowledgment is made to L. H. Banning and H. Bizot, formerly members of this group, who participated in the early experiments. Special acknowledgment is made to George E. Biser for his able assistance in constructing and operating the furnace; to A. M. Sherwood for the chemical analyses; to M. J. Peterson for spectrographic analyses; and to other members of the Eastern Experiment Station who contributed to this work.

Determination of Boundary Stresses during the Compression of Cylindrical Powder Compacts

M. E. SHANK,* Junior Member and JOHN WULFF,* Member AIME

Introduction

At the present time, the designer of dies for metal powder pressing is handicapped by relative ignorance of stress distribution and frictional effects at the interior surface of the die. Unckel¹ was the first to develop a method for the study of wall friction. He used three Brinell balls on which the die rested during pressing. The total frictional wall force was determined by the size of impression these balls left on a soft metal plate. Since the method does not give radial pressures, or distribution of such pressures, coefficients of friction could not be determined. Although Unckel measured density distribution, he was not able to determine radial or shear stresses. Shaler² has proposed theoretical expressions for the stress and density distribution within cylindrical compacts during pressing, in accordance with the experimental results of Kamm, Steinberg, and Wulff.³

By application of Siebel's method,⁴ Kamm et al³ plotted stress trajectories for two compacts. From the stress trajectories they calculated coefficients of friction from point to point along the die wall. As pointed out by Shaler in the discussion of Ref. 3, these values are based on progressive point-to-point calculations on finite size grid squares across the compact. In the region of the die wall such calculated values may therefore have considerable cumulative error.

The purpose of the present paper is to develop an experimental method by which the nonhydrostatic pressures and shears acting on the interior wall of a cylindrical die can be measured. Such measurements can then be correlated with existing data to aid in the explanation of the pressing process.

The method used is based on the elastic properties of the thick-walled

tube used as the die. The principle of super-position of force systems on an elastic body is assumed to hold. Electric strain gauges were mounted in adjacent positions on the exterior die wall in order to get an exact measurement of the variation of tangential strain over the length of the die during pressing. While in this paper, measurements in terms of only tangential strains are considered, it is well to note that similar calculations may be set up for axial strains. The latter are not preferred, since they tend to be smaller than the tangential strains and therefore permit less sensitive measurements. Discussion in this work is restricted to compacts pressed from both ends, since the elastic deformation of the die is then more amenable to analysis.

Before choosing the electric strain gauge method, a more direct line of attack was considered and discarded. The discarded idea was the insertion of a pressure gauge through a hole in the die wall.* The gauge would have been in the form of a small piston. If pressure were exerted against such a gauge, it would move outward along a radius of the die. One disadvantage of the scheme is its inability to measure shears along the die wall. Another

* Since the completion of this paper a manuscript,⁵ now published, was received. This work describes an investigation employing such a piston pressure device. The results, insofar as radial pressures are concerned, are at complete variance with the findings of this author. They are discussed more fully below.

more serious disadvantage is the disturbance caused by the device itself. It would serve to change the forces it was designed to measure. No matter how small the movement of the gauge, when pressure is applied a discontinuity would exist in the wall surface at that point. Due to the stress concentration caused by the hole, abnormal deflections of the die wall would occur around the gauge. During pressing, powder would be forced into the resulting depression. The depression would then become larger with increasing compacting pressure. Powder, not being a fluid, is capable of supporting shear. The ease with which it would flow into the die wall depression to further move the piston is an indication, not of the radial pressure at that point, but of the state of shear retarding the movement. Thus the "pressure" gauge is really a criterion of flowability, and of the capability of the powder to support shear. For these reasons, it was decided that the electric strain method, herein employed, was more reliable, if more indirect. The gauges and lead wires, mounted on the external die wall do not in any way affect the behavior of the metal powder or the die during pressing.

Theory of the Method

THE EFFECT OF RADIAL PRESSURE ON THE DIE WALL

Effect of a Single Small Band of Hydrostatic Pressure

Consider a die which is a thick-walled cylinder of outer radius R_o and inner radius R_i . If over a small finite length L there is a normal pressure P , a tangential strain distribution at the outer wall results. This is shown schematically in Fig 1. The exact shape of the curve may be predicted by an extension of the theory of a semi-infinite beam on an elastic foundation.⁶ This

FIG 1—Schematic illustration of strain due to a single increment of pressure.

Note that in all figures, strain abscissa correspond with outer die wall unless otherwise indicated. Z-axis is the axis of the die.

extension has been developed and experimentally verified by MacGregor and Coffin⁷ in their work on symmetrically-loaded thick-walled cylinders. For the calculation of external strains due to increments of pressure the accuracy of their theory is well within 5 pct for very small strains, and within 2 pct for larger strains. Since in our experiments the ends of the tube are not capped, the normal forces in the axial direction are carried by the die plungers, and we thus need not consider the effect of an axial tensile force on the die wall.

Using the above-mentioned theory, values of strain may be calculated along the length of the die at stations a distance L apart (See Fig 1). It is well to note that L should be small enough so that a powder compact of height L will exhibit fairly uniform normal pressure over its length while under compression. The calculations may be verified by filling the die with a hydrostatic fluid in sufficient quantity to occupy a length L in the die, the pressure P being exerted by loading the die plungers in a press. Readings may then be taken on the tangential electric strain gauges.

The calculated tangential strain ϵ_P caused by P is noted at each station.

Values of $F_n = \frac{\epsilon_P}{P}$ may then be calculated, and F_n is called the pressure influence factor. The subscript n indicates the station (distance) from the center of increment L . Since the die is elastic, if the value of P is increased, ϵ_P will increase in proportion. If a measured tangential strain ϵ_{Pn} at station n is caused by an unknown pressure P , then:

$$P = \frac{\epsilon_{Pn}}{F_n} \quad [1]$$

Effect of Several Small Bands of Hydrostatic Pressure

In a compact pressed from both ends, conditions will be symmetrical about the center.⁸ Suppose for the time being that the compact exerts no shear force on the die wall, and that the length of the compact is broken down into five increments, each of length L . Each increment L is assumed to exert uniform radial pressure over its length, as shown in Fig 2. The strain due to each pressure band (increment) is similar in shape to that of a single band. By the principle of elastic superposition the total strain at any point along the die axis is the sum of the five individual strains at that point (see Fig 2). The previously calculated influence factors hold for each of the five individual strain curves. Applying these elastic influence factors to each of the five strain curves, there result five expressions for the total strain due to pressure at stations 0 to 4 inclusive:

$$\begin{aligned} (\epsilon_P)_0 &= F_0 P_0 + 2F_1 P_1 + 2F_2 P_2 \\ (\epsilon_P)_1 &= F_1 P_0 + (F_0 + F_2) P_1 + (F_1 + F_3) P_2 \\ (\epsilon_P)_2 &= F_2 P_0 + (F_1 + F_3) P_1 + (F_0 + F_4) P_2 \\ (\epsilon_P)_3 &= F_3 P_0 + (F_2 + F_4) P_1 + (F_1 + F_5) P_2 \\ (\epsilon_P)_4 &= F_4 P_0 + (F_3 + F_5) P_1 + (F_2 + F_6) P_2 \end{aligned}$$

The above constitute five equations for the three unknowns P_0 , P_1 , and P_2 , any three of which may be used for a solution after measurement of $(\epsilon_P)_0$, $(\epsilon_P)_1$, etc. by the electric strain gauges. A similar equation may be written for the total tangential strain at any point along the die.

EFFECT OF SHEAR ON THE DIE WALL

Effect of a Single Small Band of Uniform Shear

A compact undergoing compression will exert shear force in an axial direction on the inner die wall. Consider a shear stress exerted over an increment of length L in the die. The total resultant force T on the wall is then:

$$T = 2\pi R_i L \tau \quad [3]$$

Fig 3 shows this wall shear force T ; it is statically equivalent to the compressive force B , plus the moment couple $T-C$. From the separate consideration of the couple and the com-

FIG 3—Shear system and equivalent moment-compressive force system.

FIG 2—Schematic illustration of strain due to five increments of pressure.

pressive force one may calculate the shape of the strain curve due to the shear stress τ acting over the increment L . The compressive force gives rise to a linearly increasing tangential strain ϵ_r'' throughout the increment L . This strain is then a constant along the remainder of the tube to the end, where an equal and opposite shear force T must be applied to maintain equilibrium. The couple causes the strain ϵ_r' , which is antisymmetrical about the center of L . In effect, to the left of L the tube is constricted. To the right it is bulged. The sum of two curves is ϵ_r , the total tangential strain caused by the shear stress and is shown in Fig 4.

Since the total strain curve due to shear is asymmetrical account must be taken of this in denoting stations. As shown in Fig 4, positive stations will be taken on the side of positive strain; negative stations on the side of negative strain. At each station a shear influence factor $f_n = \frac{\epsilon_r}{\tau}$ is calculated.

On the positive strain side of the shear curve, the strain approaches a constant value (end effect). Correspondingly, for all stations in this region, the shear influence factors will be constant, and will be designated as f_e . The subscript e signifies end effect. Shear influence factors may then be tabulated.

Calculations of shear influence factors may be verified by placing a suitable material, such as metal powder, in the die. It should be of such quantity that a compact of length L will result after compaction to some arbitrary plunger pressure. While maintaining the plunger pressure an axial force T is applied to the circumference at one end of the die (see Fig 5). Such force should not be large enough to cause the

FIG 4—Schematic illustration of strain due to a single increment of shear.

die to slide by the compact. Readings may now be taken on the electric strain gauges. Such readings represent the sum of strain due to radial pressure exerted by the compact, and strain due to the applied shear. The shear force T is then removed. Readings of the strain gauges are again taken. Such readings represent strain due to pressure only. Difference between the two sets of readings yields values of strain due to shear. The shear stress is known from Eq 3, and the shear influence factors may then be checked.

Effect of Several Small Uniform Bands of Shear

Here, use is again made of the fact that in a compact pressed from both ends conditions will be symmetrical about the center. According to Kamm et al,⁸ the powder at the center does not move axially during pressing. The wall shear will therefore vary symmetrically about the center, with a value of zero for the center increment.

Consider in such a compact the strains due to shear caused by two shear increments equally and oppositely placed about the center. Strain distributions are schematically illustrated in Fig 6. Unlike the case of the single increment of shear, the die no longer need be supported at one end by a force T in order to be in equilibrium. Instead the compressive (end) effect of one increment is opposed by the compressive effect of the opposite increment. The compressive effect thus exists only between the increments, and does not persist down to the end of the die, as in the single increment case. In effect, the strain abscissa is moved up to 0-0 (see Fig 6), thus sub-

FIG 5—Schematic diagram for the arrangement for a shear check test.

FIG 6—Schematic illustration of the addition of strains due to equal and opposite shear increments. The new strain abscissa is indicated by the line O-O.

tracting the end effect strain beyond the increments (the portion of the die between either end and the edge of the nearest increment). Mathematically, this is accomplished in subsequent equations by subtracting the influence factor for end effect f_e from all terms involving the addition of strains due to opposite shear increments.

Note that the foregoing correction does not invalidate the principle of superposition. It is necessitated only because the boundary conditions of the force system (with several shear increments now present) are different from the boundary conditions for the single increment of shear. In effect, the force T has been moved from the end of the die to the body of the die.

With this correction in mind, and the fact that the wall shear at the compact center is zero, the expressions may be written (analogous to Eq 2) for total strain due to shear at any point. For five increments these are:

Similar equations may be written for the total strain due to shear at any station.

SOLUTION OF BOUNDARY STRESSES ON THE INTERIOR DIE WALL

In pressing of metal powder compacts from both ends, Eq 2 relates tangential strains with radial pressures on the die wall, and Eq 4 relates strains with shear. When both shears and pressures are present, as is usually the case, the expressions of Eq 1 and 2 are additive for each station.

Terms shown in the boxes are the ones of interest for a compact divided in three increments.

In the above, values of F_n and f_n are calculated. Strain values may be determined by experiment. Solution for the unknown shears and pressures may then be carried out.

Eq 5 treats the powder compact as a

$$\begin{aligned} (\epsilon_r)_0 &= 2(f_{+1} - f_e)\tau_1 + 2(f_{+2} - f_e)\tau_2 \\ (\epsilon_r)_1 &= (f_0 + f_{+2} - f_e)\tau_1 + (f_1 + f_{+3} - f_e)\tau_2 \\ (\epsilon_r)_2 &= (f_{-1} + f_{+3} - f_e)\tau_1 + (f_0 + f_{+4} - f_e)\tau_2 \\ (\epsilon_r)_3 &= (f_{-2} + f_{+4} - f_e)\tau_1 + (f_{-1} + f_{+5} - f_e)\tau_2 \\ (\epsilon_r)_4 &= (f_{-3} + f_{+5} - f_e)\tau_1 + (f_{-2} + f_{+6} - f_e)\tau_2 \end{aligned} \quad [4]$$

$$\begin{aligned} \epsilon_0 &= \boxed{F_0 P_0 + 2F_1 P_1} + 2F_2 P_2 + \boxed{2(f_{+1} - f_e)\tau_1} + 2(f_{+2} - f_e)\tau_2 \\ \epsilon_1 &= \boxed{F_1 P_0 + (F_0 + F_2)P_1} + (F_1 + F_3)P_2 + \boxed{(f_0 + f_{+2} - f_e)\tau_1} + (f_{+1} - f_{+3} - f_e)\tau_2 \\ \epsilon_2 &= \boxed{F_2 P_0 + (F_1 + F_3)P_1} + (F_0 + F_4)P_2 + \boxed{(f_{-1} + f_{+3} - f_e)\tau_1} + (f_0 + f_{+4} - f_e)\tau_2 \\ \epsilon_3 &= F_3 P_0 + (F_2 + F_4)P_1 + (F_1 + F_5)P_2 + (f_{-2} + f_{+4} - f_e)\tau_1 + (f_{-1} + f_{+5} - f_e)\tau_2 \\ \epsilon_4 &= F_4 P_0 + (F_3 + F_5)P_1 + (F_2 + F_6)P_2 + (f_{-3} + f_{+5} - f_e)\tau_1 + (f_{-2} + f_{+6} - f_e)\tau_2 \end{aligned} \quad [5]$$

series of average pressures and shears, varying in steps, over short increments of length L . For a given length of compact the approximation will be bettered by using a greater number (necessarily an odd number) of increments. A practical consideration limits this number. The labor of solving linear simultaneous equations increases roughly as the square of the number of unknowns. A mathematical consideration also enters. Consider, for instance, the array of numbers making up the coefficients on the right hand side of Eq 5. This array constitutes the determinant of the system of equations. If by chance this determinant has a value near zero, small errors (on the order of 0.01 pct) in the coefficients will cause huge errors (on the order of 100 pct or more) in the answers. Should the determinant approach zero, the answers approach infinity, regardless of other considerations. In either case, the error in the calculated answer may far exceed the magnitude of the true answer.

Equations similar in form to Eq 5 may be written for compacts divided into even numbers of increments. As will be pointed out, such equations were considered and discarded in the course of the present investigations.

Experimental Procedure

For investigation of boundary stresses the die must satisfy two conflicting requirements. It must be strong enough not to fail, yet be built lightly so that it will undergo large elastic strains in use. The die was therefore made ten inches long with external diameter of 2.000 ± 0.0005 in., and internal diameter (diamond lapped) of 1.128 ± 0.0005 in. Two plungers

were used, each 6 in. long and lapped to have 0.001 in. clearance with the die.

The material was an air-hardening, high carbon, high chromium steel (Airdi 150, Crucible Steel Co.), heat-treated to final hardness of Rockwell C 64. The die showed no sign of wear at the conclusion of the investigation.

Tangential strain gauges (Baldwin SR-4, type A-12) were mounted on the outer wall every 0.10 in. along the axial distance of the central portion of the die, and every 0.80 in. near the ends. Alternate gauges were 180° apart on the die. A total of 41 gauges was employed. The die was then placed in a loose-fitting frame, baked in a drying oven, and the gauges then wax-coated to seal out moisture. Two devices were available for strain measurement. The first was a manual SR-4 indicator, and the second an automatic scanning recorder which read and recorded all 41 gauges in less than a minute.

Pressing of compacts was performed on a standard type of testing machine. Lubricated spherical seats were mounted on the top and bottom platens of the press to prevent transmission of bending forces to the die.

After all equipment was assembled, the behavior of the gauges was checked by loading the die internally with oil under hydrostatic pressure. This method was also used to find the modulus of elasticity of the die steel which was $E = 31.65 \times 10^6$ psi. Poisson's ratio was determined as 0.273. Both the constants were necessary for calculation of the influence factors for pressure and shear (see Tables 1 and 2).

Check tests for the influence factors were performed in accordance with the principles previously described. As a hydrostatic medium, paraffin sealed in a thin rubber bag (0.002 in. wall) to

prevent leakage was employed. The amount of paraffin was such that it occupied the proper length in the die while under pressure. The center of the paraffin plug was located by measuring the distance which the plungers extended beyond the die. Results of one pressure check test are plotted in Fig 7. For the shear check test, a copper powder compact, exactly 0.20 in. high under 40,000 psi plunger pressure was used. The die was placed in the press, with the compact inside, and with the plungers loaded. A known force was then applied axially to the die wall, in accordance with the previously described principles. (See Fig 5.) Strain readings were then taken, the load re-

moved, and readings taken again. Results for one test appear in Fig 8. The scattering about the theoretical curve in Fig 8 is due largely to the low strain being measured.

In subsequent pressing tests it is certain that no powder was squeezed up into the space between plungers and die wall (except test C-10-a, copper, at 60,000 psi), since the plungers could be pulled out by hand following the tests.

Wall lubrication was used in several of the pressing tests. Stearic acid was one lubricant employed, and was applied by dissolving in benzene, until a supersaturated slurry was formed. Three coats of this slurry were painted on the die wall. Each was allowed to dry thoroughly before application of the next coat. This procedure resulted in a final heavy coating of stearic acid which completely covered the wall. Molybdenum sulphide, when used as a wall lubricant, was applied in similar fashion. It was not, however, possible to build up a heavy coating of this material on the wall. When colloidal graphite (Aquadag) was employed, a very thin coat was painted onto the die wall and dried for two hours by means of an electric fan. A heavy coating of graphite was found to interfere with insertion of the plungers in the die.

Altogether, thirty successful tests were performed. The weight of powder used in each test was adjusted so that the final height of a compact was either 0.20, 0.60, or 1.00 in. From the recorder chart in each case the strain distribution along the length of the die was plotted and stations noted. For a compact with final height of 0.20 in., the average radial pressure was calculated directly by application of the pressure influence factors of Table 1. A compact of 0.60 in. height was broken into three increments. Shear and pressure influence factors of Table 1 were inserted into the boxed-in expressions of Eq 5, resulting in three simultaneous equations. With strain values at stations 0, 1 and 2 (determined from the

test curve) solution for average pressure and shear at each station was carried out.

It had been originally intended to solve the 1.00 in. compacts by the five increment solutions of Eq 5, using values listed in Table 1. However, the value of the determinant of the system was close to zero and the solutions of the equations were therefore meaningless. Equations were then derived for four increments, but in this case the determinant was even closer to zero. Solutions of the 1.00 in. compacts were finally accomplished by treating them as composed of three increments. Method of solution is exactly as described for a 0.60 in. compact, except that influence factors listed in Table 2 are used. Stations, of course, are then 0.33 in. apart, rather than 0.20 in.

Since there is symmetry to the left and right of station 0, strain values for like-numbered stations either side of station 0 should be alike. In the values of strain used in the equations, small differences at such stations were therefore averaged. With such averaging, reproducibility of strain data at any station was within ± 3.6 pct for the smallest values of strain involved. Large values of strain were completely reproducible. This was demonstrated by repeating two pressing experiments. The range of ± 3.6 pct is due to lack of sensitivity in the scanning recorder at low strain readings. The strain gauges themselves are accurate to ± 1 pct. Two other considerations enter into the final accuracy of solutions to the simultaneous expressions of Eq 5. The first is error in the calculated influence factors (Tables 1 and 2). As pointed out, it may amount to ± 5.0 pct for the numerically smaller factors and much less for the larger. The second consideration is the method employed to solve the simultaneous equations.⁹ With the errors in theory and data enumerated, the method¹⁰ employed in the present investigation was found to propagate a maximum possible error

of ± 23 pct in the final calculated values of pressures and shears.

Selected and typical data are presented in Table 3. A total of fourteen pressing tests were performed on type LB (−100 mesh) electrolytic copper powder (U. S. Metals Refining Co). Eight of these were pressed, without lubrication, to a final height of one inch. Compacting pressures varied from 3900 to 60,000 psi. Of these eight, two (tests C-16-a and C-13-a) were duplicates of other tests. Two compacts, with final heights of 0.20 and 0.60 in., were pressed, without lubrication, at 40,000 psi. Wall lubrication was used in four other compacts, all of 1.00 in. final height. Three of these were pressed at 30,000 psi, and the fourth at 18,600 psi. Stearic acid, molybdenum sulphide, and colloidal graphite (Aquadag) were the lubricants employed.

The second series of three tests was performed on type C (−325 mesh) electrolytic copper powder (U. S. Metals Refining Co.). All of the compacts were pressed to a final height of 1.00 in. without lubrication. Compacting pressures of 7100, 9200 and 18,600 psi were employed.

Carbonyl iron, type L (General Analine and Film Co.) was used for a third series of six compacts. Two each were pressed at 9100, 21,000 and 32,000 psi. Stearic acid was used as a wall lubricant in one of the compacts pressed at each pressure. All final heights were 1.00 in.

For the fourth series, Swedish sponge iron, type MH (−100 mesh Ekstrand and Tholand Co.), was used. Pressures, height, and lubricants were the same as for the six carbonyl iron compacts, so that a direct comparison could be made.

Experimental Results

final height of compact, average density increases with compacting pressure. Likewise, for constant compacting pressure and die diameter, average density decreases with increasing height of compact. Side wall lubrication is of great importance in securing greater average density of compact. When wall lubrication was employed, the average density of the compact was always greater than that of an unlubricated compact of the same final height and pressed at the same pressure. The foregoing also confirms the work of previous investigators.^{3,8}

In addition, it was found that in all cases but one (Test E-1-3, in which there was evidence of the die acting in bending) the average radial pressure exerted on the die was greater at the center increment of the compact than at the end increments (adjacent to the plungers). In other words, P_0 , the pressure at the center, is greater than P_1 , the pressure at the ends. A possible explanation of this is based on the fact that the most dense part of the compact is at the outer circumference adjacent to each plunger, and the least dense part is at the middle outer circumference.³ Thus the metal powder adjacent to the plungers comes closest to behaving like a solid metal. On the other hand, the central portion of the compact is closer to being an aggregate of metal powder particles. Such an aggregate if placed between two plungers (with no surrounding die wall present) and squeezed, would flow radially, retarded only by the interparticle friction.

A solid plug, if similarly pressed, would offer considerable resistance to any such flow. As a consequence, in a compact undergoing compression from both ends in a die, the central portion, being the least dense, is the most capa-

ble of exerting radial pressure. Of course, the foregoing picture is highly simplified. Strain-hardening of the metal powder particles, change of particle shape, and bonding of the particles during pressing all play a role. The picture is supported, however, by the low radial pressure (18,000 psi for P_0) measured in compact C-3-a (type LB copper powder) which had a final height of 0.20 in. after compaction at 40,000 psi. This compact was pressed to 87.5 pct of solid density. In compact C-2-a, made of the same material and at the same pressure, but with a final height of 1.00 in. the value of the radial pressure P_0 at the central increment was 23,129 psi. Compact C-2-a was only 80.9 pct of final density.

The compact of intermediate length, C-4-b, again of the same material, pressed at the same pressure, but to a final height of 0.60 in., at first examination does not support the above argument. For this compact, the average radial pressure of the center increment is higher than that in either of the two compacts cited above. This is due, it is believed, to compact C-4-b being broken down into 0.20 in. increments for calculation, whereas compact C-2-a was broken into 0.33 in. increments. Since the central portion of a compact has the highest radial pressure, then the shorter the center increment length L over which an average is calculated, the higher such average will be. As a corollary of this statement, it follows that since the end increment has the lowest radial pressure the shorter the length over which it is figured, the lower its average will be. This is the case. The average and radial pressure P_1 for compact C-4-b was 12,120 psi, less than for either of the other two. (In compact C-3-a 0.20 in. high, figured as composed of one increment, P_1 is iden-

tical with P_0 .)

As mentioned previously other investigators,⁵ whose results were received after completion of the present experiments, found a completely different type of radial pressure distribution. Their work was performed on compacts pressed from one end. Their method of measurement employed a piston-type pressure gauge, set in a hole through the die side wall. They state that radial pressure varies from a maximum at the end of a compact adjacent to the moving plunger, to a minimum at the static plunger, in linear fashion. In terms of a compact pressed from both ends, it would mean a V-type distribution of radial pressure, with the point of lowest pressure at the center, and the point of highest pressure next to the plungers. The nature of the results obtained by the above workers may be attributed to the fact that their piston type pressure gauge disturbs the uniform flow of powder and measures the ability of the powder to support shear. Thus as pointed out in the introduction it measures the flow of the powder rather than true radial pressure.

It is unfortunate in the present investigation that the one inch compacts could be treated only as composed of three increments. As a consequence no indication of point to point stress distribution along the length of a compact could be ascertained. Certain general trends are nevertheless evident. Fig 9 shows a plot of average radial pressure P_0 (center increment) versus compacting pressure. It indicates a straight line relationship between radial and compacting pressure for all four metal powders pressed without lubrication.

Fig 10 shows a similar plot, but for tests in which stearic acid wall lubrication was used. Again for copper, type

C (-100 mesh) and Swedish sponge iron, a straight line relationship exists. The slope of the line is almost identical with that in Fig 9. Within the limits of experimental error, the values of P_0 are equal for like metals (except carbonyl iron) pressed at like pressures in both wall-lubricated and unlubricated compacts. For carbonyl iron, with wall lubrication, the values of P_0 , when plotted as in Fig 10, fall well below the straight line relationship, and well below the P_0 values for unlubricated carbonyl iron powder. If, as has been proposed, radial pressure is in some fashion inversely proportional to densification (as distinguished from density distribution) then one would expect Fig 9 and 10 to have similar plots. It is not clear why carbonyl iron should depart from this. It may be related to the fact that of all the powders here used carbonyl iron compacted with wall lubrication showed the greatest increase in percent of solid density over compaction in the unlubricated state. It thus behaves more like a solid than the other powders used.

Fig 11 and 12 are plots of average radial pressure P_1 (end increment) versus compacting pressure. Fig 11 is for metal powders pressed without lubrication, and Fig 12 for those pressed with stearic acid wall lubrication. Both plots are in the form of shallow curves, slope gradually increasing with plunger pressure. For copper powder, type C, pressed at like pressures, values of P_0 (within the limits of experimental error) are equal for lubricated and unlubricated compacts. For Swedish and carbonyl irons, (especially the latter) pressed with wall lubrication, values of P_0 in Fig 12 appear to be somewhat higher than for the unlubricated state. It cannot be said whether or not the departure is due to error, since it is not a marked deviation. It is possible

that the stearic acid wall lubrication, being in a thick coating, is acting as a semifluid, transmitting pressure to the die wall in a quasihydrostatic fashion.

Some of the most significant results obtained are those concerning average shear stress τ_1 and coefficient of friction on the die wall adjacent to the plungers. These results are for unlubricated pressing to a final height of one inch. (See Fig 13 and 14). For copper, type LB (-100 mesh), the curve of shear stress (Fig 13) rises sharply with steadily increasing slope. The point for 60,000 psi compacting pressure (Test C-10-a) is very low because of extrusion of copper into the space between plunger and die wall. Due to such extrusion a large shear stress was acting on the wall toward the ends of the die (negative shear). This caused the average value of shear stress to be very low. The shear stress curve for copper type C (-325 mesh) follows more or less parallel and below the curve for type LB. There are only three points on this curve, however. The ductility of the copper undoubtedly accounts for the sharp rise of the copper shear curves. At the beginning of pressing, the copper particles have only point contact with the wall. As pressing continues they deform, increasing the area in contact with the die wall, and thus increasing the shear stress acting on that wall. The type C copper, having only fine particles, initially has a smaller total contact area with the die wall and thus a lower shear stress for given plunger pressure. As the fine particles are pressed, they do not pack as well as the type LB copper, which has a wider particle size distribution. Consequently the area of contact with the die wall, while it increases, never reaches (for a given plunger pressure) that of the type LB copper. Thus the curves of shear stress versus plunger

pressure rise sharply, in parallel fashion for the two types of copper powder.

The shear stress plot (Fig 13) for carbonyl iron appears to be a straight line, and that for Swedish iron nearly so. This is because of the lesser ductility of the two metals as compared to copper. While at low compacting pressures the shear stresses for iron are higher than those of copper, this is not true at higher pressures. The wall-particle contact area cannot increase as rapidly. Plots for the two types of iron are nearly parallel, with the carbonyl iron values being higher, even though the Swedish iron is more ductile. This is in part related to the fact that Swedish sponge iron cannot (under like conditions) be compacted to as high an average density as carbonyl iron. The less dense packing of the former contributes to a lower wall-particle contact area. In addition, the wide difference in chemical composition of the two types of irons affects their mechanical behavior.

Fig 14 shows the variation of coefficient of friction with compacting pressure. The plots for all the metal powders (with the exception of copper, type C, for which only three points are known) show an increase, followed by a decrease. The decrease is especially marked for type LB copper due to the low shear stress of test C-10-a before noted. Initial increases, with higher compacting pressure are due to increase in wall-particle contact area by particle deformation. The final decrease is probably caused by the compact reaching a point where strain hardening of the metal slows down the deformation of particles. Thus the wall-particle contact area and shear stress no longer increase rapidly. The coefficient of friction $\frac{\tau_1}{P_1}$ then decreases because the radial pressure P_1 continues to rise

FIG 13—Variation of shear stress τ_1 (end increment) with plunger pressure, both in pounds per square inch.

steadily as compacting pressure becomes greater. (See Fig 11 and 12). This explanation is borne out by the curve, in Fig 14, for copper. It strain hardens less rapidly than iron, and therefore the coefficient of friction does not reach a maximum until plunger pressure is quite high. The curves for iron fall off much sooner.

From the curves of shear stress and coefficient of friction versus compacting pressure plotted in Fig 13 and 14, we may draw some conclusions about ejection pressures. For soft ductile metals, the ratio of ejection pressure to compacting pressure should be high. On the other hand, harder, less plastic powders should have a low ratio of ejection pressure to compacting pressure. It is known that tin compacts, for instance, require a greater force for removal from the die; they seem to "drag" on the die wall. Tungsten compacts, pressed under like conditions, are much more easily ejected.

The data for shear and coefficients can be compared to some results obtained by Kamm, Steinberg and Wulff,³ working with lead grids. These authors calculated point-to-point values of the coefficient of friction. One of their compacts, number S-66 (carbonyl iron, type L), was pressed in a die of 0.560 in. diam, at 32,000 psi, from an initial height of 0.55 in. No lubrication was used, and pressing was from one end only. The average coefficient of friction, over the entire final height (obtained by averaging their point-to-point data) was 0.282. The test in the present investigation that compared to their compact was number E-5-d. This was performed on the same material, pressed from both ends at the

same pressure, without lubrication, but to a final height of 1.00 in. The die was 1.128 in. in diam. The average coefficient of friction over the end increment ($L = 0.33$ in.) was 0.261. Even with the entirely different sizes of compact and die and different method of measurement the results are within 8.0 pct of each other. In their point-to-point calculation Kamm et al found the coefficient of friction to be zero adjacent to the static plunger. Therefore in pressing from both ends, the shear stress would be zero at the center of the compact. This was the assumption made in developing the present theory.

The surprising results of the present tests are the relatively small magnitudes of wall shear stresses. The largest is less than 5000 psi. The test results are confirmed, however, by the small magnitude of shear stress that could be supported without slippage between compact and die in the check test, described under *Experimental Procedure*. It was 6381 psi, and its value was ascertained by a direct calibration. Since sliding friction is in general less than static friction, the magnitude of stress encountered in the die must be of that order, or less.

All shear stresses in compacts pressed with stearic acid wall lubrication were in the neighborhood of zero, some in fact being negative. This latter has no physical significance, being due rather to errors of the method. It can only be concluded then that stearic acid, when used as a wall lubricant, reduces wall shear stress to nearly zero. Tests C-12-b, C-14-a, and C-15-a give comparative data for different wall lubricants. All three compacts were type LB copper, pressed at

30,000 psi to a final height of one inch. They show that stearic acid is most effective in reducing shear, while colloidal graphite and molybdenum sulphide are not as good. The last two lubricants are, however, better than none.

A further interesting experiment was performed with compact C-2-a (copper type LB) after the plunger pressure had been released. The compact had been pressed to a final height of one inch, at 40,000 psi. Radial pressure P_0 in the center increment of the compact was 23,129 psi; that in the end increment, P_1 , was 15,756 psi. The average shear τ_1 over the end increment, acting axially on the die wall toward the center of the compact, was 4799 psi. After release of plunger pressure in test C-2-a, another strain record was taken. This showed P_0 had dropped to 9503, P_1 to 7213, and τ_1 to -3098 psi. The negative sign before the shear stress indicates a reversal of direction. The shear stress then acted on the die wall away from the center of the compact. (Or, if looked at the other way around, the shear acting on the compact is toward the center.)

Physically interpreted, the results may explain the cause of lamination cracks in hard powders. When compacting pressure was released, the die (which had been bulged elastically), contracted about the compact. This tended to squeeze it axially from the center of the die towards the ends, thus reversing the direction of shear acting on the die wall. This squeezing action causes the center of the compact to be extruded toward the ends of the die. The circumferential surface of the compact, in contact with the die wall,

cannot move. Thus it is along the axis that such extrusion takes place. The plane of the center of the compact (parallel to the end of the die) is subjected to axial tensile stress. In a hard powder this causes a crack to start, which spreads across the compact resulting in a laminar crack. If such be the case, lamination cracks probably originate while the compact is still in the die, following the release of plunger pressure. They spread to the surface following ejection from the die.

The foregoing explanation of lamination cracks has immediate practical implications. Wall lubrication, by lowering the retarding friction, will permit the circumference of the compact to move with the axial portion, and prevent laminar cracking following the release of plunger pressure. The tendency to crack will thus be reduced. It is well known that hard powders, compacted without lubrication, will almost always form cracks. However, the cracking of compacts made of soft powders, but pressed at extremely high pressures, is also explained. Because of the high pressure, the elastic bulge of the die will be large. After release of plunger pressure, the shear stress acting on the die wall toward the ends of the die is therefore very large. The extruding force, acting to push the axial portion of the compact toward the end of the die, is also large. Consequently, even though the compact is of a comparatively soft, ductile material, a laminar crack will result. The most important implication, however, is of interest to the die designer. Since cracks are caused by the elastic bulge of the die during pressing, the controlling factor in die design is rigidity, not strength. Whereas a die wall ratio (ratio of outer wall diameter to bore diameter) of 3 or 4 might satisfy even the highest requirements for strength, it may very well not result in a die rigid enough to prevent cracking in the compaction of hard powders. With knowledge of radial pressures acting on the interior die wall, it is possible, in the light of existing theory,⁷ to calculate elastic strains and deflections of the die.

Discussion of Results and Conclusions

By analysis of elastic strains of the die during pressing, average shear and radial pressures may be calculated over the length of a compact pressed from

both ends. The results of the analysis aid in forming a picture of the pressing process. During compaction, the powder flows axially through the die, propelled by the plunger. If the die walls are smooth and well-lubricated, the flow will be fairly even across the die and thus a higher average density, and a more even density distribution result. If the die walls are rough, or there is no wall lubrication, frictional effects cause marked retardation of powder movement at the die wall. More flow then takes place in the axial portion than in the circumferential portion. Average density will, as a result, be lower and density distribution will be less even. Die wall friction is therefore one of the most important factors controlling the density distribution of a metal powder compact.

Friction between the compact and the die wall is responsible for shear stresses at the wall of the die. Such stresses are of least magnitude at the middle circumference of the compact (when pressed from both ends) and highest adjacent to the plungers. Radial pressures on the other hand are distributed in a reverse fashion, the maximum stress being at the middle circumference and the minimum at the plungers. The magnitude of the radial pressures are, as to be expected, largely a function of the compacting pressure employed. The one exception found in this work was the extremely fine and hard carbonyl iron powder.

Wall shear stresses during compaction without lubrication are functions of ductility and particle size distribution of the metal powder. Fine particle size (with attendant less dense packing and low wall-particle contact area) in general gives rise to lower shear stresses. Hard metal powders, the particles of which cannot deform to a great degree, will have a relatively low wall-particle contact area for a given compacting pressure. Because of strain hardening, this area does not increase rapidly. For soft, ductile powders, the opposite is true. Consequently, for the latter type, shear stresses rise rapidly as compacting pressure increases.

The same two factors, ductility and particle size distribution, affect the variation with compacting pressure of the coefficient of friction. Radial pressure increases steadily with increasing plunger pressure. Therefore, the coefficient of friction at first increases as wall-particle contact area increases

rapidly and then decreases as strain hardening effects arise. Hard powders usually strain-harden at a faster rate than ductile powders. For the former, therefore, maximum coefficient of friction is reached at a lower compacting pressure.

The results of the present investigation also show that the strength of a die may not necessarily be the controlling factor in the problem of proper die design. A die may adequately withstand, without plastically yielding, the stresses involved in pressing. During pressing, however, the center portion may bulge elastically. Following the release of plunger pressure, the walls try to assume their normal configuration. Die-wall friction then retards movement of the compact surface, yet the center is squeezed in the axial direction. The resulting axial tension starts a laminar crack, which more often spreads to the surface following ejection from the die. While the condition can be partially relieved by wall lubrication, a more satisfactory solution lies in design of the die. The die should be strong enough to not only withstand the stresses, but also to prevent large elastic radial deflections. A thin-walled steel or carbide die is then best mounted in a heavy-walled steel or cast-iron jacket.

The experimental work reported in this paper may be summarized as follows:

1. For a given height of compact, average density increases with compacting pressure. For constant compacting pressure and die diameter, average density decreases with increasing height of compact.
2. Radial pressure on the die wall is greatest at the center of the compact, and least at the ends. Shear stress has the reverse type of distribution.
3. Die-wall friction is the most important single factor controlling density. With no lubrication, frictional shear stresses are a function of particle size distribution and ductility of the metal powder. Wide particle size distribution, with attendant dense packing, causes the shear stresses to be high. Soft metal powders cause shear stresses to increase rapidly with compacting pressure.
4. The coefficient of friction between powder and die wall first increases, then decreases with increasing compacting pressure. Increasing radial pressure, which continues to rise steadily with compacting pressure, is responsible for the decrease in coefficient of friction.

cient of friction. For soft powders (low rate of strain hardening) the coefficient of friction reaches a maximum at a higher compacting pressure than for hard powders.

5. For a die with smooth interior wall, frictional shear stresses may be reduced to practically zero by the use of wall lubricants.

6. Because of elastic deformation of a die during pressing, rigidity rather than strength is a necessary criterion for die design. Elastic bulging of a die results in the formation of laminar cracks.

Rectangular Hysteresis Loops of Co-Ni-Fe Alloys

R. A. CHEGWIDDEN*

In view of the current interest in magnetic materials having rectangular hysteresis loops, as for example those obtained with the grain oriented 50 nickel 50 iron alloys,[†] we wish to call attention again to the results obtainable with the permivar (Co-Ni-Fe) alloys heat treated in a magnetic field.

Data taken from direct current measurements made prior to and during World War II give the typical values shown below for two of the permivar alloys. Fig 1 and 2 show the hysteresis loops for these samples.

The first sample above consisted of small rings punched from 0.014 in. sheet stock. These rings were heat treated at 1000°C for one hour in a hydrogen atmosphere and then cooled with the furnace to 750°C at which point they were subjected to a magnetic field of 15 oersteds maintained during cooling to room temperature. The molybdenum permivar sample consisted of a spirally wound core of 0.001 in. tape. The heat treatment was the same except that box annealing methods were used and no hydrogen atmosphere was employed. Even better properties might be expected using hydrogen. The heat treating temperatures and cooling rates are not critical. Rectangular hysteresis loops produced in other permivar alloys by heat treatment in a magnetic field were described earlier.^{1,2}

Properties similar to those described

FIG 1—Hysteresis loop for 0.014 in. permivar rings (43 Ni 34 Fe 23 Co) heat treated in a magnetic field.

A Dilatometric Study of the Sintering of Metal Powder Compacts

POL DUWEZ* and HOWARD MARTENS†

Introduction

Dimensional changes generally occur during the sintering of metal powder compacts. These changes may have several causes and their magnitude depends upon the numerous variables involved in the process, such as the nature of the powder, size and shape of the grains, compacting pressure, rate of heating, maximum temperature, length of time at temperature, and furnace atmosphere. Among all the variables, time, temperature, and compacting pressure are probably the most important ones, and the effect of each one of the other variables can be studied separately once the effect of these is well understood.

The most precise method of studying the phenomenon of dimensional changes in a compact consists of heat treating the compacts at various temperatures for different lengths of time. In this method, only very small specimens can be used, in order to achieve rapid rates of heating and cooling. The technique involved in these measurements is very simple, but is time consuming. Another experimental approach to the problem consists of measuring the change in length of a compact as it is being heated at a constant rate. Although the two variables, time and temperature, are combined into a single one (rate of heating), the results obtained by this technique may be of great interest from both practical and theoretical points of view. The purpose of this paper is to describe a systematic investigation of the change in length during sintering of compacts made of one or several metal powders.

Experimental Procedure

The change in length of compacts

during sintering was measured with an automatic recording dilatometer. In this instrument the change in length and the temperature are recorded as

Cleveland Meeting, October 1949.

functions of time on two separate charts and the rates of heating and cooling may be varied from 1 to 20°F per min. The temperature may be kept constant at any value up to 2200°F during any predetermined length of time and the change in length recorded as a function of time. Provision is made for atmosphere control inside the fused silica tube containing the specimen. Three different magnifications are provided, so that 1 in. on the chart corresponds to 0.002, 0.005, or 0.010 in. change in length.

The mechanism following the change

in length of the specimen consists of a mechanical pickup coupled with an electrical transmission to the recorder. The principle of this method is shown in Fig 1. The motion of the specimen is transmitted by the quartz rod to the movable section *B* of a reed gauge mechanism. When the movable section *B* of the gauge is displaced with respect to the fixed section *C*, the wand *D* is displaced from its equilibrium position. The scissors mechanism *E* transfers the movement of this wand as an angular displacement of the clutch bar *F*. The rotating cams *G* reposition the clutch bar *F* to equilibrium position causing rotational movement of the drive disk *H* and the contactor *J*. This motion also rotates the lead screw *K* which causes the fixed section *C* of the reed mechanism to follow the motion previously imposed on the movable section *B* and thus return this mechanism to equilibrium. The position of the contactor *J* on the slide wire *M* is transmitted electrically to the slide wire in the recorder.

The standard specimen used in this investigation was 1 in. long and $\frac{1}{4}$ in. square in cross-section. These specimens were compacted in a hard steel die in which the pressure was applied in a direction perpendicular to the length of the specimen. All tests were performed in an atmosphere of pure hydrogen.

Compacts Made of a Pure Metal

A thermal expansion curve which

may be considered as typical of a pure metal compact is shown in Fig 2. This curve was obtained with a copper specimen compacted at 20,000 psi and made of a classified powder having particle sizes between 74 and 43 microns. The compact was heated at a rate of 7°F per min. The first portion of the curve, up to a temperature of about 600°F represents the normal thermal expansion of copper. As soon as sintering takes place in the compact, shrinkage counteracts the normal thermal expansion and the curve deviates from that of a solid bar of copper. As the temperature increases, shrinkage proceeds faster, the thermal expansion curve reaches a maximum, and finally drops very rapidly.

The change in length occurring during cooling at a constant rate can be measured, and the shape of the expansion curve is also shown in Fig 2. At the beginning of the cooling stage, the contraction of the specimen is larger than that which would correspond to the normal coefficient of thermal expansion of the metal. It is probable that during this period some sintering is still in progress, but at a lesser rate than during the heating period in the same temperature range. As the temperature is lowered the expansion curve follows closely that of a solid metal, showing that all contraction caused by sintering has ceased.

In interpreting the thermal expansion curves of a compact during sintering, it must be remembered that the two variables, time and temperature, are combined into one. Obviously, such curves do not represent equilibrium

FIG 3—Thermal expansion curves of copper compacted at 80,000 psi.

Recorded at various rates of heating:

— 3°F per min. — 7°F per min. — 11°F per min. — 18°F per min.

conditions, and would be affected by the rate of heating. For rates of heating normally used in practice, however, the effect is relatively small. A series of curves obtained at rates of heating from 3 to 18°F per min is shown in Fig 3. As could be expected, after definite contraction has set in, the expansion curve drops faster for smaller rates of heating. There should be a limit, however, to the shift of the expansion curve toward greater shrinkage as the rate of heating becomes smaller. The limiting curve, which would correspond to an infinitely slow heating can be approximated by making isothermal experiments and measuring the change in length of a compact versus time. Such experiments have been described in a previous paper¹ and the results obtained with a copper powder with particle size ranging from 74 to 43 microns are reproduced in Fig 4, in which the percentage shrinkage is plotted as a function of time. For a given temperature, shrinkage proceeds very fast during the first few hours, and little additional decrease in dimensions is obtained after a long sintering time. From these results it is not possible to decide whether the shrinkage, after the initial period of sintering, tends toward a limiting value or increases at a constant rate. In any case, the shrinkage obtained after a sintering time of the order of 50 hr may be assumed to represent a practical limiting value. Within this approximation, it is possible to trace on the graph of Fig 2 the limiting thermal expansion curve which would correspond to a very small rate of heat-

¹ References are at the end of the paper.

FIG 4—Shrinkage vs. time curves during sintering of copper compacts at various temperature.

ing. Above the temperature at which shrinkage becomes measurable, this curve deviates from that recorded at a rate of 7°F per min but both curves have essentially the same shape. It is particularly interesting to note that both curves separate from the normal thermal expansion curve of solid copper at almost the same temperature. Hence, the thermal expansion curve of a compact recorded at a normal rate of heating can give valuable information on the minimum temperature at which sintering proceeds at a measurable rate.

The influence of the compacting pressure can also be detected by thermal expansion analysis. In general, the expansion curves illustrate clearly the well known fact that the shrinkage of a compact is greater for smaller compacting pressure. As an example, a series of thermal expansion curves recorded for copper, cobalt, and molybdenum compacts prepared at various compacting pressures are shown in Fig 5, 6, and 7, respectively. All the curves are essentially of the type previously described as normal, and for the three metals the effect of increasing the compacting pressure is to increase the temperature at which a given percentage shrinkage is reached.

Most of the pure metal powder compacts studied in this laboratory so far have exhibited the normal type of thermal expansion curves described above. One of the copper powders tested, however, showed an abnormal behavior under compacting pressures above approximately 60,000 psi. At a temperature of about 1600°F, an abnormal expansion or swelling took place. This swelling, almost negligible at 60,000 psi, became greater with

increasing compacting pressure and was about 1.2 pct at 90,000 psi. The thermal expansion curves recorded with this particular copper powder have been published elsewhere.² Thermal expansion curves showing a similar swelling of copper compacts have been obtained by other investigators.³

The first possible explanation for the swelling of a compact is based on the existence of gas pockets enclosed in the compacts by the high compacting pressure. When the temperature is increased, sintering may start before the gas can escape between the particles and the increasing gas pressure may cause plastic flow of the partially sintered metal. In the particular case considered here, the explanation was weakened by the results of experiments made with the same copper powder in which both the pressing of the compact and the recording of the thermal expansion curve were done in vacuum.⁴ The specimens still expanded at high temperature and essentially the same thermal expansion curves were measured. The entrapped gas theory would still remain an explanation, however, if it were supposed that the gas pockets were already inside the particles of powder before pressing and are therefore not affected by vacuum. The existence of such gas inclusions is consistent with the spongy structure of the powder, and the explanation seems at the present time a logical one.

Special Case of Iron Compacts

The dimensional changes taking

FIG 5—Thermal expansion curves of copper compacted at various pressures and recorded at a rate of heating of 7°F per min.

place during the sintering of iron compacts are greatly influenced by the allotropic change from α to γ iron. The thermal expansion curve (see Fig 8 A) is of the normal type previously described, up to the critical temperature at which an abrupt contraction indicates the transformation from α to γ iron. As soon as this transformation has taken place, the curve starts upward with a slope corresponding approximately to the coefficient of expansion of γ iron. As the temperature increases, shrinkage due to sintering becomes noticeable and the curve deviates from the normal thermal expansion of solid iron, as in the α range.

Before discussing the particular shape of the thermal expansion curve of iron, other features shown in Fig 8 require a short explanation. The influence of compacting pressure, which is quite apparent in the two sets of curves, is in accordance with the previous observation on other pure metal compacts. The influence of the particle size is not very marked, and it would be difficult to base any conclusion from the small difference existing between the two sets of curves, mostly because the two powders are probably different in impurity content. The effect of impurities is clearly shown by the temperature at which the transformation took place. The critical temperature of the fine powder is 1670°F, which is that of pure iron. The coarse powder transformed at about 1570°F, and this low critical temperature is an indication of the presence of impurities, most probably carbon.

FIG 6—Thermal expansion curves of cobalt compacted at various pressures and recorded at a rate of heating of 7°F per min.

As stated above, the most important feature of the thermal expansion curves of iron compacts is the upward trend of the curve just above the critical temperature. The discontinuity in the rate at which shrinkage proceeds through the critical temperature suggests that near the transformation point the rate of sintering of γ iron is much smaller than that of α iron. In an effort to bring more evidence to this conclusion, the following experiment was performed: An iron compact, prepared with MD-111 powder, was heated in the dilatometer at a rate of 7°F per min. up to a temperature of 1620°F, that is, slightly below the transformation. At this temperature the shrinkage was recorded as a function of time. A second compact was then investigated by the same method, but the isothermal measurements were started at 1690°F, that is, slightly above the $\alpha \rightarrow \gamma$ transformation. The two resulting curves are reproduced in Fig 9, in which the expansion (or shrinkage) is plotted versus time, together with the temperature versus time curves of the two experiments.

Up to 1620°F, the two expansion curves are obviously very close to each other, the slight difference being due to experimental errors and most probably also to the lack of perfect similitude of the two specimens after compacting. During the isothermal part of the test it is quite clear that the sample maintained below the critical temperature contracted at a much faster rate than that maintained above the critical temperature. The net shrinkage one hour after the temperature reached a constant value was 0.85 pct for the specimen heated to 1620°F and only 0.05 pct for the specimen heated to 1690°F. The obvious conclusion is that in the region of the $\alpha \rightarrow \gamma$ transforma-

tion temperature, the rate of sintering is much greater in the α range than in the γ range.

This result may be correlated with observations previously reported by various investigators. For example,⁵ it was shown that both density and tensile strength of sintered iron compacts increase first with sintering temperature, but undergo a marked drop in the vicinity of the critical temperature. Most of the systematic investigations of sintered iron, however, have been made at sintering temperatures above the transformation.⁶ The fact that the rate of shrinkage of a compact heated just below the critical temperature is greater than that above this temperature might be used advantageously in practical application where maximum density and hence maximum tensile strength are desired. In this case, the sintering should be carried on at approximately 1600°F for as long a time as practical, then the temperature should be increased to a higher value, for example 2000°F as was used in Ref. 6. By this technique, advantage could be taken of the rapid rate of shrinkage occurring in the α range, while the final high temperature treatment would achieve a satisfactory sintering.

Case of Alloyed Powders

Apriori, it could be stated that the mechanism of sintering of a compact made of alloyed powder is not essentially different from that of a pure metal compact. As far as the dimensional changes are concerned, this statement has been verified in the cases of a copper-nickel powder (30 pct copper and 70 pct nickel) and a stainless steel powder of the 18-8 type. A

FIG 7—Thermal expansion curves of molybdenum compacted at various pressures and recorded at a rate of heating of 7°F per min.

set of thermal expansion curves of compacts made with the copper-nickel powder is shown in Fig 10, and similar curves for stainless steel powder have previously been published.⁷ All these curves are of the normal type generally encountered with pure metals.

Compacts Containing Two Metal Powders

During sintering of a compact containing two metal powders, relatively large dimensional changes are frequently observed. The swelling of copper-tin and copper-zinc compacts are familiar examples. These dimensional changes may be studied by dilatometric measurements. The interpretation of thermal expansion curves, however, is often more complicated than in the case of a pure metal. To make this interpretation as clear as possible, it is recommended procedure to prepare the mixtures with powders which, tested individually, would have the normal type of thermal expansion curve described in the previous section. If this precaution is taken, any abnormal swelling observed during the sintering of the mixture is most probably due to interaction between the two powders. As a result of numerous experiments performed at this laboratory on the sintering of compacts made of two powders, it was found that the thermal expansion curves during sintering were of two basic types. These two types will first be described and tentative explanations for the dimensional changes will then be discussed.

COPPER-NICKEL COMPACTS

During the sintering of copper-nickel compacts, no abnormal expan-

FIG 8—Thermal expansion curves of iron powder compacts recorded at a rate of heating of 7°F per min.
A. Particle sizes between 147 and 104 microns.
B. Particle sizes smaller than 43 microns.

sion has been observed. The thermal expansion curves recorded with powders of various kinds and pressed at compacting pressures varying from 20,000 to 100,000 psi were all of the normal type which is characteristic of each powder taken separately. This study was supplemented by X ray diffraction measurements which showed that simultaneously with the shrinkage of the compact, diffusion takes place and when the compact reaches a temperature of 2200°F at a rate of 6°F per min. its structure is that of the equilibrium solid solution between copper and nickel. The details of this investigation have been published elsewhere.^{2,8}

As far as the present study is concerned, suffice it to say that for copper-nickel compacts the diffusion of the metals into each other does not cause any perturbation in the progression of the normal shrinkage during the process of sintering and the thermal expansion curve is of the type observed for a normal pure powder.

COPPER-ZINC COMPACTS

The salient feature of the thermal expansion curves of copper-zinc compacts during sintering is a large swelling of the compact in a range of temperature from about 300 to 700°F. This has been previously discussed for compacts

containing 70 pct copper and 30 pct zinc.² It was shown that the critical temperature marking the beginning and the end of this abnormal expansion depended upon the fineness of the powders but not upon the compacting pressure. The effect of composition has been recently investigated, and typical thermal expansion curves for compacts containing from 5 to 45 pct zinc are shown in Fig 11. The copper powder

(MD-151) from Metals Disintegrating Co., Elizabeth, N. J.) used for these measurements was 50 pct between 200 and 325 mesh and 50 pct finer than 325 mesh and the zinc (MD-201 from the same source) was all finer than 325 mesh. The curves of Fig 11 indicate clearly that by increasing the percentage of zinc in copper, the magnitude of the swelling of the compact is steadily increased, but the two temperatures between which this swelling occurs do not seem to be affected.

A study of the various phases present during the sintering of 70-30 copper-zinc compacts has been previously made by X ray diffraction.² It was shown that the temperature at which the thermal expansion curve has a sudden increase coincides with a rapid diffusion of zinc into copper and at 300°F the presence of the ϵ phase was already noticed. At all temperatures along the ascending portion of the expansion curve, pure zinc and intermediate phases were present and at the end of the ascending portion (about 550°F) all the zinc had been absorbed into β and α phases. It is therefore apparent that the abnormal thermal expansion between 300 and 550°F coincides with the progressive disappearance of the particles of zinc and their absorption by the particles of copper. A tentative explanation of the increase in volume during the sintering of copper-zinc compacts may be based on the assumption that during the process of diffusion, the zinc particles are absorbed by the copper particles, which, as a result, grow in size leaving cavities in place of the zinc particles. The mass transfer of zinc into copper

FIG 9—Expansion and temperature vs. time curves for two experiments made with iron powder compacts pressed at 80,000 psi.
— Isothermal test in α range
--- Isothermal test in γ range

FIG 10—Thermal expansion curves of alloyed copper-nickel powder compacts.

during diffusion is the main hypothesis in this explanation. It may be justified on the basis that zinc is soluble in copper, whereas copper is practically insoluble in zinc. The results of the measurements described above provide a new argument in favor of the absorption of zinc hypothesis. It is indeed quite clear that if zinc moves into the copper particles, cavities are formed and the amount of swelling of the compact should increase steadily with the percentage of zinc. This is exactly what has been found experimentally, as shown by the curves of Fig 11.

FACTORS INFLUENCING THE DIMENSIONAL CHANGES OF COM-PACTS CONTAINING TWO POW-DERS

The nature of the phase diagram between two metals is a determining factor controlling the occurrence of the swelling of the compact. In the case of copper-nickel, in which no abnormal expansion is observed, the two metals form a complete series of solid solutions, so that either one of the two metals is able to dissolve the other. This condition may be necessary to prevent any swelling, but does not seem to be sufficient. Experiments performed on chromium-molybdenum compacts ranging in composition from 10 to 90 pct, by steps of 10 pct, exhibited a maximum increase in dimensions of 16 pct, as shown in the curve of Fig 12, and yet these two metals form a complete series of solid solutions.⁹

There is therefore another condition

which must be fulfilled to prevent swelling of the compact during diffusion, and it is quite logical to believe that this condition is that the rates of diffusion of either one of the two metals into the other should be approximately the same. This condition is satisfied in the copper-nickel system. Unfortunately it is not possible to apply it at present to the chromium-molybdenum system because the diffusion constants for this pair of metals have not been determined.

The explanations suggested for the swelling of the copper-zinc compacts are supported by several experimental results obtained in this laboratory. The system copper-10 pct tin exhibits a swelling which, by means of X ray diffraction, has also been related to the absorption of tin into copper.² Compacts made of 25 pct molybdenum and 75 pct nickel also have an abnormal thermal expansion. The mechanism is, in this case, similar to that described for the copper-zinc system, since molybdenum is soluble in nickel up to about 35 pct at 2500°F while molybdenum does not dissolve any appreciable amount of nickel and in addition, three intermediate phases are present in the phase diagram.

Conclusions

The results of experiments described in this paper have demonstrated the usefulness of the dilatometric method in studying the sintering of metal powder compacts. In the case of a compact made of a pure metal, the thermal expansion curves recorded on a dilatometer at a constant rate of heating give valuable information on the rate at which shrinkage proceeds as the temperature is increased. In addition, a dilatometric test offers a simple means of detecting the abnormal behavior of some metal powder compacts which exhibit a swelling during sintering.

FIG 11—Thermal expansion curves of copper-zinc compacts containing various amounts of zinc and pressed at 40,000 psi.

FIG 12—Expansion of chromium-molybdenum compacts measured after sintering for 4 hr at 2500°F.

When a binary alloy is prepared by powder metallurgy by mixing the two powders before pressing, abnormal dimensional changes are likely to take place as the result of diffusion. In most cases, a swelling is observed in the range of temperature in which one of the constituents is absorbed by the other. This critical range of temperature is clearly detected on a thermal expansion curve. Since in the sintering of large compacts the temperature may not be uniform during sintering, the existence of large dimensional changes may result in an objectionable distortion of the compact. There is therefore an advantage in reducing the rate of heating in the critical range of temperatures determined from dilatometric measurements.

As stated before, the thermal expansion curves of a compact during sintering do not provide the kind of data that would contribute most to the search for a theory of sintering, the reason being that the two independent variables, time and temperature, are combined into one, namely the rate of heating. The importance of the dilatometric method should not be mini-

mized, however, in view of the fact that it has already furnished very valuable results, especially in the determination of the critical range of temperatures of compacts containing two metal powders. Considered as a first step, the method is of great help in determining the conditions under which the more reliable, but also more tedious, isothermal experiments should be conducted to bring out the maximum amount of information in the minimum time.

Composition of Steels

Four steels, of the compositions given in Table 1, were used for the experiments to be described. Steel A is the present-day grade of M-2 high speed steel. Steel B is the war-time equivalent of the same grade, with reduced alloying elements. Steels C and D are low-alloy laboratory heats being studied for other purposes at M. I. T.

These materials were received in the form of annealed (spheroidized) centerless-ground bars, $\frac{1}{4}$ in. in diam.

The Citrate Cell

PROCEDURE

A number of double electrolytic cells based on that of Treje and Benedicks¹⁴ were built in an attempt to devise a method which would permit rapid, yet quantitative isolations of the carbides from high speed steel. The apparatus found most satisfactory is illustrated in Fig 1. Its principal features are:

1. The anolyte is an aqueous solution of 15 pct sodium citrate, 1 pct potassium bromide and 0.1 pct potassium iodide, having a pH of 7.0 ± 0.2 . The catholyte is an aqueous solution of 10 pct copper sulphate.

2. The specimens to be dissolved are 5 in. long by $\frac{1}{4}$ in. diam and are supported in pairs from the bottom on the fixture shown in Fig 2. These rods form the anode of the cell, and are rotated at 1 rpm during electrolysis to promote even solution.

3. The anode and cathode compartments are separated by a porous cylinder made by cutting the bottom off a porcelain cup used for Daniel cells.

4. Continuous removal of the iron-rich anolyte and replenishment with fresh solution is necessary to prevent the anolyte from becoming too acidic during the course of electrolysis. The cell in Fig 1 provides for such replenishment automatically. With this arrangement, the pH of the anolyte drops only to about 6.6 after a 24 amp-hr run. Without it, the pH decreases to 3.6 over the same period.

After a normal run of 24 hr at 1 amp,* the two specimens are not completely dissolved, and in the case of the annealed steels, a large proportion of the carbides adheres to the remainder of the specimens. The specimens are removed from the cell, and the attached carbides are scraped into a beaker with a rubber "policeman" and a jet of water. The syphon that

Wt. pct of carbides

$$= \frac{(\text{Wt. of filter crucible} + \text{contents}) - (\text{Wt. of filter crucible})}{(\text{Wt. of specimens before run}) - (\text{Wt. of specimens after run})} \times 100 \quad [1]$$

* Current density = 0.14 amp per sq in.

supplies fresh anolyte from the reservoir is shut off, and the solution in the anode chamber is drawn through the alundum filter crucible (Fig 1) with the aid of an aspirator pump. When the anolyte level drops below the ground-glass joint just above the filter crucible, the joint is broken and the filter assembly is lowered away from the apparatus. The carbides in the aforesaid beaker are transferred to the filter crucible, and the entire residue thus collected is washed with 300 cc of distilled water, followed by 50 cc of 1:20 ammonium hydroxide* and finally 500 cc of distilled water. The filter crucible and its contents are then dried in vacuum at 165°F (60°C) for 12 to 14 hr.

The carbide content of the steel is taken as:

* The ammonium hydroxide wash is used to dissolve any tungsten acid which may possibly form from the tungsten originally in the steel matrix.

FIG 1—Schematic diagram of sodium citrate cell for electrolytic isolation of carbides. Anolyte: aqueous solution of 15 pct sodium citrate, 1 pct potassium bromide and 0.1 pct potassium iodide. Catholyte: aqueous solution of 10 pct copper sulphate.

RESULTS ON ANNEALED SPECIMENS

The amounts and compositions of the residues obtained by citrate-cell extractions of annealed steels B, C and D in the annealed condition are listed in Table 2.

The fact that the carbon content of the residues isolated from the low alloy steels C and D closely approximates the theoretical composition of cementite (6.67 wt. pct) offers one criterion that the cell is quantitative, even for low alloy carbides. In addition, it is known that virtually all the carbon in the three annealed steels is tied up in the carbides. This circumstance may be employed as a second criterion for the quantitative-ness of the isolation, since the amount of carbon in the residue can be compared with that originally existing in the steel as electrolyzed:

Fraction of carbon of steel found in residue

$$= \frac{(\text{Wt. of residue}) \times (\text{Wt. pct carbon in residue})}{(\text{Wt. of steel dissolved}) \times (\text{Wt. pct carbon in steel})} = \frac{(\text{Wt. pct residue})}{100} \times \frac{(\text{Wt. pct carbon in residue})}{(\text{Wt. pct carbon in steel})} \quad [2]$$

On this basis, the data of Table 2 demonstrate that all of the carbon in each steel is accounted for in the extracted residue.

Steel A did not dissolve like the other three during electrolysis. Rather, a porous skin of partially attacked metal remained around the specimens after the runs. Inasmuch as it was difficult to wash the adhering carbides from beneath this skin, the results ob-

tained for steel A are not considered sufficiently accurate to be included in Table 2. Numerous attempts were made to eliminate the undissolved skin by carefully degreasing the specimens, altering the surface finish, and varying the current density, but no success was achieved. The method devised for coping with this troublesome occurrence will be discussed later in the paper.

RESULTS ON HARDENED STEELS

* Peeling occurred, no magnetic separation applied.
† Peeling occurred, but magnetic separation was applied.

austenitizing temperature is raised to 1900°F (1040°C), and then increases with further increase in temperature. The latter trend is distinctly anomalous, and indicates that the cell operation becomes unreliable when the austenitizing temperature is too high. It was found that somewhat the same phenomenon occurs during the electrolysis of quenched steel B as previously described for annealed steel A; that is, a tenuous layer of metal remains undissolved. However, unlike the case of the annealed steel, the metallic skin tends to split during the run (probably due to the relief of quenching stresses while the electrolysis proceeds), and drops into the filter crucible along with the isolated carbides. This undesirable state of affairs seems to become more pronounced as the alloy content of the steel matrix is increased, and accounts for the erroneous results after austenitizing at the higher temperatures.

The authors are not aware that this "peeling" phenomenon has been observed before in the electrolysis of high speed steel, but Gulyaev¹⁰ has mentioned that it occurs with high-alloy chromium steels, electrolyzed in 1:20 hydrochloric acid. He further states that it may be eliminated by using more concentrated acid. Consequently, experiments were undertaken in the present work with hydrochloric acid cells in an effort to avoid the "peeling" of high speed steel. At the same time,

FIG 2—Fixture for holding and rotating specimens in electrolytic cell of Fig 1.

because of the increased danger of carbide attack by the electrolyte in this type of cell, the quantitative aspects of the isolations were cross-checked by lineal analysis¹⁶ and density measurements as well as by chemical analysis.

The Hydrochloric Acid Cell

PROCEDURE

A schematic drawing of the hydrochloric acid cell finally adopted is shown in Fig 3. The anode is a single specimen 5 in. long by ¼ in. diam, the general arrangement being quite similar to that used by Bain and Grossmann.⁷ Satisfactory runs are carried out at 0.5 amp* for 48 hr in an electrolyte of 1 part hydrochloric acid (sp. gr. = 1.19) and 10 parts distilled water. About half the electrolyte is replaced with fresh solution at the end of 24 hr; otherwise iron may deposit loosely on the cathode and fall into the carbide residue when the cathode is disturbed.

When hardened specimens of steel B are electrolyzed in this simple cell, it is found that the peeling phenomenon occurs only with austenitizing temperatures above 2100°F (1150°C). Thus, although the acid cell does not completely eliminate this interfering condition, it does help appreciably.

The particles of the undissolved skin that contaminate the carbide residue are ferromagnetic and are strongly attracted to a permanent magnet. Fortunately the carbides themselves are nonferromagnetic and this circumstance provides the basis for a method of separation in those runs where the peeling occurs. After electrolysis the spent electrolyte is decanted from the residue in the cell-beaker through a fine-porosity fritted-glass filter crucible, while an Alnico-5 horseshoe magnet is held under the spout of the beaker to prevent magnetic particles from going into the filter. The residue retained in the cell-beaker is then transferred to a smaller beaker together with the particles adhering to the specimen. About 50 cc of 1:20 hydrochloric acid is added to form a slurry, and any large agglomerates of the residue are dispersed with a glass rod. Then, the Alnico-5 magnet enclosed in a thin-walled lucite box is immersed in the slurry, withdrawn and the liquid is allowed to drain back into the beaker. The lucite box is next held over a third beaker, the magnet is removed and the particles adhering to

the box are washed into the third beaker with a stream of distilled water. This operation is repeated several times until no magnetic particles can be withdrawn from the original residue.

Then the same procedure is carried out on the magnetic residue thus transferred, and the nonmagnetic particles finally remaining are added to the first batch of nonmagnetic residue. This is filtered, washed (200 cc of 1:20 hydrochloric acid and 100 cc of distilled water in that order) and dried in vacuum at 165°F (60°C). The magnetic residue, consisting of relatively coarse particles of undissolved steel, settles readily and requires no filtering. The supernatant water is merely decanted off and the residue is washed with alcohol and ether, after which it is dried in vacuum.

The carbide content of the steel is calculated as:

$$\text{Wt. pct carbides} = \frac{(\text{Wt. of filter crucible} + \text{nonmagnetic residue}) - (\text{Wt. of filter crucible})}{(\text{Wt. of specimen before run}) - (\text{Wt. of specimen after run}) - (\text{Wt. of magnetic residue})} \times 100 \quad [3]$$

The magnetic separation described above requires due care but is entirely practicable when applied in conjunction with the hydrochloric acid cell. This is not the case with the citrate cell because of the continuous-filtration feature. In other words, the complexity of the citrate cell is hardly worth contending with, if magnetic separation is necessary—provided, of course, that the hydrochloric acid cell can be shown to yield quantitative results.

RESULTS ON ANNEALED AND HARDENED SPECIMENS

Table 3 offers a comparison of extractions performed on steel B with both the citrate and hydrochloric acid cells. These data cast a favorable light on the acid cell, at least for studies on high speed steel, because it not only alleviates the tendency toward peeling but gives good agreement with the citrate cell in those cases where peeling does not interfere. Where peeling does occur, however, it remains to test the quantitateness of the procedure in which the magnetic process is used to correct for it. Steel A was selected for this purpose.

Weight percentages and compositions of the carbides isolated from steel A are given in Table 4. The heat treated specimens were austenitized for 10 min. in a salt bath at the indicated temperatures and quenched in

Table 4 . . . Weight Percentage and Composition of Carbides Obtained from Steel A in Hydrochloric Acid Cell

| Austenitizing Temp. °F | Weight Pct Carbides | Composition of Carbides, Wt Pct | | | | | |
|------------------------|---------------------|---------------------------------|------|------|------|------|-----|
| | | C | W | Mo | Cr | V | Fe |
| Annealed | 21.7 | 3.72 | 27.3 | 21.4 | 9.34 | 8.05 | Bal |
| 1700 | 19.5 | 3.90 | 29.5 | 22.8 | 5.28 | 7.70 | Bal |
| 1900 | 17.3 | 3.97 | 31.9 | 23.7 | 4.26 | 7.38 | Bal |
| 2000 | 16.2 | 3.69 | 31.6 | 22.8 | 2.83 | 6.73 | Bal |

| 2250 | 10.7* | 3.12 | 22.9 | 32.1 | 1.81 | 5.22 | Bal |

* Peeling occurred, but magnetic separation was applied.

oil. It is interesting to note that steel A as annealed does not exhibit an undissolved skin when electrolyzed in the hydrochloric acid cell, unlike the results obtained with the citrate cell. Furthermore, virtually all the carbon of the annealed steel is accounted for

in the extracted carbides (using Eq 2:

$$\frac{21.7}{100} \times \frac{3.72}{0.83} = 0.97).$$

It might be possible to find all the carbon in the residue even if the carbides were partially decomposed by the hydrochloric acid because free carbon could be precipitated. Hence, the results were checked independently by density measurements and lineal analysis. It can be shown that

$$\text{Density of carbides} = (\text{Density of steel}) \times \frac{(\text{Wt. pct of carbides})}{(\text{Vol. pct of carbides})} \quad [4]$$

In addition to the weight percentage of carbides in the steel as determined by extraction, the other three quantities are directly measurable: the density of the carbides by the pycnometer method,¹⁷ density of the steel by the loss-of-weight in water,¹⁸ and volume percentage of the carbides by lineal analysis¹⁶ on the butt ends of the electrolyzed specimens. Table 5 shows a comparison of the density of the carbides from annealed steel A, as measured and as calculated from Eq 4. The close agreement indicates that, as far as the annealed steel is concerned, the hydrochloric acid cell not only isolates the carbides quantitatively, but leaves them intact.

Unfortunately, in the case of the hardened specimens, the extracted carbides are found to be contaminated

* Current density = 0.28 amp per sq in.

with free carbon which materially reduces the measured density of the carbides. This trend is shown by the

Table 5 . . . Comparison of Measured and Calculated Density of Carbides Obtained from Annealed Steel A in Hydrochloric Acid Cell

| Austenitizing Temp. °F | Weight Pct of Carbides* | Volume Pct Carbides | Density of Steel | Density of Carbides Measured | Density of Carbides Calculated |
|------------------------|-------------------------|---------------------|------------------|------------------------------|--------------------------------|
| Annealed | 21.7 | 23.2 | 8.19 | 7.71 | 7.65 |
| 1900 | 17.3 | 16.3 | 8.08 | 6.73 | 8.58 |
| 2000 | 16.2 | 12.0 | 8.06 | 5.54 | 10.90 |

* Average of 2-4 runs.

data in Table 5. The true density of the carbides increases with the austenitizing temperature in accordance with the calculated values, but the measured density changes erroneously in the opposite direction. In view of the excellent correlation obtained with the annealed steel, it is believed that the free carbon in the residues of the quenched specimens comes from the martensite-austenite matrix and not from decomposition of the carbides themselves. Attempts to determine the amount of free carbon in the residues by chemical and differential oxidation techniques were unsuccessful. Accordingly, the carbon contents shown in Table 4 for the hardened specimens are undoubtedly somewhat too high and should be regarded as uncertain.*

CORRELATION WITH FILTRATE ANALYSES

Since the foregoing density determinations shed little light on the quantitiveness of the cell operation with hardened specimens, this approach cannot be used for testing the efficacy of the magnetic separation when peeling occurs. Consequently, an analysis was made of the filtrate remaining from one of the extractions in which abundant peeling took place. The specimen (steel A) was austenitized at 2200°F (1205°C), electrolyzed in the hydrochloric acid cell, and the undissolved particles of steel in the residue were separated magnetically. From the quantity of the filtrate and its composition, the weights of tungsten, molybdenum, chromium and vanadium dissolved from the steel

were calculated. Similarly, the weights of these elements in the nonmagnetic residue were also determined.

The resulting weight balance is given in Table 6. It is evident that there is satisfactory agreement between the weight of each element in the steel electrolyzed and the sum of the respective weights in the filtrate and carbides. Thus the magnetic separation process is suitably quantitative. A weight balance based on carbon is not feasible because part of the matrix carbon is lost from the cell in gaseous form and part reports in the residue as free carbon. The fact that the other four elements check each other so well indicates that there is not enough free carbon to affect the weight percentage of the residue materially. The maximum error in the weight percentage of the residue, and therefore in the alloy analyses, due to the free carbon and the magnetic-separation technique appears to be no greater than 1 part in 20.

However, the error in the carbon analyses of the carbides may be 5 or

Table 6 . . . Comparison of Residue and Filtrate Compositions with Composition of Steel A, Quenched from 2200°F (1205°C) and Electrolyzed in 1:10 Hydrochloric Acid (Residue = 12.6 pct by weight)

| Element | A Gm Element in Filtrate per 100 Gm Steel Electrolyzed | Composition of Residue Wt. Pct | B Gm Element in Residue per 100 Gm Steel Electrolyzed | A + B | Composition of Steel Wt. Pct |
|---------|--|--------------------------------|---|-------|------------------------------|
| W | 1.81 | 32.3 | 4.07 | 5.88 | 6.09 |
| Mo | 2.02 | 23.8 | 3.00 | 5.02 | 5.06 |
| Cr | 3.58 | 2.31 | 0.29 | 3.87 | 4.07 |
| V | 1.05 | 6.02 | 0.76 | 1.81 | 1.85 |

10 times larger because of the uncertainty in the amount of free carbon.

Despite the advantages of the hydrochloric acid cell over the more complicated citrate cell for these studies on high speed steel, it should be emphasized that the latter seems to give more reliable results when cementite is present. It was pointed out under THE CITRATE CELL—Results on Annealed Specimens, that the citrate cell operates quantitatively for the cementite in annealed low alloy steels. This is not the case with the hydrochloric acid cell. For example, an annealed steel with 1.11 pct carbon

and 4.11 pct chromium yielded a residue of 8.2 wt. pct of the steel electrolyzed, and the composition was: 8.13 pct carbon, 28.50 pct chromium and 61.38 pct iron. Thus, less than two-thirds of the carbon in the steel could be accounted for in the residue $\left(\frac{8.2}{100} \times \frac{8.13}{1.11} = 0.60\right)$. Evidently the low alloy cementite was partially decomposed during the acid electrolysis. However, since cementite is not found in the M-2 high speed steel under consideration even when the citrate cell is used, the hydrochloric acid cell can be adopted with reasonable assurance for the work at hand.

The Carbides in M-2 High Speed Steel

NATURE OF THE CARBIDES

X ray diffraction analysis of the residues extracted from steels A and B indicates that three carbide phases exist in M-2 high speed steel. These may be designated here as M_6C , $M_{23}C_6$ and MC , the M representing the sum of the metal atoms.

M_6C is a face-centered cubic carbide with a lattice parameter of 11.04₄ A.U. It is identical with the (Fe, W, Mo, Cr, V)₆C phase commonly found in high speed steels.^{19,20}

$M_{23}C_6$ is a face-centered cubic carbide with a lattice parameter of 10.56₄ A.U. Its diffraction pattern also corresponds to that of $Cr_{23}C_6$ as determined by Westgren.^{21,22} Like the M_6C , this phase is capable of dissolving iron, tungsten, vanadium and molybdenum, along with the chromium.

MC is a face-centered cubic carbide with a lattice parameter of 4.18 A.U. It is essentially a vanadium-rich carbide.^{23,24}

The above carbides are present in M-2 high speed steel in the annealed condition and after austenitizing. Therefore, the observed weight percentages and compositions of the extracted residues are not representative of single carbides, but of carbide mixtures. The lattice parameters of these carbides are not appreciably affected by austenitizing, and hence it may be assumed that no gross variation in composition of the individual carbides occurs as result of hardening. This suggests that the observed changes in composition of the extracted carbides as a function of austenitizing temperature (Table 4) are due primarily to a shift in the relative amounts of the three carbides.

* Gulyaev¹⁰ estimates that the free carbon in extracted residues of 18-4-1 high speed steel, austenitized at 2370°F (1300°C), is 0.25 pct of the steel electrolyzed.

METALLOGRAPHIC IDENTIFICATION OF THE CARBIDES

Once the existence of the three carbides in the residues was established, a systematic study was made of their etching characteristics in the solid steel in an effort to identify them under the microscope. Reliable techniques were developed which not only disclosed these carbides positively but rendered it possible to determine their volume percentages by lineal analysis. Diamond dust polishing was necessary to prevent the carbides from standing in relief or from being partly smeared by the softer matrix.

All three carbides are nicely outlined by 1 pct nital or 4 pct picral. This permits the measurement of the total volume percentage of the carbides. After repolishing, the M_6C phase can be etched selectively in a 4 pct aqueous solution of sodium hydroxide saturated with potassium permanganate. The M_6C particles are outlined and stained brown in 4–5 sec. The $M_{23}C_6$ and MC carbides are not attacked. After repolishing once more, the MC carbide is darkened selectively with an elec-

trolytic etch in 1 pct chromic acid, stainless steel being the cathode. In 3–4 sec at about 3 volts, the MC particles are colored grey or black. The M_6C and $M_{23}C_6$ carbides are not attached. Lineal analysis is applied after each of the above etches, and the volume percentage of $M_{23}C_6$ is taken by difference. Proof of the effectiveness of these procedures is presented elsewhere.²⁵

EFFECT OF AUSTENITIZING TEMPERATURE

The pertinent results obtained by lineal analysis on the carbides as polished and by chemical analysis of the carbides as isolated are summarized in Fig 4. For correlation purposes, the percent of retained austenite is also shown.

It is immediately evident that the $M_{23}C_6$ carbide dissolves more readily than the other two on austenitizing, and is practically absent above 2000°F (1090°C). The M_6C carbide dissolves more gradually, while the MC carbide hardly dissolves at all below 2200°F (1205°C). In the customary austen-

itizing range of 2200–2250°F (1205–1235°C), there remains 5–8 vol. pct M_6C and 0.5–1 vol. pct MC. The progressive solution of the $M_{23}C_6$ and M_6C carbides causes an increase in the carbon and alloy contents of the matrix, as shown by the partition curves in Fig 4. These values are calculated from the alloy content of the steel and that of the isolated carbides (Tables 1 and 4). It is interesting to note that most of the chromium in the steel dissolves in the austenite at relatively low temperatures, and this coincides with the decrease in the amount of $M_{23}C_6$ carbide, the amount of M_6C and MC then remaining essentially unchanged. Clearly, $M_{23}C_6$ is a chromium-rich carbide. While the solution of the other elements proceeds during this early stage, signifying that $M_{23}C_6$ also contains these elements, most of the tungsten, molybdenum and vanadium and part of the chromium go into solution above 2000°F. Here the $M_{23}C_6$ has disappeared, the MC remains constant and the M_6C is decreasing. Therefore, the M_6C phase certainly contains tungsten, molybdenum, chromium and vanadium. Other evidence²⁵ not considered here shows that most of the tungsten and molybdenum in the carbides is associated with the M_6C phase, while MC is a vanadium-rich phase.

The curve in Fig 4 showing the partition of carbon between the matrix and the carbides must be regarded as very approximate. The values plotted are admittedly questionable because the carbon analyses of the carbide residues tend to be high in view of the free carbon that precipitates during electrolysis of the quenched samples. The other partition curves in Fig 4 do not suffer from this uncertainty.

Conclusions

1. Two electrolytic methods have been studied for the quantitative isolation of carbides from M-2 high speed steel. The double citrate cell, with continuous filtration of the anolyte, yields quantitative extractions for annealed low alloy as well as high speed steels. This is established on the basis that (a) the theoretical carbon content of cementite is found in the extracted residues of annealed low alloy steels, and (b) the total carbon of these steels and of annealed M-2 steels is accounted for in the residues.

2. The citrate cell possesses the experimental disadvantage, aside from its complexity, that portions of the

FIG 3—Schematic diagram of hydrochloric acid cell for electrolytic isolation of carbides.
Electrolyte: 1:10 hydrochloric acid.

matrix of high alloy steels may not dissolve during the electrolysis and may thus contaminate the carbide residue. This characteristic becomes more pronounced, the higher the austenitizing temperature. Because the steel particles are ferromagnetic and the carbides are not, it is possible to effect a magnetic separation. However, this procedure is not convenient with the citrate cell.

3. Electrolysis in a simple 1:10 hydrochloric acid cell reduces the extent of the above contamination, and when it does occur, the particles of base metal can be separated reliably with a magnetic method. The hydrochloric acid cell yields quantitative extractions on annealed M-2 steel as shown by the fact that (a) all the carbon in the steel is accounted for in the residue, and (b) the measured densities of the carbide residues are in good agreement with the calculated values based on lineal analysis of the solid steel. The magnetic separation procedure is also quantitative since the total amount of each alloying element in the residue plus electrolyte checks that present originally in the steel.

4. In the electrolysis of hardened M-2 steel, both cells precipitate free carbon from the martensite-austenite matrix. The presence of free carbon lowers the observed density of the carbides extracted from quenched specimens but is not sufficient in weight to have a significant effect on the weight percentage or composition (except for carbon) of the carbides. The carbon values reported for such carbides are undoubtedly high.

5. Three face-centered cubic carbides exist in M-2 steel: M_6C which is based on a complex iron-tungsten-molybdenum carbide, $M_{23}C_6$ which is essentially a chromium-rich carbide, and MC which is a vanadium-rich carbide. $M_{23}C_6$ dissolves completely on austenitizing at temperatures above 2000°F; M_6C dissolves partially, and MC hardly at all. Curves are presented showing the quantitative solution of these carbides and the corresponding partition of the elements between the carbides and the matrix.

Acknowledgments

The authors are grateful to the Vanadium-Alloys Steel Co. for a grant-in-aid to finance this research, for furnishing the steels to be investigated, and for making most of the chemical

analyses. The cooperation of Dr. George A. Roberts, Chief Metallurgist of the above Company, is sincerely appreciated.

Solubility of Titanium in Liquid Magnesium

K. T. AUST* and L. M. PIDGEON*

There has been considerable interest in the possible use of titanium in magnesium alloys.¹ Zirconium has shown some promise in this connection² and its general similarity with titanium suggests that the latter might act in a similar manner. A literature survey revealed that quantitative data on the Mg-Ti system was unavailable. Several patents³ have claimed that titanium additions from 0.2 to 4 pct to magnesium alloys were possible, but no mention was made as to the form in which the titanium existed in the alloy. Kroll⁴ succeeded in introducing only traces of titanium into magnesium by bubbling $TiCl_4$ through the metal under argon or by reacting it with sodium titanium fluoride. The application of theoretical data given by Carapella⁵ based on Hume-Rothery's principles, involving atomic size factor, crystal structure, valency and the electro-chemical factor, suggests that a Mg-Ti alloy is a favorable case, and the system appeared to warrant experimental examination.

Experimental Procedure and Results

THERMAL ANALYSIS

If titanium is appreciably soluble in magnesium, a change in the melting point of the magnesium might be detectable using standard cooling curve methods. Magnesium was melted in graphite crucibles under an argon atmosphere, the assembly being enclosed in a silica tube. Graphite thermocouple protection tubes served also to stir the melts. The apparatus was very similar to Fig 1, with the addition of a refractory and baffle system to prevent undue heat losses from the top of the crucible. Chromel-alumel thermocouples were calibrated using Al of 99.97 pct purity.

Dominion Magnesium Limited sup-

plied redistilled high purity magnesium of the analysis given above.

Titanium was added in three different forms:

1. Titanium powder -100 mesh, from the Titanium Alloy Manufacturing Co., Niagara Falls, N. Y.

2. Sheet titanium from the U.S. Bureau of Mines, produced by Mg reduction of $TiCl_4$.

3. Magnesium -50 pct titanium master alloy from Metal Hydrides Inc., Beverly, Mass.

The melting point of the high purity magnesium used was measured experimentally as 651.0°C. More than a dozen tests were conducted using titanium from the three sources referred to above, in calculated additions up to 20 pct titanium, at temperatures between the melting point and 1000°C and holding periods up to 6 hr. In no case was evidence obtained of solubility of titanium in magnesium, using inverse-rate and time-temperature curves. The melting point of the magnesium was unchanged within the accuracy of measurement, namely $\pm 0.5^\circ\text{C}$; and no other thermal arrests were detected.

Metallographic investigation of the thermal analysis billets indicated that the titanium additions were apparently mechanically entrapped in the magnesium in segregated areas. Consequently, these samples were not analyzed for titanium. The master alloy proved to be a mechanical mixture of titanium particles in a magne-

sium matrix.

These results indicated that the titanium solubility, if such existed, could not be obtained by the usual thermal methods.

X RAY DIFFRACTION INVESTIGATION

In an effort to detect solubility of titanium in magnesium, samples were investigated using both the Debye-Scherrer and the Focusing Back-Reflection methods. Filings from samples of the thermal analysis billets and from pure magnesium were annealed in argon one hour at 350°C to relieve mechanical strain. Measurements made of the interplanar spacings showed no difference between the Mg-Ti samples and pure magnesium. The interplanar spacings could be measured to within 0.0002Å, and the greatest variation found was 0.0004Å, in the back-reflection method. The diffraction lines for magnesium were not shifted by the titanium additions indicating that the solid solubility of titanium in magnesium is of a very low order—less than 0.5 pct. From both diffraction methods, a d or interplanar spacing of 0.817Å was obtained for the redistilled high purity magnesium. This latter value is not given in the standard X ray diffraction cards for magnesium metal or vacuum distilled magnesium. Theoretical calculations for a close-packed hexagonal space lattice for magnesium indicate that the planes {2134} should give a line which was found. The relative intensity for this reflection at 0.817Å is slightly less than that at 0.870Å for magnesium.

SOLUBILITY OF TITANIUM IN LIQUID MAGNESIUM

The Mg-Mn system was examined by Grogan and Haughton⁶ who were

and 0.08 pct. These erratic analytical results suggested that finely divided titanium particles, despite the substantial density difference, do not settle readily in liquid magnesium and may not be employed as a source of titanium in liquid solubility tests. Titanium sheet, obtained from the U.S. Bureau of Mines, was used in the remainder of the tests.

Experimental Procedure

The apparatus used for the solubility tests is shown in Fig 1. Each charge consisted of 135 g of the high-purity magnesium and 15 g of titanium sheet. The titanium sheet was wrapped around the graphite thermocouple protection tube and kept in the molten magnesium during the holding periods at the desired temperature. The graphite protection tube also acted as a stirrer during the early portion of each holding period. It was assumed that titanium and graphite would not react to form titanium carbide in any appreciable quantity at the temperatures used in these solubility tests. Cylinder argon of commercial purity was passed through an oil filled bubbler, absorbent glass wool, anhydrous calcium chloride, and a "getter" furnace which contained magnesium chips at 600°C to remove oxygen and nitrogen. The purified argon passed to the system through the steel tube as shown, and escaped to a water trap and bubbler, maintaining a positive pressure of argon in the melt chamber. A chromel-alumel thermocouple was placed in the top part of the melt and the temperature was maintained within $\pm 5^\circ\text{C}$ by an automatic temperature controller.

Sampling

After each holding period, the Ti sheet was lifted from the melt and a steel sampling tube was quickly lowered into the top half of the melt. A liquid sample was pulled into the tube by a static vacuum sufficient to remove samples ranging from 2 to 5 g. After removal from the melt, the steel was stripped from the magnesium, and the entire sample analyzed for titanium except for a very small portion taken for metallographic purposes. Drillings were taken from the top section of the solidified billet to obtain the solubility at the freezing point. The analysis of titanium in magnesium was done colorimetrically using an adaptation of a well-known color reaction.¹² The method was calibrated with a standard titanium solution prepared from ti-

unable to determine the liquidus line by thermal analysis, since it was found impossible to obtain any definite evidence of arrest points. The liquidus line, however, was successfully determined by the analysis of dip samples taken from the top of the melt at definite temperatures. This method has proved satisfactory where the primary insoluble crystals separating from the liquid have a different density from the liquid. A similar technique was used by Fink and Van Horn⁷ to determine the liquidus line for the Al-Ti system and

has also been employed by other investigators.^{8,9,10,11} It was decided to apply this method to the Mg-Ti system.

In preliminary tests, titanium powder was added to liquid magnesium under an argon atmosphere. Analytical results on these dip samples showed gross segregation. For example, titanium analyses of triplicate portions from a test that had been held at 850°C for 8 hr gave 0.012, 0.57 and 0.052 pct, while another group which had been held at 700°C for 8 hr showed 0.28, 0.01

tanium dioxide (NBS Std 154). A blank run of the apparatus with no titanium introduced gave no indication of titanium which, under the conditions of the method, means a content of less than 0.001 pct. None of the other elements present in the magnesium in normal amounts interferes with the analysis.

Experimental Results

If incomplete separation of melt and solid had taken place, the liquid samples as withdrawn might contain some of the solute metal as solid particles. If such had occurred, erratic results would again have appeared, the presence of such an error would be obvious, and those samples would be disregarded. The analytical results obtained on different samples from the same test strongly support the belief that the titanium found was in solution when the sample was taken from the melt (Table 1). The average results are plotted in Fig 2. Fig 3 is a typical photograph taken from the cross-section of the liquid solubility samples. Small dark particles of Ti which have come out of solution on cooling from the sampling temperature to the freezing point may be seen. Magnesium samples without titanium additions did not show this second phase. The even size and distribution of these particles support the belief that they were in solution at the sampling temperature.

Table 1. Experimental Results

| Test No. | Temp. °C | Holding Time, Hours | Pct | Titanium |
|----------|----------|---------------------|--------|----------|
| 35 | 651 | | 0.0027 | 0.0027 |
| 46 | 651 | | 0.0028 | 0.0023 |
| 40 | 651 | | 0.0043 | 0.0025 |
| 42 | 651 | | 0.0020 | 0.0013 |
| 42 | 700 | 48 | 0.0062 | 0.0066 |
| 35 | 775 | 24 | 0.011 | 0.010 |
| 40 | 775 | 24 | 0.013 | |
| 41 | 850 | 24 | 0.015 | 0.019 |
| 46 | 850 | 48 | 0.015 | 0.014 |

Conclusions

1. The solubility of titanium in liquid magnesium is extremely small, increasing approximately from 0.0025 pct at the freezing point of magnesium to 0.015 pct at 850°C. This titanium solubility is far less than that reported for zirconium¹³ or for iron in magnesium.¹⁴

2. Solid solubility of titanium in magnesium could not be detected using X ray diffraction methods.

3. The freezing point of redistilled high-purity magnesium is 651.0°C.

4. An interplanar spacing or d value was obtained for magnesium, 0.817Å, a value which has not been reported in the standard X ray diffraction card index system.

The Lattice Parameters of High Purity Alpha Titanium; and the Effects of Oxygen and Nitrogen on Them*

HOWARD T. CLARK, JR.,† Member AIME

Introduction

Within the last twenty years at least three sets of lattice constants for the room temperature (alpha, hexagonal close packed) phase of titanium have been reported in the literature. These values, summarized in Table 1, differ one from another by amounts far greater than can be explained on the basis of inaccuracies in parameter measurements.

This paper presents new values determined for high purity titanium. It also details the effect of two elements, oxygen and nitrogen, on these parameters and shows that two of the previously reported values are probably in error because of the presence of one or both of these elements in the material used for examination.

Preparation of Samples

The titanium‡ used for this study was prepared by the thermal decomposition of titanium tetraiodide⁷ on a hot titanium filament. This titanium rod was prepared for X ray examination by melting about 10 g in purified argon in an electric arc furnace on a cold hearth. This cast button was cold rolled to 0.040 in. thick sheet, cleaned, annealed in vacuum at 1000°C and cold rolled to 0.020 in. thickness. About 0.003 in. of surface material was then removed by hand grinding on papers to remove any contamination caused by the rolls and the sample was bent to the radius of the focusing camera. The sample was then vacuum annealed at 600°C, a temperature just high enough to cause recrystallization, producing a fine grained structure. Such a structure is essential in sheet

Table 1 . . . Summary of Literature† Values of Alpha Titanium Lattice Parameters

| Worker | a_0 | | c_0 | | c/a |
|--------------------------------|-------|----------|-------|---------|-------|
| | KX | Å | KX | Å | |
| G. Haag ¹ | | 2.953 | | 4.729 | 1.60 |
| J. D. Fast ² | 2.945 | (2.951)* | 4.67 | (4.68)* | 1.59 |
| Greiner and Ellis ³ | 2.945 | (2.951) | 4.684 | (4.694) | 1.591 |

* Figures in parentheses have been calculated from the reported KX units for comparison (KX units $\times 1.00203$ = Angstroms).

† Since the preparation of this paper the following values for the lattice parameters of high purity alpha titanium have been published by Bruce W. Gonser (*Metals Progress* (1949) 55, p. 346):

$a_0 = 2.946$ KX units (2.952 Å), $c_0 = 4.686$ KX units (4.695 Å). A comparison of these values with those presented in this paper and with other literature values shown in Table 1 suggests that the X ray samples used by Gonser were contaminated with oxygen and/or nitrogen. This conclusion is based on the fact that his value of a_0 is approximately correct, but that his value of c_0 is extremely high compared with both Fast's value and the writer's, the writer's explanation for which is detailed in this paper.

specimens prepared for focusing cameras in order to have a sufficient quantity of grains to develop continuous diffraction lines.

The use of sheet specimens rather than powder samples appears to be essential for the X ray examination of titanium. This is because of titanium's exceptionally high gettering power and its rapid absorption of adsorbed gases, water vapor, and the like at annealing temperatures. While the effect of this contamination may be neglected for sheet specimens, its effect on 200–300 mesh powder is appreciable.

Titanium alloys of oxygen and nitrogen were prepared by a technique simi-

lar to that described above except that the required amount of the highest purity titanium oxide or nitride available was added prior to melting in the arc furnace. These materials were added by placing them in holes drilled in the titanium. A small weight loss invariably occurs during the melting of these oxygen and nitrogen alloys. This is believed to be due entirely to the loss of some of the powdered compound in the blast of the electric arc, an assumption which is justified on the basis that there is no weight loss during the melting of titanium metal and that wet analyses for nitrogen on representative samples have checked with the calculated analyses when it was assumed that the entire loss during melting was due to the loss of titanium nitride powder. These alloy buttons were reduced to sheet in the same manner as used for the unalloyed titanium.

* Values of $\sin^2 \theta$ greater than 1.0 result from the conversion of measured values of $\sin^2 \theta$ to equivalent Cu $K\alpha_1$ values.

† A probability of 0.05 has been taken for determining limits of accuracy.

Room temperature remained fairly constant at about $25 \pm 2^\circ\text{C}$ during these exposures. The camera is so constructed that the synchronous motor used to oscillate the sample does not appreciably increase the sample temperature.

Experimental Results

Table 3 lists the lattice parameters of several different samples prepared from different titanium tetraiodide decomposition runs and reduced to sheet as discussed above. All values for both a_0 and c_0 agree very well.

Oxygen and nitrogen form interstitial solid solutions with alpha titanium, and, as would be expected for interstitial solutes, increase the titanium parameters. The amount of this change produced by each of these elements is shown in Fig 1 and 2 respectively.

Discussion of Results

It will be noted in examining Fig 1 and 2 that the addition of the common contaminants to alpha titanium expands the lattice in the c direction much more than in the a direction. With this in mind, it is interesting to look again at Table 1 and to compare the values presented there with those of Table 3. Such an examination leads to the following conclusions:

1. Fast's values, which were determined on titanium prepared by the same method used for preparing the titanium employed in this investigation, agree with the writer's values.

2. All reported values of a_0 agree within reasonable limits, a condition which is to be expected.

3. The reported values of c_0 vary greatly, the two values reported by Haag and Greiner and Ellis being appreciably higher than the values re-

ported here and by Fast. Greiner and Ellis worked with titanium⁷ produced by the Kroll⁴ process which is reported to have small amounts of manganese, magnesium, and silicon present. This material was prepared by powder metallurgy, and undoubtedly also contained oxygen and nitrogen picked up during both the reduction and the leaching and grinding operations, and diffused into the metal during sintering.

Conclusions

1. The lattice constants of alpha titanium are:

$$a_0 = 2.9504 \text{ \AA} \pm 0.0003$$

$$c_0 = 4.6833 \text{ \AA} \pm 0.0003$$

2. The lattice constants of alpha titanium, especially the value of c_0 , are increased appreciably by the addition of small amounts of oxygen or nitrogen.

SEPTEMBER 1949

FIG 1—Martensite crystal in nickel steel.
White area is a single crystal of martensite; see text for details of specimen preparation. Etched with Nital. $\times 6$.

Most martensite crystals in steel are far too small for the above method to be practical. Judging from past experience, it was decided that the alloy that offered the best chance of success would be a steel containing about 22 pct nickel and 0.8 pct carbon. This alloy is all austenite at room temperature (even after very slow furnace cooling), and small amounts of martensite may be formed by cooling to -77°C . Accordingly, 35 separate 50-g melts of this alloy were prepared in a high-vacuum molybdenum-wound resistance furnace, using as raw materials a 1.3 pct carbon drill-rod steel and nickel shot.* Many ingots were remelted and all melts were solidified very slowly. Resulting austenite grain size averaged about 1 cm. Suitable ingots were cut and ground to form specimens about 1 cm cube, which were then given a metallographic polish on all six surfaces. Each specimen was carefully cooled by successive stages in mixtures of solid CO_2 and acetone; the cooling was halted after a few martensite crystals had formed. The largest martensite plates were about 2 or 3 mm^2 in area, and about 30 microns thick; most crystals were considerably smaller than this. Suitable specimens were then ground and carefully polished on a surface parallel to a single martensite plate, exposing the crystal for an area of 1 mm^2 or more. Four martensite crystals from 4 different ingots were prepared in this manner; the largest crystal of this group is illustrated in Fig 1. Back-reflection Laue patterns

* Most of the ingots were used to prepare specimens for shear studies, described in the second section of this report.

FIG 2—Martensite crystal of Fig 1.
Etched with Nital. $\times 1000$.

were obtained from martensite crystals and the matrix austenite both before and after tempering. The location of the basal plane pole of martensite was checked by means of oscillating crystal X ray patterns.

In addition to the above orientation work, several Debye X ray patterns were prepared from slivers (cut from the ingots utilized) deformed and recrystallized at 1100°C and then cooled to -195°C . Austenite lattice parameter was $3.592 \text{ \AA} \pm 0.005$; martensite parameters were $a_0 = 2.845 \text{ \AA}$, $c/a = 1.045$, both ± 0.005 .

RESULTS

All 4 martensite crystals studied yielded the same solution ($\pm 0.5^{\circ}$); these relationships are expressed in gnomonic projection in Fig 3. It will be noted that the (111) austenite plane is not parallel to the (101) of martensite; the planes are separated by an angle of about 1° . Likewise, no important zones are parallel. Except for the nonparallelism of these two closely packed planes, the evaluated relationship may be described as about midway between the Kurdjumov and Sachs and the Nishiyama relationships. The relationship shown in Fig 3 is for the untempered "tetragonal martensite"; in the process of tempering the relation-

ship changes slightly. The first evidences of tempering are observed in the back-reflection Laue patterns (after only 2 or 3 days at room temperature) by an elongating of the Laue spots on the $[11\bar{1}]$ zone. After a month at room temperature, these spots are considerably elongated, while the spots on both the $[\bar{1}11]$ and $[10\bar{1}]$ zones remain nicely rounded, but shift position slightly. After tempering 2 days at temperatures between 500 and 900°C ,* all spots from the tempered martensite crystal are well rounded, $(111)\gamma$ and $(101)\alpha$ are parallel, and the lattice relationship departs only about 1° from the Nishiyama relationship. Note that the slight change in lattice relationship that occurs during the tempering process (the approximate direction of shift is indicated by the small arrows in Fig 3) is decidedly not in the direction that one would expect from a simple change in axial ratio from 1.045 to 1.

The narrow, dark-etching bands illustrated in Fig 2 were found to be parallel to $\{112\}$; 6 trace normals were located and all of these deviated less than 2° from a $\{112\}$ pole of martensite. The bands are thus probably twin bands, which may have formed during

* After one-half hour at 1000°C , the tempered martensite disappears and the original all-austenite crystal is retained at room temperature; if the austenite is heated to 1100°C , it recrystallizes.

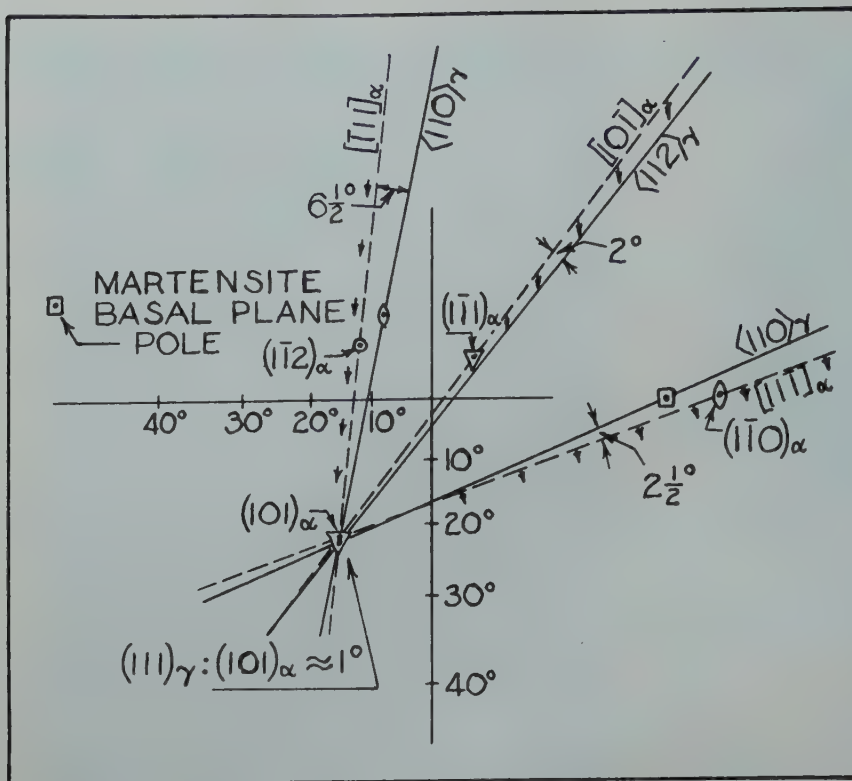

FIG 3—Orientation relationships between austenite and martensite in nickel steel. Relationships are projected gnomonically. Plane of projection is the plane of the martensite plate.

the polishing operation. Individual twin bands seldom are continuous across the midrib of a martensite crystal, and occasionally very small (less than 0.5°) angular differences are observed between bands on opposite sides of the midrib. It is safe to conclude that the midrib plane represents a discontinuity in the lattice of a martensite crystal.

The Martensite Shear*

If a suitable specimen of metastable austenite is polished metallographically and cooled to some subatmospheric temperature to form small amounts of martensite, the martensite may then be seen as a relief effect on the polished surface. This fact has been known for many years, but evidently no one has attempted to measure and analyze this relief.

Fig 4 and 5 illustrate the appearance of the relief formed by martensite in the steel used in the present investigation. A careful inspection of many of these "needles" led us to the conclusion that the relief is caused by a deformation that closely resembles homogeneous shear and that the shear must be in the plane of the martensite plate. Now, it

may readily be proved stereographically that it is impossible to transform a face-centered cubic lattice into a pseudobody-centered tetragonal lattice by a single shear. However, it is possible that two shears are involved in the transformation. If so, and if the first shear can be described by analyzing the martensite relief, then it should be possible to determine the remainder of the transformation mechanism by simple subtraction, inasmuch as the final result of the transformation is known from the lattice relationship and habit information given in Fig 3. Accordingly, attempts were made to analyze the visible martensite shear by methods outlined in Fig 11, Appendix A; the results of this analysis are summarized below.

RESULTS

Twelve martensite crystals in 3 specimens from 3 different ingots were studied. The results obtained for the direction of shear and the shear angle are shown by the small arrows and numbers on the primitive circle of Fig 6; the average γ_0 of the 12 measurements is 10.75° . The accuracy of an individual measurement is about $\pm 10^\circ$ in direction and about $\pm 2^\circ$ in angle. Some measurements were considerably better than this, notably the fifth arrow from the top in Fig 6, which is believed

good to within 5° in direction and 0.5° in angle. If a martensite crystal could be found having a surface like that shown in Fig 4 on two faces of a specimen, the direction could be evaluated to within less than 1° and the angle to within a few minutes. Unfortunately, no near-perfect martensite crystal of this type was found in the dozens of specimens examined, though, of course, only plates that were reasonably well formed were measured. The plates with perfect faces show a definite tendency to be grouped at the centers of the specimen surfaces, instead of at the edges where they must be if they are to be analyzed.

A continuation of the stereographic manipulation yielded the following important result: When the austenite lattice was deformed stereographically in accordance with the average experimentally determined direction and angle of shear, it was found that a second shear could transform this triclinic lattice into a pseudobody-centered tetragonal lattice of the same orientation and almost the same parameters as martensite (having an atomic volume equal to that of austenite). Furthermore, this second shear is on the (112) martensite plane in the $[11\bar{1}]$ direction; these are the elements for twin gliding in the body-centered cubic or tetragonal lattice. This second shear cannot, of course, be homogeneous on a macroscopic scale, though atomically it is; it must be confined to the volume of the triclinic lattice produced by the first shear. In the twinning shear of the body-centered cubic lattice, points on every sixth (112) layer are common to both the twinned and the untwinned lattices.¹⁴ In the second shear of the martensite mechanism, the shear angle (the optimum angle is between 12° and 13°) is about one-third as large as the shear angle for twinning, hence the second shear will take place in layers of about 18 atomic planes. The deformation of the austenite lattice into a martensite lattice by means of these two shears is illustrated stereographically in Fig 6,* and the data and results of calculations are summarized in Tables 1 and 2. An inspection of Tables 1 and 2 and of Fig 6 will reveal that the optimum calculated direction for shear No. 1 has been bracketed by directions A and B of Fig 6.

Another possibility for the second shear is that it be on $(123)_\alpha$ in the direction $[11\bar{1}]_\alpha$. These shear elements give

* Readers will find it advisable to examine Appendix A before continuing with this paper. Symbols, equations, and conventions are defined or derived in Appendix A.

* The stereographic portion of this analysis was carried out with the aid of a 15.75 in. diam stereographic net.

slightly better results than (112) and [111] but not sufficiently better to warrant their selection as the true elements. No better results are obtained with irrational shear planes and directions for the second shear.

The missing parameter that makes it impossible at present exactly to define the mechanism from beginning to end concerns the change in atomic volume. When a volume of austenite transforms to martensite, it increases about 4 pct in size; this volume increase is uninfluenced by carbon content (see Table 3). Shear can produce no change in volume; hence, a small but nonetheless important part of the transformation consists of an expansion. If the expansion occurs either at the beginning or end of the transformation, it would produce no change in orientation, and the spacing changes are readily calculated. If the expansion occurs during the transformation, it could have a maximum effect of about 1° on the resulting orientation of the martensite lattice. The "unexpanded martensite" interplanar spacings listed in Tables 1 and 2 were calculated from the measured martensite parameters of the steel used in this study, assuming that the expansion is merely one of a change in atom radius.

Most of the experimental results described above will be discussed in the following section.

The Mechanism of the Martensite Transformation

In the following is presented a brief exposition of the movement of atoms in a martensite transformation. The general statement is really nothing more than a rewording of the experimental results reported in this paper. Application of the theory in a specific case will provide a solution for both lattice relationship and orientation habit for any martensite transformation in steel occurring near room temperature or below. The probable effect of the temperature variable is predicted and it is pointed out that the most important problem awaiting solution is the complete experimental determination of the effect of temperature change on the mechanism of an individual martensite transformation.

GENERAL STATEMENT

In a martensite transformation, billions of atoms move from their positions on the matrix lattice to positions

† In pure iron, the ratio of the atomic volume of ferrite to that of austenite¹⁹ is: at 900°C, 1.007; at 20°C, 1.039. The average temperature coefficient of expansion of gamma iron is almost twice that of alpha iron. See Ref 18.

on the martensite lattice. This change in position can be described almost entirely by two homogeneous shears (if the transformation cannot be accomplished by one shear, as it can be for the transformation: hexagonal close-packed \rightleftharpoons face-centered cubic). The function of the first shear is to create a

lattice containing a unique set of parallel atomic planes whose interplanar spacing and atom positions are the same as those of a set of parallel atomic planes in the martensite lattice; a second shear, on this unique plane, will then be capable of generating the martensite lattice. In the usual case,

FIG 6—Stereographic projection illustrating the transformation from austenite to martensite by means of two homogeneous shears.

Plane of projection is the plane of the martensite plate (plane of shear No. 1). Small arrows and figures at the right represent the experimentally determined directions and angles of shear for shear No. 1. Trial shears "A" and "B" are directions for shear No. 2 assumed and for purposes of calculating orientation and spacing changes of planes in the austenite lattice. Squares, triangle, and oval designate $\{100\}$, $\{111\}$, and $\{110\}$ austenite poles respectively. Austenite and martensite poles were plotted from experimental data of Fig. 3. The travel of each austenite pole as a result of shear No. 1 is along an equatorial line; the additional shift resulting from shear No. 2 is along a great circle joining the pole of the second shear plane (see Tables 1 and 2). The numbers attached to indices of the axial planes of martensite are (1) numerators—interplanar spacings calculated from shear data—and (2) denominators—actual interplanar spacings of the "unexpanded martensite" lattice.

the complete transformation cannot be accomplished *precisely* by two shears; hence a very small readjustment will be needed, most logically after the first shear. The selection of planes and directions for the two shears will be governed by considerations of minimum shear angle and minimum readjustment. The second shear plane will probably be a low-indices plane of the martensite lattice, the first shear plane

(and direction) will be an irrational plane in the matrix lattice because its selection is governed by requirements that cannot be expressed in terms of the matrix lattice itself. The solution of the above problem begins with the selection of the second shear plane.

THE PLANE OF THE SECOND SHEAR

The designation of the second shear plane is arrived at from a comparison of

interplanar spacings of, and atom positions on, the lattice planes of the matrix and martensite lattices; the object is to designate a martensite plane that most easily may be generated from an austenite plane. This comparison must be made with due regard to the principles of lattice shear illustrated in Fig 10, Appendix A. For the transformation face-centered cubic \rightarrow body-centered cubic, the following combinations* are most probable; other possible combinations will have indices higher than those shown:†

- $$\begin{aligned} (a) \quad & (220)_\gamma \rightarrow (112)_\alpha \\ (b) \quad & (331)_\gamma \rightarrow (123)_\alpha \\ (c) \quad & (442)_\gamma \rightarrow (134)_\alpha \end{aligned}$$

If expression (a) can be fulfilled exactly, then expressions (b) and (c) cannot be. Actually, neither (a) nor (b) nor (c) can be fulfilled exactly; the differences in readjustments required by expressions (a) and (b) are so small that for the extension of this analysis, it makes no difference which of the two is selected, or which one actually operates as the second shear plane.

THE PLANE AND DIRECTION OF THE FIRST SHEAR

If $(220)_\gamma \rightarrow (112)_\alpha$ could be fulfilled exactly, the plane and direction of the first shear for minimum γ could be accurately determined mathematically. Actually, the expression cannot be exactly fulfilled, and the optimum plane and direction of the first shear are more readily located by trial-and-error meth-

* The expression $(220)_\alpha \rightarrow (112)_\gamma$ means: As a result of a single homogeneous shear in the austenite lattice, the orientation, the interplanar spacing, and the atom positions of the $(220)_\gamma$ plane become (very nearly) the same as those of the $(112)_\alpha$ plane.

† These expressions (with the direction of the arrows reversed) must also hold for the reverse transformation body-centered cubic \rightarrow face-centered cubic.

ods of stereographic manipulation; of course, there can be no single solution, but instead the shear plane will be located as a small area and the shear direction as a small oriented angle. The spread or scatter for the plane and for the direction will be a function of the readjustments required for the generation of $(112)_\alpha$. For the case of the martensite transformation illustrated in Fig 6, the permissible scatter for the pole of the shear plane was determined stereographically as about $\pm 4^\circ$ and for the shear direction about $\pm 5^\circ$; both of these agreed with those experimentally determined.

LATTICE RELATIONSHIPS

After the elements of the two shears have been determined, the resulting lattice relationship may be solved stereographically. For the transformation face-centered cubic to body-centered cubic, a pseudo body-centered tetragonal lattice of axial ratio greater than 1 will always form; for the reverse transformation, the tetragonal cell must have an axial ratio slightly less than 1 (see Fig 6). The continuation of the transformation to the final cubic form may be hindered by the presence of certain solute atoms;* notably, carbon is responsible for the retention of the tetragonal lattice of martensite in steel. For the martensite transformation in iron-nickel alloys, the tetragonal stage is not retained; we may confidently predict that for nickel contents above about 29 pct† this transformation will proceed along the same paths as the transformation shown in Fig 3, and that the final lattice relationships will be very close to the Nishiyama relationship.‡

THE EFFECT OF TEMPERATURE

It is quite likely that with an increase in the temperature of the transformation, there will be a tendency for the first shear elements to assume lower indices and higher symmetry. However, a change in the elements of the first shear will be possible only when the temperature of the transformation and thus the atomic mobility is increased sufficiently so that larger readjustments are possible. A stereographic

* It is probable that the temporary retention of the tetragonal transition lattice is always due to the proper ordering of solute atoms. The tetragonal lattice that results from the martensite transformation in β brass¹⁰ is remarkably stable; there is good reason to believe that quenched β brass is ordered.¹⁰

† See the first footnote in the next column.

‡ No explanation is advanced for the small lattice-relationship changes observed to occur during the change from tetragonal to cubic martensite, and illustrated in Fig 3.

FIG 7—Origin of the martensite midrib.

solution for probable first-shear planes and directions of higher symmetry suggests that the shear plane should become $(422)_\gamma$ and the direction of shear $[\bar{1}\bar{1}\bar{1}]_\gamma$.* The resulting lattice relationship would then be $[110]_\gamma \parallel [11\bar{1}]_\alpha$, and $(111)_\gamma \cdot (101)_\alpha = 0^\circ$ to 3° , depending upon the directions of readjustment; the readjustments necessary are 3 to 5 times as great as those required by the "lowest temperature" mechanism shown in Fig 6. For still higher temperatures, the only probable change in the pole of the first shear plane would be along the $[01\bar{1}]_\gamma$ zone in the direction of $(111)_\gamma$ and for highest temperature, the first shear should be on $(111)_\gamma$ in the direction $[2\bar{1}\bar{1}]_\gamma$ —these are the elements of twinning shear for the face-centered cubic lattice. The above statements are based upon the assumption that the elements of second shear do not change with temperature; there should be no tendency for change, inasmuch as at lowest temperatures, the elements of the second shear are the same as those of the twinning shear in the body-centered cubic lattice. With increasing temperatures, there should be an increasing probability that actual twins will be produced in the body-centered cubic lattice.†

THE MARTENSITE MIDRIB

The plane of the martensite midrib represents a region of discontinuity in

* This predicted shear plane is located only 5° from the experimentally determined plane of martensite plates in plain carbon steel containing 0.9 to 1.4 pct carbon.⁹ Martensite of this habit is also formed in iron-nickel-carbon alloys in certain composition ranges. Martensite in iron-nickel alloys has the "lowest temperature" irrational habit for nickel contents above about 29 pct nickel; for lower nickel contents the habit is octahedral, but poorly developed.

† Abundant twinning results from the $\gamma \rightarrow \alpha$ transformation in iron; see Ref. 15. For the martensite transformation: body-centered cubic \rightarrow hexagonal close-packed, the plane of second shear is $(10\bar{1}\bar{1})$, and polysynthetic twinning on $(10\bar{1}\bar{1})$ results from this transformation at moderately low temperatures; see Ref. 6.

the lattice of a martensite crystal.* The manner in which this plane of discontinuity probably originates is illustrated in Fig 7. Shearing action starts on the plane of the midrib, and is propagated in parallel but opposite directions on both sides of this plane. The final tetragonal crystal could be identical and continuous on both sides of the midrib plane if the transformation could be completed without readjustments. The small readjustment that must occur would permit a difference in orientation of about 0.5° , hence a discontinuity at this plane of contact. An additional and probably more important consideration is that it is very unlikely that the shear can be perfect near its plane of origin when it must be propagated on both sides of this plane.

Summary

An X ray and microscopic study of the martensite transformation in steels containing about 22 pct nickel and 0.8 pct carbon has been made, and a brief exposition of the movement of atoms in this martensite-type transformation has been advanced. The martensite crystal is formed from an austenite crystal almost entirely by means of two homogeneous shears. The function of the first shear is to create a lattice containing a unique set of parallel atomic planes whose interplanar spacings and atom positions are the same as those of a set of planes in the martensite lattice; a second shear on this unique plane will then generate the martensite lattice.

The theory predicts both lattice relationships and orientation habits for martensite transformations. The two

* See p. 592. Another fact supports this statement: The midrib plane is the region where carbon first precipitates when martensite is tempered.

principal experimental determinations were:

1. The evaluation of the lattice relationship between austenite and individual crystals of martensite. (See Fig 3.)
2. The measurement and analysis of the change in position that a volume of austenite undergoes when it transforms into a crystal of martensite (see Fig 6).

Appendix A

The Stereographic Analysis of Shear

In Fig 8 a lattice segment having the shape of a rectangular parallelepiped is deformed by homogeneous shear upon the basal plane in the direction of the long axis. The displacement of any point within the lattice segment is a linear function of its distance from the undistorted base plane. The displacement at unit distance from this base plane is s ; the shear angle is γ . Plane abs is any lattice plane in the undistorted segment; as a result of the deformation, plane abs moves to its new position efs . The position of plane abs is fixed with respect to the plane and direction of shear by the modified spherical polar coordinates ϕ and ρ . ϕ is the angle between the trace normal of plane abs (on the shear plane) and the direction of shear, and ρ is the angle between abs plane normal and the shear plane; ρ is measured in a clockwise direction from the shear plane, and thus may have values between 0° and 180° . The plane $spdgrq$ is perpendicular to planes abs and efs . pt is perpendicular to plane abs , and pr is perpendicular to plane efs . If, then, we designate the angle between planes abs and efs as γ' , the following relations obtain:

$$\tan \gamma = \frac{s}{u}$$

$$\tan \rho = \frac{cg}{u}$$

$$\tan (\rho + \gamma') = \frac{cd}{u}$$

$$qd = s \cos \phi$$

$$\therefore \tan (\rho + \gamma') = \frac{\tan \rho + \tan \gamma}{\cos \phi} \quad [1]$$

In the undistorted lattice, planes parallel to plane *abs* have interplanar spacing *d*; after the deformation, the interplanar spacing of these planes in their new positions is *d*₁. Then,

$$\begin{aligned} \cos \rho &= \frac{pq}{ps}, & \cos (\rho + \gamma') &= \frac{pr}{ps} \\ \therefore d_1 &= \frac{d \cos (\rho + \gamma')}{\cos \rho} \quad [2] \end{aligned}$$

All angular distances contained in Eq 1 and 2 are depicted stereographically in Fig 10, in which the plane of projection is the plane of shear and the direction of shear is as indicated. Note that the shear angle γ has been replaced by the quantity γ_0 . (The reason for doing this is that γ_0 is the quantity that is directly determined in the stereographic solution of a shear problem—see Fig 11.) The relation between the shear angle γ and the angle γ_0 is shown in Fig 9. γ_0 is the angle between the circular section of the strain ellipsoid* and the plane that all points on this section occupied in the undistorted lattice; these two surfaces are represented as great circles in Fig 10.

The relationships expressed in Fig 10 are quite general; they may be applied to any case of a single homogeneous shear.† Note that as a result of shear, all poles travel along equatorial lines; the only poles that do not change position are those lying in the zone of the shear direction. The angular displacement, γ' , as well as the change in interplanar spacing may be calculated precisely for any pole that is plotted, so long as the plane and direction of shear and γ_0 are known.‡ The value of γ' and thus of d_1 , are relatively insensitive to small errors in ϕ and ρ .

In the experimental problem that arises, the conditions are the reverse of those outlined above; namely, we measure γ' , ϕ , and ρ for two poles and we wish to solve for the direction of shear and γ_0 . This problem and its stereographic solution are illustrated in Fig 11. In Fig 11, a small plate-shaped volume of the crystal has undergone a deformation as illustrated. Within the distorted volume, surface I has moved to a new position I_a ; similarly, surface II is now in position II_a . If we assume that the deformation has been a homogeneous shear along the plane of the plate, we may evaluate the direction and angle of shear. The measurements that must be made are: (1) those ordinarily needed to plot the location of a pole from the measurements of

FIG 11—Stereographic determination of the direction and angle of shear. Plane of projection is the plane of shear.

traces of the plane on two surfaces, and (2) angles γ_I' and γ_{II}' ; these latter are measured with an optical goniometer. The steps in the stereographic solution are as follows:

1. With surface I as the plane of projection, plot stereographically the poles of surfaces I, I_a , II, and II_a , and the pole of the shear plane.
2. Rotate the projection to make the shear plane the plane of projection.
3. Replot surfaces I, I_a , II, and II_a as great circles. (This stage is illustrated in Fig 11.)
4. Point a then represents a line in the undistorted crystal (the intersection of surfaces I and II), and as a result of the deformation this line has moved to the position represented by point b (the intersection of surfaces I_a and II_a).

5. The stereographic net is then rotated until a and b lie on the same great circle, and the straight line joining the two diametrically opposite poles of this great circle is parallel to the shear direction. The direction of movement is ascertained from the fact that a moves to b (not b to a), hence the direction of shear indicated by the arrow in Fig 11.

6. To evaluate γ_0 , the stereographic net is rotated until its equator coincides with the direction of shear, and points c and d are located by the requirement

that great circles fad and ec must be at equal distances from the center of the projection and points c and d must lie on the great circle that is shown. Another way of stating the requirement is that the angle between point c and the equator must be equal to the angle between point d and the equator. Angle cd is then equal to γ_0 and angle ef must be equal to cd inasmuch as all points on the great circle ec move to positions on the great circle fad as a result of the deformation.

The stereographic method for solving the above problem represents a graphical solution of two simultaneous equations of form (1). If it is possible to measure γ_I' and γ_{II}' to within a few minutes of arc, and extreme precision is needed, then the shear direction and γ may be solved as follows:

Two equations of form (1), after substituting the known values of γ_I' and ρ for surfaces I and II, reduce to

$$\tan \gamma \cos \phi_I = a \quad [3]$$

$$\tan \gamma \cos \phi_{II} = b \quad [4]$$

divide [3] by [4]

$$\frac{\cos \phi_I}{\cos \phi_{II}} = c \quad [5]$$

then, inasmuch as $(\phi_I + \phi_{II})$ is known, an accurate solution of expression [5] may be obtained by trial and error.

* The other circular section of the strain ellipsoid is, of course, the undistorted base plane. Crystallographers usually designate these two planes as K_2 and K_1 , respectively.

† In the information given by Fig 9, the following space relationships between the hemisphere of projection, the specimen, and the observer are either stated or implied: The hemisphere is located between the specimen and the observer; the shear direction is toward the right of the observer; plane normals proceed from the specimen toward the observer, and intersect the hemisphere of reference in their path; the distortion that is analyzed lies between the undistorted base plane and the hemispherical surface.

‡ The angular displacement may also be determined by stereographic manipulation (see Ref. 13). For most work, however, the stereographic solution of γ' provides insufficient accuracy.

Effect of Composition on the Wire Textures of Copper and Its Solid Solution Alloys

WALTER R. HIBBARD, Jr.,* Junior Member AIME

It has been proposed¹ on the basis of slip and flow that the ideal deformation texture of drawn wire for face-centered cubic metals is a [111] direction parallel to the wire axis. Under these considerations, an intermediate [100] texture is permissible but should eventually change to the stable [111] orientation. This theory does not explain why copper and its alloys containing up to about 30 pct nickel, 5 pct zinc and 1 pct aluminum were found to have a double [111], [100] texture, while alloys with at least 8 pct zinc and 2 pct aluminum developed essentially a single [111] texture.^{1,2} It does suggest, however, that the [100] component of the former alloys should disappear with additional deformation.³ Some evidence exists to support this suggestion. Howald⁴ reported that annealed copper wire previously drawn 93.8 pct and 98.5 pct developed a single [111] texture. Since, in wire, the drawn and annealed textures are similar, these wires probably had a single [111] deformation texture before annealing. In addition, although cold rolled polycrystalline copper and 80-20 brass were found to form different types of pole figures,^{5,6} single crystals of these metals when rolled from the stable (110) [112] orientation were found to produce essentially the same pole figure.^{7,8} It may be, therefore, that while the addition of solute elements changes the path by which the final

texture is obtained, the final texture is not changed.

Experimental Results

The wires remaining from the previous investigation¹ already drawn about 50 pct reduction in diameter were further drawn to 86 pct and then to 96.4 pct total reduction in diameter. The textures were determined after these stages by transmission X ray photograms taken with a copper K-alpha beam rotated θ degrees toward the wire axis. It was found that the ratio of the [111] and [100] intensities of the double texture in copper and its alloys containing 0.94 pct aluminum, 30.70 pct nickel, 2.61 pct zinc and 4.99 pct zinc increased from about 3:1 for the 50 pct reduction to about 9:1 for the 86 pct reduction. After 96.4 pct reduction, these wires exhibited essentially a single [111] texture.

Summary

Thus, the drawn wire deformation texture of copper and its alpha solid solution alloys containing aluminum,

nickel or zinc is essentially a single [111] texture as predicted by theoretical considerations of slip and flow.¹ For copper and its alloys containing up to about 1 pct aluminum, 5 pct zinc and at least 30 pct nickel, an intermediate [100] component is found after about 50 pct reduction in diameter, but disappears after about 95 pct reduction in diameter. For alpha solid solution alloys containing at least about 2 pct aluminum and 8 pct zinc the single [111] texture is developed considerably more easily and is found after about 50 pct reduction in diameter. No explanation of this compositional effect is apparent. Similar work is contemplated for cold rolled and cold compressed alloys.

Structure and Nature of Kink Bands in Zinc*

J. B. HESS,† Junior Member, and C. S. BARRETT,† Member AIME

Single crystal rods of cadmium collapse under uniaxial compression into peculiar kinks if the (0001) glide plane is nearly parallel to the axis of compression. In his report first describing this behavior, Orowan¹ proposed that these "kink bands" do not develop entirely by ordinary gliding and twinning but by a special mechanism in which glide lamellae of uniform thickness snap abruptly to a tilted position that permits lattice continuity across the glide planes. He concluded that a portion of each boundary of a kink band consists of a plane (non-crystallographic) which bisects the angle between the glide planes on the two sides of it, and along which the bending and the dislocations are concentrated.

The data presented by Orowan seemed to us to be insufficient to conclude that a wholly new mechanism of deformation was responsible for the kinks. Therefore, we have investigated zinc, which is hexagonal close-packed and has an axial ratio near to cadmium, to see whether similar bands are produced, and whether the ordinary mechanisms of glide, bend-gliding, twinning, and the formation of deformation bands can account for its mode of deformation.

We find that kinks form profusely in zinc as shown in Fig 1. The structure of these kinks, reported below, seems to require no new mechanism for their explanation, but indicates that kink bands are a special form of deformation bands and develop gradually, solely from basal glide. A theory covering the formation and structure of the bands is presented in detail because it is seldom possible to study deformation bands under such simple conditions, yet many principles applying to these kinks

FIG 1—Typical kink bands in compressed single-crystal zinc rod. 3X.

should also apply to deformation bands in general.

Experimental Procedures

Single crystal rods of 2–3 mm diam and 10–15 cm length were grown by the Bridgman technique from swaged wire of Horsehead Special zinc in uncoated pyrex tubes. Orientations of the rods were determined with an optical goniometer after cleaving the rods at

liquid air temperature. Crystals of desired orientations were then selected and used as "seeds" to grow additional crystals approximately 4 ft in length from which all specimens were cut.

The wires were compressed in two ways: in a simple hydraulic handpress—a "soft" machine—and in a Riehle hydraulic testing machine modified to produce very "stiff" action by the simple expedient of inserting lengths of steel bars at the sides of the zinc crystals between the compression plates.

For metallographic examination, the specimens were mounted in sealing wax. Hand polishing was employed, with no grits coarser than No. 1 paper; following the abrasives about 0.025 in. was removed by an etch-polishing reagent.* Final etching to reveal ori-

Experimental Results

CONDITIONS FOR KINK FORMATION

A single crystal zinc rod of suitable orientation deforms by kinking when it is compressed axially provided the rod ends are restrained from rotating. Such restraint is provided by inserting the ends into axially aligned holes in the compression plates, or, with short specimens, merely by permitting the squared-off ends of the crystals to rest directly upon the compression plates.

Axial compression alone is not sufficient to cause kinking, for when the ends of a zinc rod are inserted into hardened steel caps having axially-aligned conical points which rest against the compression plates, kinking does not result. Instead, the crystals buckle into a smooth sine-curve without abrupt bend angles on either the convex or concave surfaces. Continuing compression under these conditions leads to twinning at the convex (tension) surface and ultimately to cleavage on the new basal planes of the twinned region; the fracture is then propagated jerkily across the section by the process of further (10 $\bar{1}2$) twinning at the base of the crack and basal cleavage through these twins, and the final cleavage surface has a striated, stepped appearance in units corresponding to the widths of the succes-

sive twin bands. Crystals subjected to pure bending without simultaneous compression deform and cleave in like manner.

All crystals having their basal (0001) planes nearly parallel to the wire axis could be made to kink. As the inclination of the basal plane to the wire axis increased, kinking became erratic, so the present work was done on crystals having the basal plane within 3° of the wire axis. The appearance of the kink bands in zinc, Fig 1, 2, and 5 are identical to the photographs of kinks in cadmium published by Orowan.

The kinks occur at several reasonably definite locations along the specimen lengths. For example, in one group of 14 specimens of widely differing lengths, the first kink to appear in 5 specimens occurred at the end of the unsupported length, that is, where the rod entered the hole in the compression plate; in 5 others the first kink formed $\frac{1}{3}$ of the way along the unsupported length, and the remaining 4 kinked at $\frac{1}{4}$ -length positions. Invariably the kinks that formed at the ends formed only in those specimens whose surfaces appeared to be completely free of pits, small laps, or other defects. Conversely, the $\frac{1}{3}$ and $\frac{1}{4}$ locations occurred in specimens containing such blemishes, and, with only few exceptions, the kinked regions were observed to terminate at such visible defects.

There was no correlation between specimen length and kink location. However, in the case of end-kinked specimens, there appeared to be a direct relation between the specimen length and the length of the kink that

FIG 3—A kinked crystal subsequently cleaved on the basal plane. 3X.

formed—the longer the specimen the longer the kink, as illustrated in Fig 2, and equal length specimens yielded equal length kinks. Furthermore, whenever a second kink formed in such specimens, the new kink was always shorter than the initial kink and always tilted the opposite way. An example is shown in Fig 1c.

The sudden buckling discussed by Orowan is characteristic only of kinking in a “soft” machine; in a “stiff” machine the kinks form gradually, with progressive reorientation of the crystal within the kink bands. For a typical example, a simple kink such as shown in Fig 1a was found to have the basal planes bent 12.5° at the kink notches when it was first unmistakably recognized, but continued compression in a “stiff” machine increased these angles gradually to 27.5° before the test was halted. Final bend angles as large as 88° have been measured.

REORIENTATION IN SIMPLE KINK BANDS

The reorientation caused by kinking is a rotation around an axis that lies parallel to the glide planes. This fact is demonstrated convincingly by cleaving a kinked crystal at liquid air temperature so that the bends and curvatures of the glide planes are revealed, as shown in Fig 3. During the initial stages of kinking the rotation axis is normal to the [2 $\bar{1}10$] slip direction that lies closest to the compression axis. In the late stages the rotation axes

FIG 4—Structure of typical simple kink.

Thin parallel lines indicate glide planes; broken lines, kink boundaries; dash-dotted lines, undistorted parallelogram.

deviate slightly from this crystallographic direction to become non-crystallographic and more nearly normal to the rod axis, though still remaining parallel to the glide planes. For the special case in which a $[2\bar{1}10]$ direction is parallel to the rod axis, the rotation axis does not shift from a position that is normal to both the rod axis and the slip direction.

It is simpler to consider the latter case and to represent the orientations present by a sketch in which the rotation axis is normal to the plane of the drawing. This is done in Fig 4 for a simple kink. It will be noted that on the cross-section of the specimen illustrated in this figure there are two symmetrical areas of oppositely bent glide planes, between which there is a parallelogram of unbent, but rotated, material. The parallelogram has diametrically opposite corners at the kink grooves *a* and *b*. At an earlier stage in the development of a simple kink such as this, the grooves are at the same places and the parallelogram is wider, with sides extending across from grooves *a* and *b* more nearly perpendicular to the wire axis, and with the orientation of material within the parallelogram more nearly like that of the original undeformed crystal. At a later stage in the compression of such a crystal the sides of the parallelogram may meet, leaving no unbent area. When this happens the loci of those parts of the crystal that have been rotated the greatest amount then lie along the line joining the grooves.

In the regions of a simple kink band neighboring the parallelogram of un-

distorted material, the bent glide planes approach the form of arcs of concentric cylinders, with their axes of curvature at the grooves on the surface, as indicated in Fig 4. However, where the arcs approach junction with the undeformed matrix, their radii of curvature decrease progressively, with the centers of curvature for these decreasing radii lying in the two symmetrical boundaries of the kink band. The bending of the glide planes may be considered a special case of the "bend-gliding" studied by the early investigators of crystal plasticity.

KINK BAND BOUNDARIES

The abrupt bends in the glide planes at the boundaries of a kink band, which are the loci of centers of the various radii of curvature mentioned above, mark out a pair of surfaces which are slightly but definitely curved and nearly normal to the axis of the wire at the convex side. The angle of abrupt bending at these boundaries is a maximum at the groove on the surface and decreases gradually across the specimen toward the convex side, corresponding to the changes in radii of curvature.

To study the structure of a kink at the very earliest stage of its formation, a wire was coated with diluted Canada Balsam cement and dried for several days at room temperature. The coated specimen was then compressed in small increments and examined microscopi-

FIG 5—Macrograph of ridges produced in late stage of kinking.

(The striations are due to the method of preparing the single crystals, but in this example correspond to the traces of the (0001) planes as well). 11 X.

cally after each increment until two small cracks were detected in the brittle cement coating. At this stage no macroscopic bend was measurable, but metallographic examination of the cross-section at the cracks revealed a single pair of boundaries, approximately normal to the specimen axis, where abrupt bending through a slight angle occurred. The boundaries extended entirely across the specimen with uniform (though slight) contrast, differing in this respect from the later stage of Fig 4, where contrast increases on approaching the grooves. The material between the boundaries appeared to be unbent, though slightly rotated.

The abrupt boundaries of a simple kink are fixed in the earliest detectible stages of deformation and do not wander through the specimen as deformation proceeds.

SECONDARY BOUNDARIES AND RIDGES

A number of complexities were noted. Additional faint boundaries of abrupt orientation changes were frequently detected. These boundaries occurred either as branches from the primary or other secondary boundaries, or as new and independent boundaries. Their low contrast indicated that their abrupt bend angles were small.

Ridges like those shown in Fig 5 and sketched in Fig 6 often develop in the later stages. Goniometric measure-

FIG 6—Structure of complex kink of Fig 5.

Numbers at the dots indicate the rotation of the glide planes from their original orientation (0°) parallel to the rod axis. Abrupt bending of the glide planes occurs across the boundaries shown as thin solid lines. Overlapping segments and varying orientations within a segment are seen.

ments such as those recorded in Fig 6 indicate that the ridges are at the boundaries of segments that are rotated in opposite direction, an amount that increases with the amount of deformation. In one example, the bend at a boundary reached 110° . The ridges form on the curved surfaces of prior simple kink bands only after several of these have formed elsewhere along the specimen, and when the local stress conditions must have been greatly altered. They form on the side of the specimen where the compressive strain is the greatest. Branched, intersecting, and overlapping ridges are not uncommon. The ridge and segment boundaries do not, in general, extend across the entire cross-section.

Deformation twinning does not appear to be involved in any manner in the sequence of events of kinking. While there were occasional twins pre-existing in some of the specimens, these did not appear either to initiate or to inhibit kinking. Orientation measurements in the segments at the ridges indicate that these are not twins; the directions of their boundaries are incompatible with twinning, as is also the fact that the ridge angle becomes gradually more acute with continued deformation.

Discussion of Results

The characteristics of kink bands in zinc (and we believe in cadmium also) allow them to be classified as a special form of deformation bands. Deformation bands are lamellar regions in crystals and polycrystalline grains within which there has been reorientation by rotation as a result of slip, the amount of rotation increasing gradually with increasing strain. There are abrupt changes in orientation at the boundaries of deformation bands, and fre-

quently there is also bending (bend-gliding) within the bands. While deformation bands have apparently not been reported previously in zinc, they are a common mechanism of deformation in many cubic metals,³ and no principle is known that would indicate that they should not occur in zinc, cadmium, or other hexagonal crystals provided the applied stress does not first cause twinning. Since compressive stress directed along the basal plane is required for kink bands, they can be expected only in those crystals that are not subject to twinning from this type of stressing, hence only in hexagonal metals or alloys having an axial ratio c/a greater than 1.732.

Actually, nearly analogous structures have been reported by R. F. Miller^{2,4} near the grips in zinc single crystals elongated in tension. Miller identified a "bend-plane"—the locus of abrupt bend angles in the basal plane—and showed that it was non-crystallographic and that its orientation was dependent upon the amount of deformation. However, he described the phenomenon as a new type of twinning, and failed to recognize the structures as deformation bands.

Orowan's suggestion¹ that a new mechanism of deformation is involved in the formation of kink bands seems unnecessary, at least in zinc, since the structure and formation of the bands can be accounted for by the accepted mechanisms of slip and bend-gliding that operate in forming deformation bands. Contrary to Orowan's conclusions regarding kinking in cadmium, the glide planes do not snap over suddenly to the kinked orientation, nor is there a " k plane"¹ extending from the grooves to the center of the wire over which there is a constant bend angle equal to the bend angle at the groove.

FIG 7—Formation of a kink by dislocations.

Each dislocation is marked by a T with the extra plane of atom indicated by the stem of the T . Successive stages are shown in drawings A, B and C.

However, we are in agreement with Orowan's suggestion that there are dislocations concentrated in the boundaries, and we develop in the following section a detailed qualitative theory of the bands based on the formation and movement of pairs of dislocations.

The fact that there is an axis of rotation lying in the glide plane of zinc and parallel to the boundaries of the band, suggests that rotation axes may be similarly oriented in deformation bands of other metals, but observations on this point seem to be lacking. The rotation axis should be crystallographic and lie in the glide plane normal to the glide direction when a single slip system operates, but could well have irrational indices if two glide systems are active. A single slip system appears to be active in zinc during the initial stage of kinking, because the rotation axis $[01\bar{1}0]$ is exactly that predicted for such behavior.

In a crystal oriented with the glide direction parallel to the axis of compression, the rotation is such as to keep the maximum resolved shear stress in the glide plane continually parallel to the glide direction. Wandering of the maximum resolved shear stress direction occurs, however, in less symmetrically oriented crystals and may ultimately induce glide in a second glide direction, with a corresponding change in the axis of bending of the glide planes. If two glide directions are at equal angles to the axis of compression initially, they would be expected to remain so throughout, and bending would then be around $[1\bar{2}10]$. Such behavior was confirmed experimentally in most specimens of this orientation; however, a few did exhibit less symmetrical rotation and had axes with irrational indices. In these exceptional cases the behavior was not consistent throughout the region of a single kink,

suggesting that defects are possible in a glide plane which do not affect all slip directions equally.

A DISLOCATION THEORY OF KINK BANDS

The development of a kink band can readily be described in terms of dislocations. Initial plastic flow in these specially oriented zinc crystals appears to be confined to the volume of the kink band and does not extend to the ends of the specimen. From this and considerations discussed below we conclude that flow begins by the generation, within the volume that is to become the band, of pairs of dislocations of opposite sign, the positive and negative dislocations collecting, respectively, in two parallel planes that are nearly perpendicular to the glide planes.

The generation of such pairs of dislocations may be expected from consideration of the elastic distortions produced in slender rods by compressive loading. According to the theory of elasticity,⁵ an isotropic slender rod with fixed ends buckles in the shape of one full period of a cosine function, the ends being tangent to the wave at successive crests. If the anisotropic zinc crystals of the present experiments are assumed to buckle elastically in similar cosine shape, then this distortion produces a shear stress along all the basal planes, the magnitude of which is a sine function of position along the rod length and is proportional to the amplitude of the cosine flexure. Shear stress maxima consequently occur at the points of inflection of the cosine flexure, the quarter-length locations. Further decrease of the distance between the compression plates increases the amplitude of the cosine flexure, and hence increases the shear stresses. At

FIG 9—Formation of a ridge by dislocations.

some critical shear stress a pair of dislocations of opposite signs might be generated, either as linear dislocations, or more probably as screw dislocations spreading out from some point, possibly at the surface, and becoming a pair of linear dislocations. Since the critical shear stress is attained on all planes simultaneously but is localized to a short length of area on each, its relief must entail the generation of pairs of dislocations on many separate planes approximately evenly spaced over the cross-section rather than the generation of an equal number of pairs on one, or only a few, planes. We conclude that the positive and negative dislocations must collect, respectively, into planar arrays because, if they did not, there would be additional local stresses set up around them that would increase the strain energy of the structure.

The result of such a pair of planar arrays of dislocations of opposite signs is a slight bend of the glide planes at one of the planes of dislocations and an equal reverse bend at the opposite plane of dislocations. This bend is illustrated in Fig 7a for the simplest case where a slip direction is initially parallel to the rod axis. Each plane of dislocations bisects the angle between the glide planes on the two sides of it because, if it did not, the interplanar spacings of the glide planes could not be equal on both sides of the bend angle, and hence the strain energy of the configuration would be increased. Because the symmetrically oriented planar array is a configuration of minimum strain energy for a given bend angle, individual dislocations that depart from it will be forced back into it. Strain energy considerations also

FIG 8—Tensile strain by the separation of like planar arrays of dislocations.

lead to the conclusion that dislocations are approximately evenly spaced over these planes, from one side of the wire across to the other side, because if this were not so some portions of the crystal would be bent more than others and an additional strain energy would be introduced. Local lattice imperfections and stress raisers might distort the regular array of dislocations on a local (atomic) scale, but on the average there should be a remarkably uniform distribution over the planes.

The planes of dislocations are forced apart by the applied stress and thereby shorten the distance between the compression plates. The possibility of deformation by the movement of such arrays of dislocations has previously been proposed by Bragg.⁶ For the case sketched in Fig 7a the shortening is given by the formula $s(1 - \cos \alpha)$ where s is the distance between the planes of dislocations, and α is the bend angle at each. This angle is proportional to the number of dislocations in the arrays.

The planes of dislocations move apart until they are stopped by some agency, discussed below, where they become the permanent boundaries of the kink band. Further compressive strain occurs not by increasing the spacing between the boundaries but by increasing the rotation, that is, by generating new pairs of dislocations. Since the glide planes within the band are now rotated to a position where they have a higher resolved shear stress than the glide planes in the matrix outside of the band, the new pairs will be generated within the band.

The new dislocations array themselves on a new pair of planes, the position of minimum energy for them. These planes begin to separate as the first pair did, and continue until they encounter the first set, as illustrated in Fig 7b. Since each of the second pair of planes bisects the glide planes on each side of it, and since the second pair is generated in glide planes that have already been reoriented by the first pair, it follows that the second pair will be tilted with respect to the first pair in the manner illustrated (in an exaggerated way) in the sketch, and the first contact of the second pair with the first pair will be at the grooves. As successive pairs are generated (Fig 7c), the bend angle at the groove will steadily increase. If each pair has about the same number of dislocations in it, the result of many successive pairs of planes will be a bending of the

glide planes into concentric cylinders with the axis of the cylinders centered at the grooves.

However, if the movement of all successive planes of dislocations were stopped by initial contact with the first planes as sketched in Fig 7b, there would be no visible grooves extending nearly half-way around the rod circumference such as is observed experimentally. Instead it appears that the movement of the second pair of dislocation planes is not stopped immediately by contact with the first pair at the groove locations, but is merged with the first set over part of its area, increasing the uniform bend angle over the coalesced area and producing bending elsewhere as sketched in Fig 7c. Then if succeeding pairs contact the boundary set along progressively decreasing areas following their encounters at the grooves, the final pattern of dislocations will yield the orientations sketched in Fig 4. The boundaries will be slightly curved, as indicated in Fig 4 and 7c, and the minimum strain energy argument would suggest that the boundaries be curved so as to bisect the abrupt bend angle of the glide planes at all points.

Reasoning from the minimum strain energy argument, we would expect complete merging of two arrays of dislocations that have contacted each other at a point, because near the contact region there would be local distortions on an atomic scale from the close approach of the arrays that would not be required for a coalesced array, so that progressive merger should ultimately produce the minimum strain energy configuration. Accordingly, the failure to merge completely indicates an opposing tendency in the convex regions of the kinks, the probable nature of which is indicated in the sketches of Fig 8. From these it is evident that if a volume of crystal containing two arrays of like sign is subjected to tensile stress, then minimum strain energy obtains when the arrays have moved as far apart as possible; hence we conclude that the convex regions are under slight tensile stress. High tensile stress should produce twinning, which was never observed.

The formation of kinks at the $L/4$ point of the rod length has already been shown to be a consequence of the points of inflection of the initial cosine flexure of the rods, for the case of rigidly fixed ends. The $L/3$ location can result from the slightly different case

where one end is rigidly fixed while the other end is merely constrained to axial alignment but remains free to rotate, since in this case the flexure shape⁵ has a point of inflexion at $L/3$. As the single crystal nature of our specimens precluded the possibility of forcing the specimen ends into the aligning holes so as to secure really rigid mounting, it is quite possible that the slight rotations needed to permit the second type of buckling occurred frequently. When both ends of the rod are free to rotate, the flexure shape corresponds to $1/2$ period of a sine function and has no points of inflexion; hence, kinking should not occur, as was confirmed experimentally.

The grip-end kink locations require a different explanation. We shall consider, for the moment, the initial stage of kink generation shown in Fig 7a when a single pair of planar arrays of dislocations of opposite signs have formed at either the $L/4$ or $L/3$ locations and have moved apart the distance s . This movement has displaced the axis in the matrix just above the upper array from the axis just below the lower array, and since the rod ends are still axially aligned, these matrix segments must be resisting bending moments tending to curve them in opposite directions. Minimum strain energy requires that the respective radii of curvature be equal. Let us now assume that the pair of arrays may move as a unit along the rod keeping their separation s unchanged, and inquire whether there exists any more favorable location of lower strain energy. It can be shown that the strain energy is a maximum for the paired array at $L/2$ and that the energy decreases continuously as the paired array moves toward $L = 0$ or 1 ; so that, if such migration be possible, the kinks would always be expected to have migrated to the grip-ends long before they attained even microscopically observable size or shape. We conclude, therefore, that the kinks observed at $L/4$ and $L/3$ positions have been prevented from migrating from their points of origin by the surface defects observed, almost without exception, at both kink boundaries in such specimens, while the end-locations occurred only in specimens so nearly perfect that migration of the arrays through the crystal lattice is unimpeded.

In the defect-containing specimens, the kink lengths are certainly determined when the migration of the first

pair of arrays is stopped at the nearest defects. In the other specimens where the movement of the planes of dislocations is apparently unhindered, the formula $s(1 - \cos \alpha)$ suggests that the first pair of planes should separate without limit, to the full length of the specimen. However, we have already seen that the separation of the first pair of arrays creates a bending moment in the rest of the wire, and examination shows that the curvatures in these elastically bent sections produce strain gradients across the glide planes of such nature that they must oppose the advance of the separating pair of arrays. For example, if the dislocations of the upper array in Fig 7a have their extra plane of atoms on the left side of the glide planes, then in the neighborhood of each dislocation the atoms at the left side of the glide plane are compressed because of the extra plane of atoms, and similarly the atoms at the right are under tensile strain. But the rod section ahead of the advancing array is elastically bent with radius of curvature to the left, so that the atoms to the left of the glide planes are already compressed with respect to those at the right, and hence would resist the introduction of dislocations of similar strain gradient. At sufficiently great curvatures the opposing force may reach such magnitude that it becomes easier to generate a new pair of arrays within the undistorted parallelogram than for the first pair of arrays to separate further. Then the first pair would stop separating and fix the ultimate kink length. Under such conditions the kink length would become a function of the specimen length, as our experiments have suggested, for presumably the critical buckling moment would correspond to a definite radius of curvature.

The above theory accounts for the observed locations of the kink bands and for their lengths. It accounts for the fact that in simple kink bands the arcs formed by the bent glide planes always occur in symmetrical pairs, with the arcs at the two convex sides of a band being equal in length; that the grooves always occur in symmetrical pairs with bend angles equal to each other; that the bend angles at the grooves depend upon the lengths of the arcs; that the glide planes at band boundaries may be bent through progressively greater angles the nearer they lie to the grooves. In simple kink bands in zinc these features are all observed.

The planes of dislocations of each successive pair are parallel. The material between them is rotated from its original orientation but remains unbent (or nearly so). On the longitudinal cross-section, with slight or intermediate amounts of compressive strain, there will be a parallelogram within which there is negligible bending. Two diagonally opposite corners of the parallelogram will be located at the grooves at the surface (Fig 4) and the upper and lower sides of the parallelogram will be parallel because there are equal numbers of positive and negative dislocations on the two sides; hence they will be at equal angles to the glide planes between them. With increasing strain, the parallelogram rotates and narrows, becoming finally a line connecting the two grooves, after which no unbent material remains. At all places where glide has occurred it is possible, of course, that faults in stacking of the glide planes are left.

When a single kink band forms, it creates a bending moment on the rest of the rod. There is a tendency for this bending moment to be relieved by the generation of one or more kinks of reversed tilt elsewhere in the wire. When pairs of reverse kinks form, the axes of bending of the glide planes are initially always the same crystallographic direction and are parallel in the two; this has been observed in a rod with as many as four pairs.

To account for secondary boundaries in kink bands, one assumes that successive planar arrays of dislocations may be forced to contact and coalesce over part of their areas at places other than the grooves. Secondary boundaries would be expected when stress conditions change suddenly during the straining of a specimen, for example, when a new kink band starts to form and introduces a bending moment not previously present. Some secondary boundaries may result, also, from planes of dislocations that are stopped at places other than the grooves. This, too, may be a result of local imperfection or changed stress conditions that give a plane of dislocations power to penetrate otherwise insurmountable barriers, or on the other hand, that stop its migration prematurely. Change in rotation axis due to the onset of duplex slip could also be a factor.

Ridges are understandable as the result of planes of like dislocations being forced together, as sketched in Fig 9. Suppose double pairs of dislocations are generated, approximately

simultaneously, with the positive dislocations collecting in planes that are closer to each other than the negative dislocations. As progressive straining forces the positive planes together they come to rest at a plane boundary that extends out to a ridge on the surface. The negative dislocations, meanwhile, form the opposite boundary of the segment. Thus, a ridge is located on the boundary between two crystal segments within which the lattice has rotated in opposite directions about an axis lying both in the plane of the boundary and in the glide plane. During the initial stages of ridge formation while only a single glide system operates, the rotation axis is crystallographically identical to that operating during simple kinking; therefore, the ridges are parallel to the kink grooves. When duplex slip conditions are attained, the rotation axis is altered and the ridge directions become irrational. There is no requirement here that ridges occur in pairs on opposite sides of a kink band, as grooves do, and this is in accord with observation. But there is the requirement that associated with a positive boundary at a ridge there be a negative boundary on each side of a rotated segment, as is, indeed, observed.

It is perhaps surprising that elasticity theory based on the assumption of isotropic medium should hold so well for the present anisotropic crystals. It appears that the chief effect of the anisotropy is to reduce the slenderness ratio at which buckling becomes the mode of failure, for kinking was found to occur even at a slenderness ratio of 1:1. This fact suggests that deformation bands in general may be the result of buckling, for a slenderness ratio of 1:1 would correspond to equiaxed grains.

Summary

1. The formation of kink bands during the compression of single crystal rods of zinc occurs by a progressive rotation of the lattice within the band as deformation proceeds, rather than by a twin-like abrupt shear to a final orientation. Rotations from a few degrees to over 80° have been measured.
2. The width of a simple kink band is fixed by the grooves that form initially on the surface; the bands do not grow wider with increasing deformation as deformation twins do in zinc.
3. These characteristics indicate that kink bands are properly considered as

deformation bands resulting from the ordinary crystal slip process, not as a new mechanism of deformation.

4. In a simple kink the angle of bend of the glide planes at a boundary changes gradually from a maximum at the concave side to a minimum on the convex side. Each boundary is initially a surface containing the direction in the glide plane that is normal to the active glide direction. After severe bending deviations can occur.

5. Complex behavior is often noted: (1) secondary boundaries may radiate out at various angles from points on the original boundaries, and (2) sharp ridges may form in areas subjected to compression. The ridges lie on the boundary between two segments that have rotated in different directions. These complexities are not incompatible with the proposal that kink

bands are special cases of deformation bands.

6. Kink band formation is accounted for by assuming that pairs of dislocations are generated between the boundaries by buckling flexures, the positive dislocations aligning themselves in a plane and the negatives in another plane (a configuration of minimum strain energy). These planes then move apart until stopped by defects or by opposing stresses in the adjoining segments of the rod. Successive planes of dislocations follow similar paths and build up continuously increasing angles of bend.

7. Ridges are accounted for by double pairs of dislocations, with positive dislocations coming together in a plane that extends out to the ridge on the surface, and the corresponding negative dislocations migrating to the

opposite boundaries of two oppositely rotated crystal segments.

Analysis of Interstitial Diffusion Using Activity Methods

A. G. GUY

Thermodynamic activity rather than chemical composition is basic to the analysis of diffusion. This is the essential conclusion reached by Darken¹⁻³ and by Birchenall and Mehl.⁴ If so, it is reasonable to expect that diffusion calculations should be carried out using activities. This paper will illustrate a method of employing activities in analyzing interstitial diffusion.

For interstitial diffusion (of carbon in iron and probably generally) the diffusion of the solvent atoms, volume changes, and other such complexities not explicitly provided for in the usual diffusion equations cause a negligible error of the order of 1 pct. Therefore it is relatively easy to test the validity of an analysis based on activities in the instance of interstitial diffusion. The mathematical treatment of the more complex substitutional diffusion could be simplified once the adequacy of the activity method had been established for substitutional diffusion. Thus the present work has the purpose not only of providing a superior analysis of interstitial diffusion but also of indicating a possible approach to the more important question of an adequate treatment of substitutional diffusion.

Development of the Diffusion Equation

Although activities are convenient quantities to determine experimentally, they are derived from the more fundamental fugacities.⁹ Possible confusion in using activities can be avoided by basing equations involving their use on the relationship,

$$dP = -D_f \frac{\partial f}{\partial x} dt \quad [1]$$

where, dP = the number of grams of

solute crossing one cm² in the time dt sec.

D_f = the diffusion constant for use with fugacities; it is assumed to be constant at a given temperature, and has units of secs.

f = the fugacity of the solute in the solid solution; the units are those of pressure, dynes per cm².

\bar{x} = the distance in cm.

Eq 1 can be considered to be the basic form of the first Fick Law for one-dimensional diffusion.

In order to convert Eq 1 into an equation involving activities, a choice of a standard or reference fugacity, f° , must be made; then,

$$a = \frac{f}{f^\circ} \quad [2]$$

where a is the activity corresponding to the fugacity f . However, the value of a is also determined by the relation,

$$\alpha = \frac{a}{c} \quad [3]$$

where α is the activity coefficient and c is the concentration. For a given value of α (such as $\alpha = 1$) it is evident that the units used for expressing concentration will affect the numerical value of a corresponding to a given amount of carbon dissolved in γ -iron. Since weight per cent concentration is so widely used, this unit will be adopted as the standard in this paper.

When the value of f given by Eq 2 is substituted in Eq 1, the first Fick Law becomes,

$$dP = -D_f f^\circ \frac{\partial a}{\partial x} dt \quad [4]$$

Since $D_f f^\circ$ is constant (at a given temperature), the second form of Fick's Law can be obtained in the usual manner,

$$\frac{\partial c'}{\partial t} = D_f f^\circ \frac{\partial^2 a}{\partial x^2} \quad [5]$$

where c' is the concentration in g per cm³. In terms of weight per cent concentration, c , Eq 5 becomes,

$$\frac{\partial c}{\partial t} = \frac{100}{\rho} D_f f^\circ \frac{\partial^2 a}{\partial x^2} \quad [6]$$

where ρ is the density of the solid solution and will be assumed to be constant. In order to simplify Eq 6, it is necessary to consider the standard state, f° .

Standard states are chosen for convenience. There appears to be one especially convenient choice for the analysis of interstitial diffusion. If the activity coefficient, α , is set equal to unity at infinite dilution of the solute,

then $\frac{100}{\rho} D_f f_1^\circ$ is approximately equal to the usual diffusion constant in dilute solutions. This is true since the activity, a , in Eq 6 can be replaced by the concentration, c , with little error in an infinitely dilute solution.*

Here f_1° is the standard fugacity necessary to achieve this standard state. It is proposed that a diffusion constant D_A^1 be defined,

$$D_A^1 = \frac{100}{\rho} D_f f_1^\circ \quad [7]$$

where A is the metal whose diffusion is

* The second derivative of a is equal to the second derivative of c in dilute solution only if $\frac{da}{dc}$ is zero. Although theory does not require this condition, in the systems C in Fe, and Zn in Cu, $\frac{da}{dc}$ is in fact found to be essentially zero.

FIG 1—Concentration-penetration curves plotted from the data of Wells and Mehl for the diffusion of carbon in iron at about 1000°C.

being considered. For carbon diffusing in iron this diffusion constant is D_c^1 .

Using the definition of α given above, Eq 6 can be written,

$$\frac{\partial c}{\partial t} = D_A^1 \frac{\partial^2 a}{\partial x^2} \quad [8]$$

This equation would be in a more convenient form for calculation if it were written in terms of a alone, rather than in terms of a and c . From Eq 3,

$$\frac{\partial c}{\partial t} = \frac{\left(1 - \frac{a}{\alpha} \frac{da}{da}\right)}{\alpha} \frac{\partial a}{\partial t} \quad [9]$$

Therefore, Eq 8 becomes,

$$\frac{\partial a}{\partial t} = Z D_A^1 \frac{\partial^2 a}{\partial x^2} = D \frac{\partial^2 a}{\partial x^2} \quad [10]$$

where Z represents the quantity

$$Z = \frac{\alpha}{1 - \frac{a}{\alpha} \frac{da}{da}} \quad [11]$$

Since Z is a function of a (and therefore of concentration), D in Eq 10 is not a constant, and the exact solution of this equation involves the use of step-by-step methods.

The Error-function Solution

Fortunately there is an approximate method of applying Eq 10 to determine the value of D_c^1 corresponding to an experimental diffusion curve. The result is found to agree closely with that given by the exact solution—well within experimental error. If the variation of Z is neglected, and Z' is taken as the value corresponding to the median of the range of activities in question, then Eq 10 can be solved in a convenient manner using the error-function solution. When the boundary

conditions are those corresponding to a semi-infinite solid, Eq 10 can be shown to have the solution,⁵

$$a - a_0 = \frac{(a_1 - a_0)}{2} \left[1 \pm \operatorname{erf} \left(\frac{x}{2\sqrt{D't}} \right) \right] \quad [12]$$

where a = the activity corresponding to the carbon content at a distance x from the interface.

a_0 = the activity corresponding to the initial carbon content on one side of the interface.

a_1 = the activity corresponding to the initial carbon content on the other side of the interface.

erf = the Gauss error-function, values of which are given in numerous tables.⁶

$$D' = Z' D_c^1$$

Eq 12 can be used to analyze experimental diffusion data such as those obtained by Wells and Mehl⁷ to determine the value of D' . Since Z' is known, a value for D_c^1 can be obtained using the relation,

$$D_c^1 = \frac{D'}{Z'} \quad [13]$$

The data obtained by Wells and Mehl⁷ for the diffusion of carbon in iron were analyzed using Eq 12 to determine D' and D_c^1 at a number of temperatures. The activities of carbon in austenite (defined by Eq 3 and the choice of standard state) needed for this analysis were calculated from the activity data of R. P. Smith.⁸ Suitable interpolation and extrapolation from his data at 800° and 1000°C were required to cover the temperature range 800°–1100°C in the manner shown in Table 1.

Fig 1 is a conventional plot in terms of weight per cent carbon and distance from the Grube interface* of tests Nos. 9 and 10 of Wells and Mehl. These data can also be plotted in an analogous fashion in terms of activities. Using Eq 12, a value of D' can be calculated for each experimental point of such an activity-penetration plot. Results obtained for points near the ends of the plot are unreliable because of the effect of a small error in activity in greatly altering D' . The values of D' obtained from the five central points of the 42.66 hr data are listed in Table 2 together with the average.

To convert this average value of D' (which is that corresponding to the median activity, 0.642) to the activity diffusion constant D_c^1 , Eq 13 was used. In this instance Z' has the value,

$$Z' = \frac{\alpha}{1 - \frac{a}{\alpha} \frac{da}{da}} = \frac{1.037}{1 - (0.62)(0.262)} = 1.24 \quad [14]$$

and D_c^1 was determined to be,

* The Grube interface is defined as the plane in the specimen at which the carbon concentration is $\frac{1}{2}(c_1 + c_0)$; that is, where the carbon concentration has its median value. The activity interface is defined in terms of $\frac{1}{2}(a_1 + a_0)$.

$$D_c^1 = \frac{3.31 \times 10^{-7}}{1.24} = 2.67 \times 10^{-7} \text{ cm}^2 \text{ per sec [15]}$$

at 1001°C.

Values of D' can be used to calculate approximate penetration curves by means of Eq 12. Fig 2 shows the agreement between the data of Wells and Mehl's test No. 9 (25.25 hr at 997°C) and the penetration curve calculated using the D'^* of Table 2. Somewhat poorer agreement was found in using an analogous approximate method to calculate a carburizing curve in which the concentration range exceeded 1.3 pct C.¹⁰ Exact calculations could be made using the determined value of D_c^1 and Eq 10. However, a step-by-step method of solution would then be employed.

Calculations of D_c^1 at a number of temperatures were made using suitable sets of data obtained by Wells and Mehl. The results are summarized in Table 3. Since it is to be expected that the D_c^1 values will be approximately equal to the usual diffusion constant determined at low carbon contents, the latter values reported by Wells and Mehl for 0.1 pct C are included in the table.

A plot of D_c^1 vs. $\frac{1}{T}$ is shown in Fig 3. The 1102°C point does not fall on the straight line connecting the above three points, possibly because of error in extrapolating the activity data. Assuming that the variation of the diffusion constant with temperature can be written,⁵

$$D_c^1 = A e^{-\frac{Q}{RT}} \quad [16]$$

the straight line of Fig 3 can be analyzed to give the results,

$$A = 0.17 \text{ cm}^2 \text{ per sec} \quad [17]$$

$$Q = 33,800 \text{ cal per mol} \quad [18]$$

This Q value is practically the same as that found by Wells and Mehl for 0 pct C, 33,300.

Discussion of Results

The advantage of the use of activities in diffusion analysis is that a diffusion constant independent of the concentration of the diffusing element is obtained. Not only is this fact useful mathematically, but it is also of great potential value in the fundamental understanding of metal behavior involving diffusion. However, it is neces-

sary to examine more closely the significance of the multiplicity of permissible activity diffusion constants.

At a given temperature, T , where D_f is constant, Eq 7 shows that the ratio of the activity diffusion constants referred to the two different standard fugacities f_1° and f_2° is,

$$\frac{D_{ff_1^\circ}}{D_{ff_2^\circ}} = \frac{f_1^\circ}{f_2^\circ} \quad [19]$$

But since for a given fugacity,

$$f = a_1 f_1^\circ = a_2 f_2^\circ \quad [20]$$

the ratio is also equal to a_2/a_1 . Similarly, at a different temperature, T' ,

$$\frac{D'_{ff_1^\circ}}{D'_{ff_2^\circ}} = \frac{f_1^{\circ'}}{f_2^{\circ'}} = \frac{a_2'}{a_1'} \quad [21]$$

However, since the ratio a_2/a_1 , will not in general be equal to a_2'/a_1' , it follows that the various activity diffusion constants will not vary in the same ratio with temperature; that is, the activation energies for the various activity diffusion constants will be different.

At first thought this circumstance appears to destroy the usefulness of activity diffusion constants, since the activation energy is a quantity of considerable fundamental significance. Further consideration shows the situation to be quite otherwise. Certainly the activation energy of metal A diffusing in a solid solution would be expected to depend on the concentration of A atoms in the solid solution. Specifically, different values would be expected in a dilute solution (almost pure metal B) than in a concentrated solution (almost pure metal A). It appears reasonable that the Q value determined in a

given instance is that characteristic of the standard state being used. For example, the Q obtained by plotting D_c^1 data applies to the diffusion of carbon in infinitely dilute solution in γ -iron.

Since diffusion constant values applicable for different standard states are in inverse ratio to the corresponding activities, Eq 19 and 20, it is an easy matter to determine the diffusion constant, D^i , characteristic of the standard state in which $a_i = 1$ when the concentration is c_i . Considering diffusion in a solution of concentration c_i ,

$$\frac{D^1}{D^i} = \frac{a_i c_i}{\alpha[c_i]c_i} = \frac{1}{\alpha[c_i]} \quad [22]$$

* The D' value was corrected for the 4°C difference in temperature of the two tests.

FIG 3—The variation of D_{C^1} with temperature.

where $\alpha[c_i]$ represents the value of the activity coefficient for use with dilute solutions evaluated at c_i . Using Eq 22, activation energies of 33,700 and 33,300 were calculated for 0.4 and 0.8 pct C standard states by means of the D_{C^1} values at 800° and 1001°C of Table 3 and the activity data of Table 1. These are in qualitative agreement with the results obtained by Wells and Mehl. The Q value of 42,000 given by Birchenall and Mehl⁴ is of questionable theoretical significance since it was obtained using a different standard fugacity for each temperature.

A matter that has caused some concern in previous attempts to analyze the diffusion of carbon in iron has been the "interface anomaly." This term describes the fact that the respective interfaces on which the Grube and Matano solutions are based fail generally to coincide. The question then arises as to which of these is the significant interface.

There seems little doubt that the initial interface (in the Kirkendall sense) is the significant one. The correspondence of other interfaces with this one can be summarized as follows, assuming negligible density change:

1. The Grube interface should coincide with the initial interface in perfect interstitial solid solutions. The solution of carbon in iron is not perfect, and an appreciable difference between the two interfaces is found.

2. As a consequence of its definition, the Matano interface* must coincide with the initial interface during the

* For interstitial diffusion the Matano interface definition is such that the carbon atoms gained by one side equal those lost by the other.

course of diffusion in interstitial solid solutions.

3. The interface defined by the median activity (the Grube interface marks the median concentration) will coincide with the original interface when Z (Eq 10) is constant. In the Fe-C system the variation of Z is sufficient to cause absence of perfect coincidence.

The relation between the usual diffusion constant, D^* , and the activity diffusion constant, D_{A^1} , is easily derived by equating Eq 8 and the usual form of the second Fick Law;

$$\frac{\partial c}{\partial t} = D_{A^1} \frac{\partial^2 a}{\partial x^2} = \frac{\partial}{\partial x} \left(D^* \frac{\partial c}{\partial x} \right) \quad [24]$$

Integrating the second two terms gives,

$$D_{A^1} \frac{\partial a}{\partial x} = D^* \frac{\partial c}{\partial x} \quad [25]$$

since the constant of integration must be zero. By analogy with Eq 9, Eq 25 can be written,

$$D_{A^1} Z \frac{\partial c}{\partial x} = D^* \frac{\partial c}{\partial x} \quad [26]$$

or

$$D^* = Z D_{A^1} \quad [27]$$

This equation is merely another form of the relation given by Birchenall and Mehl.⁴

Summary

1. The use of the fugacity concept has permitted a more satisfactory treatment of interstitial diffusion by activity methods.

2. Of the multiplicity of possible ac-

tivity diffusion constants, it has been proposed that D_{A^1} , corresponding approximately to the usual diffusion constant in dilute solution, be adopted as standard for analysis of interstitial diffusion.

3. An equation that permits the direct treatment of activities has been developed. A convenient approximate solution of this equation was used to analyze the data of Wells and Mehl to determine diffusion constant values. The results agreed well with those obtained by Wells and Mehl.

4. It was suggested that there is an activation energy associated with each choice of standard fugacity. That found for D_{C^1} (standard fugacity being that of an infinitely dilute solution) was 33,800, in good agreement with Wells and Mehl's extrapolated value for 0 pct C.

5. Further support for the view that the activity rather than the concentration is the basic factor in diffusion has been provided. Specifically, activity diffusion constants independent of concentration have been developed for possible application to the analysis of the more complex substitutional diffusion.

Acknowledgments

The author thanks Dr. R. F. Mehl for suggesting the problem that eventually led to this study of activity methods; Dr. K. O. Beatty, Jr., for indispensable aid with the fugacity concept; Mr. J. L. Sox for carrying out many of the calculations; and Dr. W. G. Van Note, Director of the Engineering Research Department, North Carolina State College, for his counsel and aid.

The Transformations in β -CuAl Alloys*

E. P. KLIER,[†] Junior Member AIME, and S. M. GRYMKO[‡]

The transformations in eutectoidal systems have been extensively studied as they occur in steels.¹ As a consequence of these studies the martensite, bainite and pearlite reactions found for most steels are widely recognized. Further, because of the work of Smith and Lindlie² and of Greninger and Troiano³ these reactions, except for the bainite reaction, are considered as typical for all eutectoidal systems.

The primary alloy studied by Smith and Lindlie² was a CuAl alloy of near eutectoid composition as was the alloy more recently studied by Mack.⁴ The transformations in these alloys were, for the most part, studied metallographically, while an X ray analysis of structures was essentially wanting. It has appeared desirable, therefore, to investigate selected CuAl alloys at and slightly away from eutectoid composition. For this purpose three alloys were prepared containing 10.5, 11.9 and 13.5 pct Al respectively. The results of a metallographic and X ray analysis of structures obtained for isothermal transformation of the β -phase are reported here for the 11.9 and 13.5 pct Al alloys.

Introduction

The phase equilibria in the CuAl alloys of immediate concern are indicated in the equilibrium diagram section presented in Fig 1. § The equilibrium and transition structures which have been reported in this system are as follows:

- α = copper rich terminal phase (f.c.c.)
- β = high temperature eutectoidal phase (b.c.c.)
- γ_2 = aluminum-rich intermediate phase (γ -brass structure)
- α' = modified α -phase postulated by Bollenrath and Bungardt.²⁶

* Taken from Metals Handbook (1948).

FIG 1—Phase diagram for eutectoidal Cu-Al alloys. *Metals Handbook—1948.*

- β_1 = ordered β (b.c.c.)
- β' = martensite structure: Al < 13 pct (near h.c.p.)
- β'' = β' of Smith and Lindlie²
- γ' = martensite structure: Al > 13.5 pct (h.c.p.); β_2 of Bollenrath and Bungardt.²⁶

¹ References are at the end of the paper.

The eutectoid transformation can be suppressed at sufficiently high cooling velocities. The β -phase is then retained to about 500°C where ordering sets in. The ordering interval is not satisfactorily known but indirectly appears to be non-suppressible. Subsequent to the ordering reaction and consequently at lower temperatures, the ordered β_1 decomposes to a martensitic structure. The kinetics of these reactions and in particular those of the martensite reaction have an important bearing on the results obtained in this investigation. Since some confusion exists concerning certain reported aspects of these reactions, they will be considered in some detail.

THE MARTENSITE REACTION

The martensitic structure is formed on cooling through a critical range⁶

FIG 2—The effect of composition on the sub-critical transformations in eutectoidal Cu-Al alloys.

much as is martensite in steels.^{12,3} The Ar'' temperature for the CuAl alloys depends on the composition and decreases with increasing aluminum content.⁹ In certain composition ranges Ar'' is cooling velocity dependent⁸ although it is pointed out that this dependence on cooling velocity may be indirect. Thus the indicated variation in Ar'' may result from a modification of the ordering reaction with cooling velocity. At a composition of 14.5 pct Al the martensite range is entirely below room temperature but lies above -190°C .¹⁰ However, due to the reversibility of this reaction ($\beta_1 \rightleftharpoons \gamma'$) the martensitic structure is not retained at room temperature.

The inverse martensite reaction, that is, the formation of β_1 from the martensitic structure takes place on suitable heating of the martensitic structure. This reaction has been established by metallographic¹⁴ dilatometric^{7,15} and X ray^{5,6} analyses of the structures at temperature and lies above the martensite range on cooling. These data are summarized in Fig 2. The inverse martensite reaction is probably sensitive to heating velocity, but few data are available for consideration on this point.

THE STRUCTURE OF THE CuAl MARTENSITES

The microstructures of the CuAl martensites have been adequately described by Greninger.¹¹ It is sufficient to point out that two structures β' and γ' are separable on the basis of

metallographic differences. The striations in γ' arise from twin formation while those in β' seemingly do not.

The crystal structures of the martensites are close to hexagonal close packed. The departures from the close packed lattice, observed for the β' structure, are notable at low aluminum contents. Thus while the lattice for γ' containing 13.5 pct Al is described as a hexagonal close packed structure, the lattice for β' is described as differing from γ' in that the $[00.1]$ direction is at an angle of 2° to the (00.1) plane normal, and the angle between the planes (10.0) and (01.0) differs about 1° from 120° .¹³ Because of this departure from the hexagonal close packed structure the X ray pattern for the β' structure is markedly different from that for the γ' structure. This is very important as it affords an unambiguous means of determining qualitatively the compositions of the martensitic structures in partially transformed alloys without requiring the precision measurement of lattice constants.

THE REACTION $\beta \rightarrow \beta''$

The structure β'' as noted before was discovered by Smith and Lindlie² on the isothermal transformation of β for an eutectoidal alloy. Smith and Lindlie on the basis of limited X ray evidence have considered this structure as being aluminum dilute apparently tending towards the composition of the α -phase.

More recently Mack⁴ has considered this structure as being β_1 or the

ordered β structure and has defined its range of occurrence in an 11.9 pct Al alloy from about 525 to 93°C . On the basis of the discussion of the kinetics of martensite formation it is evident that the reasoning which led Mack to place the lower limit of the martensite range at 93°C is faulty.

It is emphasized that β'' is not β_1 . A specimen of 11.9 pct Al alloy quenched from 950°C is an ordered structure but does not reveal the metallographic structure β'' .

THE ISOTHERMAL TRANSFORMATION DIAGRAM FOR EUTECTOIDAL CuAl ALLOYS

Isothermal transformation diagrams in comparable eutectoidal alloys have been presented by Smith and Lindlie² and by Mack.⁴ These diagrams are in good agreement except for the martensite range which has been modified by Mack to conform with more recent knowledge about this reaction. Beyond this discrepancy both diagrams describe a pearlite range and a β'' range which stand in good agreement where comparable.

From the discussion of the inverse martensite reaction it appears that certain of Mack's tempering data may require re-evaluation.

The works of Smith and Lindlie and of Mack are the only ones in which the isothermal transformations in eutectoidal CuAl alloys have been reported in detail.

Experimental Procedure

MATERIALS

The alloys for this investigation were prepared from high purity aluminum and OFHC copper. Melting was carried out in a graphite crucible under graphite. The molten alloys were stirred several times and were then chill cast. The ingots were about $\frac{1}{4} \times 2 \times 3$ to 5 in. and were very coarse grained. These ingots were hot-rolled in part to $\frac{1}{8}$ and $\frac{1}{32}$ in. thicknesses.

The ingots were analyzed for copper by both chemical and electrolytic methods. The aluminum content was determined by difference. The results are presented in Table 1.

ISOTHERMAL STUDIES

Sliver specimens ($\frac{1}{2} \times \frac{1}{32} \times 1$ in.; $\frac{1}{8} \times \frac{1}{32} \times 1$ in.) were heated at 950°C for 10 min. in a vertical tube

furnace in an atmosphere of purified nitrogen. The specimens were quenched into a small lead furnace at the desired temperature and after holding were quenched in a 10 pct aqueous solution of sodium hydroxide. The temperature of the quenching bath was controlled to $\pm 1\frac{1}{2}^{\circ}\text{C}$. A lead-tin bath was used for the lowest transformation temperatures.

METALLOGRAPHIC EXAMINATION

The sliver specimens were polished in clamps with the final surface being obtained with magnesium oxide (Shamva) on a selvyt cloth. The specimen was etched in a fresh 1:1 solution of NH_4OH and 3 pct H_2O_2 .

X RAY EXAMINATION

The metallographic specimens were polished and etched down to slivers about $\frac{1}{64}$ in. diam. Debye-Scherrer diagrams using $\text{Cu-K}\alpha$ radiation (Ni filter) were obtained. Standard β' and γ' patterns were obtained on the 10.5, 11.9, and 13.5 pct Al alloys as quenched from 950°C into the aqueous NaOH solution. Suitable α and γ_2 reference patterns were obtained on the isothermally transformed alloys.

REPRESENTATION OF TEST RESULTS

The data have been presented in the form of isothermal transformation diagrams. Suitable micrographs and X ray diffraction patterns have been presented.

Experimental Results

Because of the emphasis with which the alloy of eutectoid composition has been studied, it appeared desirable to devote the major effort in this investigation to a study of the 13.5 pct Al alloy. The transformations in this alloy, therefore, will be considered first.

THE 13.5 PCT AL ALLOY

Metallographic Results

The isothermal transformation diagram for this alloy is presented in Fig 3. There are certain striking features to this diagram. Firstly, the temperature of maximum transformation rate for practical purposes coincides with the eutectoid temperature. Secondly, it has appeared necessary to make use of four transformation

FIG 3—The isothermal transformation diagram for a 13.5 pct Al-Cu alloy.

Table 1 . . . Analyses of the Alloys

| Alloy | Pct Al by Electrodeposition | Pct Al by Chem. Analysis |
|-------|-----------------------------|--------------------------|

| | | 13.58 |

lines to describe adequately the course of isothermal transformation, and thirdly, no pearlite reaction is indicated. These facts may best be appreciated from a consideration of the microstructures.

In Fig 4 and 5 are presented the structures corresponding to beginning and end of the first reaction at 550°C as indicated by lines 1 and 2 on the isothermal transformation diagram. The precipitate structure is truly acicular and seemingly forms on the $\langle 100 \rangle_{\beta}$ directions. The structures formed by this reaction are not stable structures and rapidly undergo alteration at this temperature. The alteration seemingly is a species of agglomeration and growth, which, as will be pointed out, is not a simple process. The third line on the diagram indicates the start of agglomeration while the fourth line indicates the time for completion of the precipitation-growth process. Further holding causes no apparent change in this final structure except for a marked coarsening. These final alterations are indicated in Fig 6 to 8. There has been no pearlite structure formed during the course of transformation. This is emphasized by a

consideration of Fig 9 which reveals the nearest approach to a pearlitic structure which has been observed in this alloy on isothermal transformation.

The transformation sequence revealed in the above micrographs is typical except for minor variations for all structures formed below the eutectoid temperature. As is implied by the fourth line on the transformation diagram, transformation above the eutectoid temperature differs in certain important respects.

The structure existing at the end of the first reaction at 650°C is presented in Fig 10. The structure existing at the end of the second reaction is presented in Fig 11. The final structure under polarized light is seen to have a matrix of an acicular nature, Fig 12. This sequence of structures emphasizes the role of the first reaction in leading to transitional structures which in turn lead to the formation of the final equilibrium structures.

The initial and final structures are modified as a function of the transformation temperature but at all temperatures the structures arising from the first reaction are closely related microstructurally.

At the highest temperatures studied the initial reaction did not lead to complete decomposition of the matrix, Fig 13. This is to be expected since presumably above the eutectoid temperature only a proeutectoid constituent should precipitate. The character of the first reaction cannot be

FIG 4—13.5 pct Al-Cu specimen transformed at 550°C for 1 sec. $\times 250$
 FIG 5—13.5 pct Al-Cu specimen transformed at 550°C for 3 sec. $\times 250$

 FIG 9—13.5 pct Al-Cu specimen transformed at 425°C for 24 hr. $\times 250$

elucidated on the basis of metallographic evidence, however.

As the transformation temperature is decreased the microstructures become finer, Fig 14 to 21. At temperatures increasingly lower than the eutectoid temperature the first reaction becomes increasingly sluggish. The times for the completion of the precipitation-growth reaction below the eutectoid temperature develop a C-shaped curve which is comparable to that developed for the pearlite reaction in steels.¹⁶ The temperature for minimum reaction time

does not coincide with the analogous temperature for the first reaction but lies below the eutectoid temperature. From this it may be concluded that stable end structures arise as a consequence of the second reaction.

These data may be summarized briefly before the X ray data are considered. The metallographic data indicate that two reactions are encountered on isothermal transformation in this alloy, one of which leads to metastable structures as indicated by its occurrence through the eutectoid tem-

perature range. After completion of this reaction a second reaction sets in and leads to the complete modification of the microstructures with the ultimate formation of stable end products. Both reactions are represented by a combination of C-shaped curves and differ in that the eutectoid temperature affects the location of the stable structures completion curve.

X Ray Results

Four different crystal structures, indicated by X ray analysis may be obtained together in the transformed specimens, namely those of α , γ_2 , β' , and γ' . Positive evidence of β_1 was not obtained for the 13.5 pct Al alloy. The diffraction patterns characteristic of these four crystal structures are presented in Fig 22 to 25. The spotted lines in the pattern in Fig 23 arise from the γ_2 lattice while the continuous lines arise from α . Many of the lines in the β' and γ' patterns correspond closely to lines in the α and γ_2 patterns. Strong lines which are characteristic for the respective structures are indicated on the patterns. All diffraction patterns were checked for these strong lines. The presence or absence of the respective lines was taken as indicating the presence or absence of the respective structures.

The pattern for the β' structure was obtained from an 11.9 pct Al specimen quenched from 950°C into water + 10 pct NaOH. From the presence of the weak lines at low θ values it is evident that this structure is ordered. The γ' structure likewise is ordered.

The results of the X ray analysis are summarized in Table 2. Important diffraction patterns of the structures reported in Table 2 are presented in Fig 26 and 27. These data indicate the following sequence of composition adjustment in the transforming specimens. Prior to the start of the first reaction, the structure as quenched is γ' with possible traces of β' , Fig 25. Through the course of the first reaction the structure in the quenched specimens becomes a mixture of γ' and β' , Fig 26. This structure exists at the times corresponding to completion of the first reaction which means that the γ' revealed is not matrix γ' , or γ' which has been unaltered in composition. Rather because of the formation of large amounts of β' it is necessary that the γ' formed be very rich in aluminum. The γ' structure is next replaced by γ_2 and the structure is γ_2 and β' , Fig 27. For the fully transformed alloy the

structure is α and γ_2 , Fig 23.

The first reaction leads to the formation of structures in the as quenched specimens, which, it is known, cannot be formed at the temperature of isothermal holding. Since β' and γ' form from β_1 (or β) of characteristic composition it is concluded that the structures resulting from the first reaction prior to the quenching process consist of β_1 of two compositions, namely, β_1^+ which is aluminum rich and β_1^- which is aluminum depleted. There are thus two β_1 structures, one tending toward the composition of α , the other toward the composition of γ_2 . It is emphasized that these structures have not precipitated at temperature, rather the process throughout is a diffusion process alone. The β_1^+ becomes enriched in aluminum to the point where it can precipitate as γ_2 . The precipitation of γ_2 at the expense of the aluminum content of the β_1^- continues to the point where α can precipitate. The final structure then being α and γ_2 . This sequence of events is indicated as follows:

The reactions on isothermal holding seemingly are not interdependent. It is assumed that the same is true for the reactions on cooling.

The transformation sequence described here is in complete harmony with that for the transformation of austenite to bainite in steels.¹⁶⁻¹⁸ The composition of the structures and the manner in which the necessary composition adjustments are achieved in this CuAl alloy, however, are much more easily determined than is true for the steels.

THE 11.9 PCT Al ALLOY

Metallographic Results

The transformation data for this alloy for stock thicknesses of $\frac{1}{8}$ and $\frac{1}{32}$ in. are presented in the isothermal transformation diagram in Fig 29.

This isothermal transformation diagram, above the martensite range, is in good agreement with those diagrams presented by Smith and Lindlie² and

Mack.⁴ The γ_2 precipitate observed by Mack in the high temperature range of transformation is not observed for this alloy. The martensite range is presented after the data of Gawranek et al.⁹

In the intermediate range in which β'' and α are formed it is interesting to note that some disagreement in the times for the β'' and α reactions exists for the two materials. The increased working or possibly the reduced grain size of the $\frac{1}{32}$ in. thick alloy promotes

more rapid transformation in the intermediate range. The results for the $\frac{1}{32}$ in. thick stock are in satisfactory agreement with the results of Smith and Lindlie, and with those of Mack where comparable.

The metallographic data for the pearlite structures are interesting with respect to the pearlite spacing. It is generally accepted on the basis of pearlite spacings measurements on steels¹⁹⁻²³ that the pearlite structures become finer with decreasing tempera-

 FIG 21—13.5 pct Al-Cu specimen transformed at 225°C for 1 week. $\times 1000$

ture of formation. This is evidently not the case for the pearlite spacing in the CuAl alloy under investigation. For this alloy the pearlite spacing first decreases with decreasing temperature of formation. After passing through a minimum value it next increases. Thus the functional relationship between pearlite spacing and temperature cannot have the same form for this alloy as it apparently has for steels.^{20,23}

In a consideration of the relationship between pearlite spacing and temperature it is pointed out that for steels the

pearlite structures are divided into the coarse lamellar types and into the rosette (lamellar) or troostitic types. The first named occur well above the nose of the "S" curve while the second occur at about the nose of the "S" curve. (It has been pointed out that pearlitic structures as yet inadequately defined occur below the nose of the "S" curve.^{16,18}) As the temperature for pearlite formation decreases the interlamellar spacing decreases. This change in dimensions of the pearlite has been advanced as indicating a limiting car-

bide nucleus size,^{20,23} and this carbide nucleation has been used to account for the pearlite reaction. By an extension of this argument to conform to the requirements of the CuAl alloy investigated here, it would be expected that microstructural variations in the pearlitic structures would be analogous to those observed in steels. Such is not the case, however. Thus the coarse pearlites are replaced at lower temperatures by nodular pearlites—at about the "nose" of the C-curve—but these in turn give way at still lower temperatures to coarse lamellar pearlites, Fig 30 to 32. Thus the kinetics of pearlite formation in this alloy cannot be accounted for by simple comparison with the analogous reaction in steels.

X Ray Results

X ray data taken on specimens of the 11.9 pct Al alloy transformed at several temperatures are presented in Table 3. The patterns taken for transformation in the intermediate range, that is, the range in which β'' and α are formed indicate that the reaction in this range is essentially the same as that encountered in the 13.5 pct Al alloy for the first reaction. The major difference appears to be the change in the sequence in which the precipitate structures appear on isothermal transformation. Thus the structure existing in specimens quenched before α precipitates is β' . The structure after longer holding is $\alpha + \beta'$ which, on further holding, is replaced by a mixed structure of α , β' , and γ' . The amount of γ' formed is relatively small as is indicated in Fig 28. The final structure is $\alpha + \gamma_2$. The γ_2 lines are very weak.

Discussion of Experimental Results

The pearlite reaction has been considered as a reaction to be expected in general in the course of the subcritical decomposition of a high temperature eutectoidal phase. That this reaction is not generally obtained is indicated by the results presented here in the study of the 13.5 pct Al alloy. Results of a similar character have recently been reported by Hibbard et al²⁴ and by Sheehan et al.²⁵

In the CuAl alloys it appears that the pearlite reaction cannot be obtained at aluminum contents of 10.5 pct* and less or at 13.5 pct and greater. This is

*Further work on this alloy is contemplated. Results to date indicate the absence of the pearlite reaction.

not readily explainable on the basis of the current concepts of the pearlite reaction for seemingly about 50 pct of the β -phase in both the 10.5 and 13.5 pct Al alloys should be available for pearlite formation.

The preliminary reaction which is obtained in the 13.5 pct Al alloy on isothermal holding seemingly is intimately related to the β'' reaction in the 11.9 pct Al alloy. Thus for both alloys it appears that the diffusion of aluminum takes place prior to any crystal structure change in the matrix. If the alloy is cooled before the crystal structure change in the aluminum rich or depleted zones can take place, the crystal structure change is effected during the quenching cycle. The structure at room temperature then is a martensitic structure, one made up of mar-

tensites of the various compositions of the transforming β_1 . Further since the crystallography of these zones of aluminum enriched and depleted β is fully determined, the martensitic structures formed during the quenching cycle are restricted by this crystallography. Thus neither β' nor γ' have the orientation habits determined by Greninger.¹¹ Since it is possible that the lattice relationships for the structures examined here and those examined by Greninger are the same, there arises the possibility that the martensite transformation mechanism varies with pretreatment of the matrix.

The first reaction in the 13.5 pct Al alloy and the β'' reaction in the 11.9 pct Al alloy are reactions which conform in all major details to the proposed bainite reaction¹⁷ in steels. In the 13.5

pct Al alloy the β_1 structure is modified by diffusion processes such that aluminum enriched and depleted zones are set up. These regions become evident at room temperature under metallographic examination, because of the different etching characteristics of the β' and γ' .

After the β_1^+ and β_1^- structures are formed, both decompose but evidently by more complicated processes than were observed for the bainite reaction in steels. This follows from the fact that the final structure is markedly different from the structure arising as a consequence of the first reaction. Thus if the γ_2 (in the 13.5 pct Al alloy) were formed in the matrix by a shearing mechanism such as is postulated for the bainite reaction in steels, a supersaturated γ_2 structure would be obtained and this

could be expected to decompose precipitating α . This apparently does not take place, rather the γ_2 seemingly

forms at selected sites in the lattice and grows at the expense of the aluminum content of the surrounding β_1 . On the

depletion of the β_1 to a sufficient degree α forms and in turn grows. By this mechanism the α and γ_2 lattices seemingly are not in contact, but are separated by untransformed β_1 until the final stages of transformation.

An apparent anomaly is accounted for on the basis of this mechanism. This consists in the apparent interchange of role of γ_2 from precipitate structure to matrix structure through the course of the transformations. Thus in Fig 8 it seems that the precipitate structure is γ_2 , while in Fig 9 the "precipitate" structure is α .

It seems that the β'' reaction is comparable to this reaction in the 13.5 pct Al alloy except that the β'' reaction does not go to completion. Thus the β'' formed above about 500°C is for the most part consumed by the pearlite reaction. At lower temperatures increasingly greater proportions of β'' de-

compose to form α , while, as noted before, the pearlite reaction undergoes some important alterations.

The β'' structure probably does not differ from the matrix structure in so far as ordering is concerned. Rather from the fact that α forms from β'' it appears reasonable to conclude that β'' is aluminum dilute. A quantitative evaluation of the β'' crystal structure is out of question with the X ray diffraction techniques used in this investigation, but it has appeared that β'' has essentially the same structure as β' .*

Summary

1. It has been shown that the pearlite reaction is not found at compositions appreciably away from eutectoid composition on isothermal transformation of β -CuAl alloys. This reaction cannot be considered as generally typical of eutectoidal transformations.

2. In agreement with previous work^{2,4} it has been found that the pearlite reaction exists in the alloy of eutectoid composition. It has been found, however, that the interlamellar spacing of this pearlitic structure first decreases and then increases with decreasing transformation temperature. This behavior was wholly unexpected and cannot be accounted for on the basis of current notions of the pearlite reaction.

3. A bainite type reaction or, for short, a bainite reaction has been found in the CuAl alloys studied. The first reaction in the 13.5 pct Al alloy and the β'' reaction in the 11.9 pct Al alloy are placed in this category. In both of the alloys studied the β_1 matrix forms zones enriched and depleted in aluminum. For the 13.5 pct Al alloy the enriched zones decompose to form γ_2 which grows by an accretion process. The depleted zones in turn form α which also grows by an accretion process. The formation of α occurs at a much later time than the formation of γ_2 . The β'' transformation in the 11.9 pct Al alloy differs from this mainly in that α precipitates before γ_2 .

Compression Textures of Copper and Its Binary Alpha Solid Solution Alloys*

WALTER R. HIBBARD, JR.,† and DELMAR E. TROUT, II,‡ Junior Members AIME

Previous investigations have shown that the cold rolling textures^{1,2} and the drawn wire textures³ of copper change their secondary components after the addition of about 1 pct aluminum and 5 pct zinc, but do not change after the addition of as much as 30 pct nickel. However, few data are available on compression textures. Barrett⁴ reports from unpublished work with E. L. Layland that compression rolled copper develops a texture which is predominately {110} in the compression plane with a secondary spread to {113} and weaker spread to {100} as shown in Fig 1. However, 70-30 alpha brass similarly treated develops a texture again predominately {110} in the compression plane and with a weak secondary spread to {113} but with moderate {111} secondary intensities illustrated in Fig 2.

Experimental Procedure

Specimens of the compositions shown in Table 1 remaining from a previous investigation³ were annealed to a grain size of 0.090 mm average diam and machined to cylinders 0.20 in. diam and 0.20 in. high. Cylinders were compressed 90 pct reduction in height between lubricated steel blocks in a tensile machine. Glancing X ray photographs using copper K-alpha radiation were taken at an angle of θ degrees to the compression surface. {111}, {002} and {220} rings were analyzed to define the textures shown in Table 1.

The results are in agreement with Barrett⁴ as to types of textures and are essentially in agreement with previous work^{1,2,3} as to the effects of composition. In the wire study³ it was reported that the 4.99 pct zinc alloy had a brass-type texture, while the data in Table 1 indicate a copper-type texture for compression. The wire specimen of the 4.99 pct zinc alloy was re-examined by X rays and it was established that the {100} component still exists in the wire axis. Therefore, Table 2 of Ref. 3 is in

error and should indicate a double [111], [100] copper-type texture for this alloy. This correction results in complete consistency with regard to compositional effects, namely that copper and its alloys containing up to approximately 1 pct aluminum, 5 pct zinc and at least 30 pct nickel§ develop a copper-type texture and more concentrated copper-aluminum and copper-zinc solid solution alloys will form a brass-type texture.

Summary

Compression textures developed in copper and its alpha solid solution alloys of aluminum, nickel and zinc are essentially the same types as those re-

Surface Orientation and Rolling of Magnesium Sheet

ROBERT L. DIETRICH*

Magnesium alloy sheet has less ability to accept bending at room temperature than most of the heavier metals. In work designed to improve the bend properties, the preferred orientation of the sheet is of major importance as it is in all studies of the properties of wrought magnesium products. When rolled into sheet, all of the common magnesium alloys form an orientation texture having the basal (002) planes approaching parallel to the surface of the sheet. This texture is only slightly affected by annealing. Magnesium single crystals are highly anisotropic, and, as might be expected, so are magnesium alloy wrought products in which a strong preferred orientation is developed. It is therefore not surprising that bend properties are affected by orientation. Ansel and Betterton¹ reported that the orientation of AZ31X† sheet varies from surface to center and that bend properties are improved by etching away the sharply oriented material at the surface of the sheet to reach the more broadly oriented structure below. This paper covers a study of that orientation, either during the rolling process or by treatment of the finished sheet, in an effort to improve the bend properties and toughness of sheet.

Literature

The orientation texture of magnesium and magnesium alloy sheet has been studied extensively. Early determinations² showed that pure magnesium sheet has a preferred orientation in which the basal planes are parallel to the sheet surface within very narrow limits. J. C. McDonald³ and J. D. Hanawalt⁴ reported that sheet containing a small amount of calcium develops a "double" texture, that is, the majority of the basal planes are a few degrees from parallel to the surface and there is a noticeable vacancy at the parallel position. Bakarian⁵ made careful quantitative pole figures of both pure magnesium sheet and MI alloy

sheet which show these features. In all of these studies, however, the orientation was determined by transmission methods in which the resulting pattern is an average through the thickness of the sheet.

The tendency of wrought metal to exhibit a different orientation at the surface from that in the center has been reported by many investigators. G. von Vargha and G. Wasserman⁶ found that with copper, aluminum, iron, and brass the textures of rolled compared to drawn wires were the same at the center but differed markedly at the surface. It was also reported by investigators⁷ that the orientation of rolled aluminum varies from surface to center. Hargreaves⁸ found that the surface texture of AM503 (magnesium alloy similar to MI) sheet was different from the center texture. It is reported by Edmunds and Fuller⁹ that zinc alloy sheet sometimes had a thin layer at the surface with a strong orientation of the basal planes parallel to the surface, which, if present, impaired the bend properties of the sheet.

Part I Surface Orientation of Magnesium Alloy Sheet and the Effect on Properties

Attempts to correlate the bend properties of magnesium alloy sheet with tension ductility over short gauge lengths proved unsuccessful and the subsequent investigation showed that nonuniformity in orientation is a con-

tributing factor as the properties of the surface material have a much more important effect in bending than in tension. A program to study the relationship between surface orientation at the surface and bend properties was then undertaken.

First, the effect of etching away the surface of sheet on the bend properties and the orientations at the various depths were studied. Sheet samples of MI, AZ31X, and AZ61X were etched in dilute nitric acid to remove the surface material for various depths to 0.015 in. As may be seen in Table I, the minimum bend radius improved considerably as the surface layers were etched away but it was necessary to etch the sheet quite deeply, much more so than was found necessary by Edmunds and Fuller⁹ on zinc sheet. It is also apparent that the amount of etching required is a function of the sheet thickness. In all of this work, radii were measured as R/t , the radius divided by the sheet thickness, in order to eliminate the effect of the reduction in sheet thickness produced by the etching.

To determine the orientation texture of the sheet, X ray reflection patterns were taken using copper radiation with the beam striking the specimen at an angle of 17° to the surface, which is the Bragg angle for the (002) planes of magnesium. Two exposures were made of each specimen, one with the beam perpendicular to the rolling direction and the other with the beam parallel to the rolling direction. The symmetry of the preferred orientation in magnesium sheet is such that these two photographs gave an approximation of the pole figure sufficiently accurate for qualitative work and it was not thought worthwhile to make complete pole figures.

These X ray patterns show that the orientation has a much narrower spread at the original surface of the sheet than below the surface. The narrow spread is found in sheet having the majority of the basal planes (002) parallel to the surface, and since this is an unfavorable position for slip, it is

Table 1 . . . Effect of Etching on Bend Radius of Mg Alloy Sheet

| Alloy | Original Gauge Inches | Minimum Successful Bend Radius (r/t) Etch in In. per Side | | | | |
|---------|-----------------------|--|-------|-------|-------|-------|
| | | None | 0.001 | 0.002 | 0.005 | 0.010 |
| AZ31X-h | 0.040 | 9.7 | 7.8 | 5.7 | 5.7 | |
| AZ31X-h | 0.064 | 6.4 | 6.0 | 5.8 | 5.8 | |
| AZ31X-h | 0.091 | 6.4 | 6.3 | | 5.7 | 4.8 |
| AZ31X-a | 0.091 | 3.3 | 2.6 | | | 2.2 |
| M1-a | 0.040 | 4.4 | 4.5 | 3.9 | 2.4 | 3.5 |

not surprising that removing this layer improves the bend properties.

In the reflection patterns of 0.091 in. AZ31Xh sheet at the original surface and after etching 0.015 in. (Fig 1), the difference in spread is quite noticeable. The minimum bend radius was 6.4*t* before etching and 4.8*t* after etching. Other samples gave the same correlation, the bend properties improve as the orientation spread at the surface increases.

Tests made to determine the depth of penetration of the X ray beam in this type of reflection photograph showed that by use of copper radiation the beam penetrates to a depth of approximately 0.003 in. before its intensity is reduced to an ineffective level. The patterns must be interpreted as an integrated pattern of a layer 0.003 in. thick but heavily weighted in favor of the extreme surface. Subsequent tests showed that iron radiation, used for much of the later work, limited the depth of penetration to about 0.002 in.

EFFECT OF ETCHING ON TENSILE PROPERTIES

Although etching away the surface layers of sheet produces a marked improvement in bend properties, it was found that there is only an insignificant change in tensile properties. Tests on etched specimens showed a slight tendency for the etching to improve the elongation and lower the yield and tensile strengths; but the decrease is so slight as to be within normal tensile test variations and is only visible as a trend. This result is very reasonable, for, in a tension test, the entire cross-section of the sample is tested, whereas in bending the maximum elongation is found only in the extreme surface fibers and hence the minimum bend radius is determined by the elongation possible at the surface.

ETCHING EXTRUDED STRIP

The effect of etching on the bend properties of sheet aroused interest in

the behavior of extruded strip having a similar orientation to sheet when a transmission pattern is taken. Extruded strips, $\frac{1}{8}$ in. by $\frac{7}{8}$ in., of AZ80X, AZ61X, M1, and AZ31X were etched in the same manner as the sheet with rather startling results. Etching AZ31X strip improved the bend properties as in the sheet, but AZ80X and AZ61X strip had poorer bend properties after etching and M1 strip showed no effect. Diffraction patterns by reflection from the surface showed that the surface orientations of the various samples correlated with their bend properties. In the predominate orientation at the surface, the basal planes are not parallel to the surface, but are inclined to it at an angle of 10° to 30°.

Table 2 shows the effect of etching 0.015 in. on the bend properties of AZ80X and M1 strip and the corresponding surface diffraction patterns are shown in Fig 2. As can be seen readily, the orientation of AZ80X at a depth of 0.015 in. has a much narrower spread than at the surface, whereas in M1 strip there is little difference. Crystallites having the basal plane at an angle to the surface are in a more favorable position for basal slip than if parallel; therefore, the greater the percentage of the material at the surface in a favorable position, the better the bend properties. The results of the experiments on extruded strip confirm

FIG 2—Effect of Etching on Surface Orientation of Extruded $\frac{1}{8}$ in. X 3 in. Strip.

the importance of surface orientation in determining bend properties.

SHOT PEENING

Having determined the importance of a favorable surface orientation in obtaining good bend properties in sheet, the problem of improving that orientation presents itself. There are two general ways in which this can be done; one is to alter the orientation of the rolled sheet, the other is to control the orientation during the rolling process.

One of the methods of altering the surface of the finished sheet is to etch away the unfavorably oriented material at the surface but because of the large amount of metal wasted by this process it is not commercially feasible. Shot peening offers a means of working the surface which utilizes flow characteristics entirely different from rolling. It was found that when AZ31Xa sheet was shot peened severely and then annealed at 600°F (310°C), a random orientation at the surface could be produced (Fig 3). Metallographic examination showed the affected layer to be about 0.003 in. deep. By this treatment the minimum bend radius was reduced from 3.5*t* to 2.5*t*.

REVERSE BENDING

A more effective and practical way to alter the surface orientation was

Table 2 . . . Effect of Etching on $\frac{1}{8}$ in. Extruded Strip

| Alloy | Etch | Min. Bend Radius | * Surface Orientation, Arc of Max. Intensity |
|-------|--------------------|------------------|--|
| AZ80X | None | 3.0 <i>t</i> | +10°, +54° |
| AZ80X | 0.015 in. per side | 4.0 <i>t</i> | -10°, +10° |
| MI | None | 4.0 <i>t</i> | +3°, +29° |
| | 0.015 in. per side | 3.9 <i>t</i> | +5°, +22° |

* Orientation is spread of basal planes in extrusion direction from parallel to surface.

found when it was learned that bending the sheet to about 15*t* radius through rolls, straightening, bending in the opposite direction and annealing produce a radical change in surface orientation and improve the bend properties. If the process is repeated a second time there is further broadening of orientation and further improvement in bend properties, but additional repetition is not effective. As is shown by the data in Table 3, AZ31X sheet had a 3.5*t* bend radius in the annealed condition, but if treated by reverse bending the minimum radius was reduced to 2.5*t* after the first treatment and 1.2*t* after the second. There is also an accompanying loss in yield strength, an increase in elongation, and a substantial increase in toughness.

The reverse bending process was studied in detail by X ray methods and it was found that the major orientation

change occurs during annealing, probably as a result of the twinning which takes place on the compression side of the bend. This is one of the few known cases in which annealing magnesium results in an appreciable change in orientation.

Roller leveling is somewhat similar to this reverse bending and has been cited in the literature¹¹ as a way to improve bend properties, but attempts to use this method were unsuccessful even when the two stage anneal was used. The difference is in the severity of the bends since the radii must be small enough to produce strong twinning on the compression side of the bend.

Part 2

The Control of Surface Orientation in the Rolling Process

Although the surface orientation of magnesium alloy sheet can be altered by etching, shot peening, or reverse bending, it is, of course, much more economical to roll in such a manner as to secure the desired properties without further treatment. A comprehensive program was undertaken to study the effect of hot and cold rolling variables on the surface orientation and properties of AZ31X alloy, the most widely used magnesium sheet alloy. The

FIG 3—Effect of Shot Peening on Surface Orientation of 0.064 in. AZ31X-a Sheet.

Table 3 . . . Effect of Reverse Bending in Both Directions on AZ31X-h

| Treatment | Tensile Properties | | | Minimum Bend Radius |
|----------------------------------|--------------------|-------------------|----------------|---------------------|
| | Ultimate psi | 0.2 Pct Yield psi | Pct E in 2 in. | |
| Original + 600°F Anneal..... | 37,800 | 23,000 | 21 | 3 5/8 |
| Reverse Bend + Anneal..... | 37,300 | 20,800 | 23 | 2 5/8 |
| (Reverse Bend + Anneal) × 2..... | 35,600 | 15,900 | 24 | 1 2/8 |

variables of temperature, reduction per pass, lubrication, and total reduction were studied as well as the effect of different combinations of them. The minimum bend radius, tension and compression strengths, and toughness gave good correlation with the resulting orientation.

EQUIPMENT

All laboratory investigations were carried out on a laboratory 2-Hi rolling mill having 8 in. diam by 12 in. rolls, and, in addition, a few pilot plant experiments were carried out on a 2-Hi mill having 32 in. by 60 in. rolls. Orientation was determined by X ray surface reflection using both copper radiation and iron radiation.

HOT ROLLING

Most of the experimental work was done on hot rolling as it was found that more could be accomplished in controlling the orientation in hot rolling even when the sheet was finished by cold rolling. The hot rolling variables of reduction per pass and temperature were studied by rolling AZ31X from 0.250 in. to 0.082 in. in four ways:

1. 800°F, (430°C), 20% reduction per pass
2. 800°F, 5% reduction per pass
3. 500°F, (260°C), 20% reduction per pass
4. 500°F, 5% reduction per pass

The resulting hot rolled material was then annealed at 700°F (370°C), cold rolled 20 pct, and final annealed at 275°F (135°C). Surface orientation and

properties were determined at each stage of the process. The higher temperatures and heavier passes produced a sheet having a much broader spread in the orientation of the basal plane at the surface. This sheet had better bend properties and, in addition, a considerably higher compression yield strength. The effect of the hot rolling conditions carried through the subsequent finishing operations of annealing and cold rolling. The properties of the sheet before and after cold rolling are given in Table 4. Surface reflection X ray pictures of the finished sheet are shown in Fig 4 with the differences in spread of the basal reflection evident.

The most probable explanation for the temperature effect is that the relative activity of the slip systems is altered by increasing temperature. There has been some indication that this may be true^{2,12,13} but no adequate proof exists. It is interesting to note Kolesnikov's¹⁴ report that three different textures were produced when zinc sheet was rolled at 20°C (70°F), 150°C (300°F), and 380°C (720°F). There are two possible reasons for the effect of reduction per pass; it may be the result of more uniform working through the thickness of the sheet or it may be the result of stress changes as discussed under lubrication. McLachlan and Davey¹⁵ found that with iron-nickel alloys, the orientation of a 0.001 in. surface layer is affected by reduction per pass but below this there is no change. Anderson and Kehl,¹⁶ on the other hand, found that with copper the reduction per pass does not influence either the surface or the overall texture.

ROLL LUBRICATION

Lubrication during hot rolling should have an effect on the stress system and possibly on the surface orientation. To study this variable, sheets were hot rolled from 0.250 in. to 0.075 in., annealed at 700°F (370°C), and cold rolled to 0.064 in. Rolling was done with palm oil on the rolls and with dry rolls. In the tests reported in Table 5, when lubricant was used for hot rolling it was also used for cold rolling; if hot rolling was dry, cold rolling was also dry. The use of lubricant causes a marked improvement in the bend properties of AZ31X but in the hard rolled condition the greatest improvement is secured if the sheet is subsequently etched to remove 0.0005 in. per side. The only explanation that can be offered for the results of etching is that even with lubrication there is a very thin layer of material with poor orientation at the surface of the sheet. The X ray method is, however, not sufficiently sensitive to prove or disprove this theory. The wider surface orientation resulting from the use of a lubricant is believed to be the result of reduction of the tensile stress on the surface due to the friction of the rolls. Experiments by the author on M1 alloy single crystals have shown that slip and fracture characteristics are different in the rolling process from those in pure compression. Single crystals having the basal plane within 5° of parallel to the rolling surface could be hot rolled successfully but fractured when subjected to compression in a testing machine operated at the same temperatures.

The use of adequate lubrication is believed to cause the stress system at the surface to approach more nearly the stresses found in the center of the sheet and, therefore, to reduce the variation in orientation from surface to center.

sheet finished by annealing and cold rolling 15 pct with dry rolls are shown in Fig 5. Further investigation shows that for best results lubrication should be confined to hot rolling, since when used for cold rolling it does not improve the resulting orientation and lubrication during cold rolling is well known to reduce the capacity of magnesium alloys to withstand cold rolling without cracking.^{1,17}

REQUIRED TOTAL REDUCTION IN HOT ROLLING

Having established that surface orientation could be altered by hot rolling conditions, tests were run to determine the minimum amount of hot rolling required under optimum conditions to secure the desired surface orientation and bend properties. These tests showed that the conditions under which the last 30 to 40 pct of the reduction in hot rolling is carried out determines the final properties.

PERSISTENCE DURING COLD ROLLING

All the data presented so far were obtained on sheet finished with 15 to 20 pct cold roll. It is surprising that the orientation produced in hot rolling persists so strongly through annealing and cold rolling operations. It would seem

probable that sufficient reduction in cold rolling would remove any influence of hot rolling conditions. Thin gauge magnesium alloy sheet is produced commercially by multiple cold rolling from a minimum hot rolled gauge of 0.075 in. Total reductions of 20 to 40 pct with intermediate anneals are used. The tests conducted in the laboratory consisted of cold rolling two batches of sheet, one of which had been hot rolled with lubricated rolls at 800°F, 20 pct per pass, and the other had been hot rolled with dry rolls at 600°F, 20 pct per pass. Two successive cold rolls of 20 pct each followed by one of 30 pct were used, annealing at 700°F (370°C) between cold rolls. The superior bend properties of the first batch persisted in the hard rolled sheet

through the entire cold rolling. It did, however, become slight after the second cold roll. In sheet final annealed at 600°F (320°C) all effect of the hot rolling conditions on bend properties was lost after the second cold roll. The sheet hot rolled at the higher temperature maintained a slightly better compression yield strength through the entire series of cold rolls.

COLD ROLLING

In addition to the work on hot rolling, the effects on surface orientation of roll lubrication, roll temperature, reversing the direction of each pass, reduction per pass, and total reduction in cold rolling were studied. The differences obtained were much less important than in the studies on hot rolling. It

† Psi.

was found that the best combination of strength and ductility in hard rolled sheet is produced by the present commercial practice of finish cold rolling 20 to 30 pct followed by a low temperature anneal at 325°F (160°C) rather than finishing with a small cold reduction without final anneal.

WARM ROLLING

As an alternative to finish cold rolling in securing the desired surface and properties, warm rolling is sometimes used. Tests on sheet finished by warm rolling at 300°F (150°C) and 400°F (200°C) showed poorer bend properties than on sheet finished by cold rolling.

OTHER MAGNESIUM ALLOYS

The work on rolling was not extended to cover magnesium alloys other than AZ31X since this alloy accounts for by far the largest quantity of production sheet, and is used almost entirely for those applications in which room temperature formability and toughness are critical factors. Some laboratory work has shown that the hot rolling temperature affects the cold rollability of AZ31X both with and without calcium and also that of AZ61X.

Summary

1. Studies of the crystallographic orientation of magnesium alloy sheet show that the spread in the orientation

of the basal plane is considerably less at the surface than in the center of the sheet.

2. A narrow orientation at the surface is detrimental to the bend properties of the sheet.

3. The layer having a narrow orientation can be removed by etching, or the orientation can be broadened by shot peening or reverse bending with a resultant improvement in bend properties.

4. The surface orientation of AZ31X sheet can be improved by higher temperature, higher reduction per pass, and adequate lubrication during hot rolling with a resultant improvement in bend properties and a slight improvement in compression yield strength.

5. The improved surface orientation resulting from hot rolling persists to a remarkable degree through subsequent annealing and cold rolling operations.

6. Variations in cold rolling have only a very slight effect on surface orientation.

Recrystallization Texture and Coarsening Texture in High Purity Aluminum

PAUL A. BECK,* Member, and HSUN HU,* Junior Member AIME

Introduction

It has been known for many years that in cold drawn polycrystalline aluminum the recrystallization texture is practically identical with the deformation texture.^{1,2,3} V. Goeler and Sachs⁴ stated that in cold rolled polycrystalline aluminum, too, the deformation texture is retained upon recrystallization. This behavior was interpreted by Dehlinger⁵ as an indication that each recrystallized grain inherits the orientation of the matrix in which it grew. However, Burgers and Basart showed⁶ that in deformed aluminum single crystals the orientation of the recrystallized grains strongly deviates from that of the matrix. Barrett demonstrated⁸ that even in deformed polycrystalline aggregates the local orientation within each deformed grain changes on recrystallization. No explanation has as yet been offered of how the aggregate texture can be retained, while the local texture is everywhere changing.

According to Burgers and Louwerse⁶ the orientation change on recrystallization in compressed and rolled aluminum single crystals corresponds to a rotation around [112] axes lying in the active slip planes and perpendicular to active slip directions. This orientation change was rationalized by them on the assumption that the orientation of the recrystallized grains is determined by the orientation of the available nuclei, and that these nuclei are small fragments of the deformed crystal, rotated in the deformation process. Barrett pointed out,⁷ however, that these assumptions were by no means proven, and that the total volume of material necessary for the nuclei is so small, that it must be available in any orien-

tation whatever. It is, therefore, unlikely that an "oriented nucleation" theory could satisfactorily explain the orientation changes in recrystallization of a deformed crystal. Furthermore, in contradiction to Burgers and Louwerse's conclusions, Barrett's results for the orientation change could be best expressed in terms of rotations around [111] axes. Thus agreement is lacking not only in the interpretations but apparently even in the experimental results contributed by the various investigators.

The orientation relationships on coarsening* in a highly oriented polycrystalline matrix were first investigated by Burgers and Basart.⁶ They produced a fine grained highly oriented matrix by the recrystallization of a compressed or rolled single crystal of

aluminum, and studied the orientation relationships in three successive generations of crystals: the "deformation texture" in the single crystal, the recrystallization texture, and the coarsening texture. Burgers^{2,4} showed that the preferred orientation of each successive generation was almost always widely different from that of the preceding one, but that the coarse grains often approximately reverted to the orientation of their grandparent, the deformed single crystal. This observation, and the idea that the orientation of the coarse grains is determined by that of the available "nuclei," led to the concept that the coarse grains are nucleated by the remnants of the deformation texture.^{12,15} On the other hand, Bowles and Boas¹⁶ found, in a carefully conducted experiment, that in recrystallized fine grained copper of cube texture coarse grains grow in orientations which can be derived from the orientation of the recrystallized matrix by rotation around a [111] direction; the coarsening texture here does not appear to be related in any simple manner to the original rolling texture from which the cube texture had been obtained by recrystallization.

It may be assumed that in a recrystallized material, even with a strong texture, there always are present some grains of practically any orientation. These may serve as "nuclei" for the coarse grains, provided that the conditions are favorable for their growth. The existence of a coarsening texture may be considered as an indication that grains with certain relative orientations with respect to the preferred orientation of their neighbors can grow much faster than others. This "oriented growth" theory was briefly suggested by van Arkel, as early as 1936,¹³ and it was mentioned by Burgers.¹⁴ Recently, C. G. Dunn produced direct

* Just as the recrystallized grains grow at the expense of the deformed matrix, and finally replace it, under suitable conditions the recrystallized grains may be in turn replaced by a new generation of grains, usually many times larger than the recrystallized grains and growing at their expense. The growth of these very large grains may be designated as discontinuous grain growth or coarsening. (The following other terms have been used by various authors: abnormal grain growth, exaggerated grain growth, germination, and secondary recrystallization. These terms are deemed to be unsuitable, as they have been used indiscriminately to describe the formation of large grains by various mechanisms.¹¹

Recent work indicates^{10,11} that an essential condition for coarsening is that in a fine grained structure continuous or gradual growth be impeded. There are at present two mechanisms known, each one of which is capable of accomplishing this, namely the inhibition by a dispersed phase and the restraint of growth resulting from a strongly developed texture. Correspondingly, one may speak of "inhibition-dependent coarsening" or "texture-dependent coarsening." In metallurgical practice intermediate cases often occur, where gradual grain growth is impeded by a combination of the two mechanisms mentioned.

experimental evidence for the orientation dependence of the rate of growth in silicon ferrite.²⁵

The present investigation was undertaken in an attempt to clarify the difficulties and contradictions described above, and to rationalize both recrystallization textures and coarsening textures from the point of view of the "oriented growth" theory.

Experimental Procedure

The plan of the experiments was basically similar to that followed by Burgers and Basart.⁵ However, high purity aluminum was used in order to eliminate the possible effect of impurities on the texture relationships. Recent work indicated¹⁰ that it is possible to induce texture-dependent

coarsening in high purity aluminum. Table 1 gives the lot analysis of the aluminum.

The method of preparing the ingot was the same as previously used.¹⁶ Large crystals were grown by annealing 0.390 to 0.535 in. thick specimens for 3–4 days at 650°C. Crystals I and II were cold rolled 88 pct, and 90 pct respectively. Crystal III was compressed 75 pct between repeatedly greased ground steel plates. The deformed crystals were carefully cut into several specimens by a jeweler's saw. One specimen of each crystal was used for determining the deformation texture. The other specimens were annealed in salt baths at various temperatures and for various lengths of time.

Fig 1 gives the outlines of crystal I and its neighbors, after rolling, the location of the saw-cuts and specimen numbers. Spec. 7 was used for determining the deformation texture. As seen in Fig 2, crystal I had a large number of deformation bands extending parallel to the rolling direction. Spec. 4, (Fig 3), was annealed for 25 min. at 400°C, giving a uniformly fine recrystallized structure. Spec. 8, which had a common side with spec. 7, was annealed for 745 min. at 400°C, giving a partially coarsened structure, (Fig 4). This specimen was used to determine both the recrystallization texture and the orientation of several coarse grains. Since both structures were located in the same specimen, the relative orientation could be determined with a high degree of accuracy. For measuring the relative orientation of the deformed grain, spec. 7 was aligned by using its common edge with spec. 8. The specimens of crystals II and III were treated similarly.

The deformation texture, the re-

crystallization texture and the coarsening texture were determined by means of an optical goniometer similar to that described by Barrett.¹⁷ The light source used was a 2 watt concentrated arc lamp, allowing a very high degree of collimation.

The annealed specimens were polished electrolytically and etched with the reagent described by Barrett.¹⁷ It was found that about 10 to 20 min. of etching were necessary to develop the cube planes accurately. In all measurements on single grains the measured angles between the cube planes approached 90° to an accuracy of better than 1 to 2° . It was found that the crystallographic definition of the etch pit faces in deformed crystals was improved when a somewhat modified etching reagent was used as given in Table 2.

Table 2 . . . Composition of Etching Reagent Used for Developing (100) Planes in Cold Worked High Purity Aluminum

It was found that the texture of the fine grained recrystallized material is usually rather sharply defined, so that the mean orientation can be satisfactorily and easily determined by the optical method, if such a polycrystalline region is treated as if it was a single grain. Reproducible average orientations were obtained, and the angles

between the average cube planes so determined were close to 90° . The coarsening texture was determined by measuring the orientation of 15–20 large grains individually.

Results

Fig 5 gives the relationship between the deformation texture, the recrystallization texture and the coarsening texture obtained in crystal I. In order to show clearly the relative orientation of these textures, the pole figure is plotted for (100) poles in such a way that the recrystallization texture is in standard position. It is readily seen that the main portion of the deformed material as well as the deformation bands can be brought into fairly good alignment with the recrystallization texture by rotation around a $[111]$ direction. The coarse grains clearly fall into two groups (A and B), each with a well-developed preferred orientation. This fact is also noticeable in Fig 4, where one group of coarse grains appears black, and the other group gray. It is notable that the orientation of both groups of coarse grains deviates from that of the recrystallized matrix corresponding to a rotation around a $[111]$ direction. The angle of rotation from the deformation texture to the recrystallization texture is about 40° , that from the recrystallization texture to the group A coarse grains is of similar magnitude in the opposite direction

(or about 80° in the same direction), so that the orientation of group A coarse grains is fairly close to that of the original deformed single crystal. It is important to note that the group B coarse crystals have an entirely different orientation from either component of the deformed crystal, although they are also connected with the recrystallization texture by a $[111]$ rotation of about 35° (see Fig 1).

The extent of rotation around a $[111]$ direction can be best studied in the corresponding $[111]$ projection of the (100) poles. This is given in Fig 6 for the three successive generations of crystals: the deformation texture of crystal I (that of both the main portion and the deformation bands), the recrystallization texture and the group A coarse grains. It is apparent that with a fair degree of accuracy all these crystals have in common the $[111]$ direction which has been used as the center of projection. The group B coarse grains were omitted here, since they are connected with the recrystallization texture by rotation around a different $[111]$ direction. Similar pole figures were prepared for all cases investigated, in order to determine the angles of rotation.

Fig 7 shows the $[100]$ projection of the (100) poles for the recrystallization texture and for the coarse grains produced by the annealing of a specimen of the rolled crystal II for 25 min. at 400°C . In this instance it was found impossible to determine accurately the

FIG 7—(100) pole figure for textures obtained in high purity aluminum crystal II.

Recrystallization texture \square is in standard position. Groups A and B of coarse grains away from sawed edges \circ , and at sawed edges \bullet are plotted together with rolling direction (R.D.), cross direction (C.D.), and normal direction (N.D.). Arrows correspond to 65° rotation around [111] and to 50° rotation around [112] respectively.

(111) of the deformation texture is center of projection. The compression axis (C.A.) is indicated. Arrows indicate rotation of 47° .

FIG 8—Specimen of high purity aluminum originally consisting of two grains, rolled and annealed 12 sec. at 400°C , showing coarse grains at sawed edges.

Reduced one half in reproduction.

deformation texture by the optical method, as the deformation bands were small, numerous and inextricably interwoven. However, the recrystallization texture was fairly sharply defined. The coarse grains showed considerable scatter, but it is apparent that even this scattered orientation range is quite clearly related to rotations around one of two [111] directions. Roughly, the scatter of one group of coarse crystals (A) may be expressed as a variation of the angle of rotation around [111] from about 17 to 65° . The orientation of the other group of coarse crystals can be derived from that of the recrystallized grains by a rotation of approximately 50° around [111].

It is of particular significance that in most specimens a tendency was noted for the coarsening to start near the two sawed edges. This is clearly shown in Fig 8. It was observed that considerable amounts of material had to be etched off the edge regions prior to annealing in order to eliminate this tendency. In Fig 7 the (100) poles for several of the grains growing from the edge are shown by solid circles. The orientation of most of these grains coincides well with the orientations of group A coarse grains, formed away from the edges.

The orientation of crystal III after compression was very similar to that shown in Fig 10, that is, the (110)

plane was close to the plane of compression. This compressed crystal had no deformation bands; its orientation was sharply defined. After annealing for 15 min. at 400°C it showed a sharply defined recrystallization texture. The relative orientation of the recrystallization texture and the deformation texture, which is shown in Fig 9 in a [111] projection, corresponds to a rotation of about 47° around [111].

Discussion of Results

The results indicate that the orientation of aluminum crystals grown in a highly oriented matrix, either by recrystallization (when the matrix is deformed) or by coarsening (when the matrix is recrystallized, fine grained), is related to the orientation of the matrix by means of a rotation around a [111] direction. The extent of the rotation is about 30 to 50° in most cases as shown in Table 3.

According to Burgers and Louwerse,⁶ the orientation relationship between a compressed single crystal of commercial purity aluminum and the recrystallization texture corresponds to a rotation around a [112] direction. Fig 10 shows a pole figure from their paper. In Fig 11 the same data are re-plotted in such a way that the [100] poles of the deformed crystal are in standard position. It is apparent that the [111] rotation expresses the orientation relationship between the compressed single

FIG 1 C—(100) pole figure for deformation texture \square and recrystallization texture obtained by Burgers⁶ in a compressed aluminum crystal of commercial purity.

Black areas represent the main component (A), and shaded areas the other important component (B) of the recrystallization texture. Arrows indicate [112] rotations.

Arrows indicate [111] rotations of 40° for A, and 37° for B.

crystal and either component of the recrystallization texture more accurately than the [112] rotations indicated by arrows in Fig 10. The orientation relationship between the deformation texture and the major component of the recrystallization texture is re-plotted in Fig 12 in a [111] projection, which again shows the excellent agreement of the data with the present interpretation. The agreement of the data reproduced in Fig 13 from ref. 6 (rolled single crystal of commercial aluminum) is again better with the [111] rotation than with the [112] rotation, as seen by comparing Fig 13 with Fig 14. It may be concluded, therefore, that the data presented by Burgers and his collaborators lend further support to the results described above. Furthermore, these data indicate that the impurities present in commercial aluminum do not affect the orientation relationship for recrystallization.

In all four instances where the relative orientation of deformation texture and recrystallization texture was determined (Fig 5, 9, 11 and 14), only one or two of the four possible [111] rotations were actually found to occur in noticeable amounts. It is to be noted that in the case of the two compressed crystals (Fig 9 and 11) the angle between the "active [111] axes and the compression axis is quite close to 90°. The [111] axes "active" in the recrystallization of the two rolled crystals (Fig 5 and 14) are those closest to the cross direction of rolling. (In the narrow deformation bands of crystal I the "active" [111]

Table 3 . . . Angle of Rotation Around [111] Direction in Degrees, Representing Orientation Change for Recrystallization and for Coarsening in a Highly Oriented Matrix

direction was found to be about 2° further away from the cross direction than an inactive one. However, the accuracy of the measurements was not sufficient to make certain that this really represents an exception to the above criterion.) Since the direction of maximum compression in rolling is the normal direction, the criterion just described for rolled crystals is not unrelated to the one for compressed crystals.

The fact that the orientation of the recrystallized grains is derived from that of the deformed crystal by a [111] rotation implies, of course, that recrystallization nuclei of suitable orientation are available. It does not prove, however, that nuclei of other orientations do not exist. The occurrence of recrystallized grains of the above orientation range is favored probably because of their higher rate of growth in the deformed matrix. In the case of coarsening, this interpretation is

strongly supported by the orientation of the coarse grains nucleated at the sawed edge, as described above. Away from the edges the deformation texture is well-developed, and consequently the recrystallization texture is also quite sharply defined. Apparently, in a structure with such high degree of preferred orientation, there are but few grains with orientations deviating considerably from that of the mass, hence few "nuclei" for coarse grains. At the sawed edge the deformation is strongly heterogeneous. It may be assumed that at such locations tiny recrystallized grains of a large variety of orientations are formed upon annealing. Many of these may serve as "nuclei" in coarsening.* The fact that only those "nuclei" grow to large size which have the correct orientation with

* The described mechanism of "nucleation" of coarsening at points of inhomogeneous deformation may explain, at least in some cases, the phenomena of "forced secondary recrystallization" as reviewed by Burgers.²⁴

FIG 12—(100) pole figure for component *A* of the recrystallization texture, as given in Fig 10 and 11.
Center of projection is (111) of the deformation texture.

respect to the highly oriented recrystallized matrix, indicates that the selective principle involved is the orientation dependence of the rate of growth. That the coarse grains are not "nucleated" by remnants of the deformation texture is shown by the group *B* coarse grains in Fig 5, the orientation of which is quite different from that of the deformation texture. However, the orientation of both group *A* and group *B* coarse grains can be accounted for on the basis of the "oriented growth" theory.

The analogous orientation selectivity

found for recrystallization and for coarsening in high purity aluminum shows that the same orientation dependence governs the rate of growth of the grains in both cases. There is no reason to assume, however, that this analogy implies essential identity of the two processes. In fact, present evidence tends to support the view that recrystallization is connected with the elastic bending of the lamellae of deformed crystals,¹⁸ whereas coarsening is connected with the surface energy of the grain boundaries.^{16,19}

It is interesting to recall that the

fiber texture of cold drawn polycrystalline aluminum is [111] in the fiber axis, and that the recrystallization texture, developed upon annealing, is the same.^{1,2,3} In the light of the present results, the retention of the [111] fiber texture in recrystallization is easily understood, even though each deformed grain changes its orientation upon recrystallization. Fig 15 shows schematically a [111] fiber texture. If each recrystallized grain deviates from its parent matrix only by a rotation around [111], which is also the fiber axis, its (100) poles will remain within the same ring-shaped area of the pole figure, and the resulting recrystallization texture will be the same as the deformation texture. Here, as in compressed single crystals, the "active" [111] axis (around which the re-orientation takes place) is perpendicular to the directions of maximum compression (the radial directions of the rod). In copper, too, the deformation fiber texture is mainly [111], and this is retained in recrystallization.²⁰ In view of this fact, and of the observations of Bowles and Boas on coarsening, the orientation relationships for copper appear to be very similar to those for aluminum.

Fig 16 shows the rolling texture for polycrystalline aluminum, according to v. Goeler and Sachs.⁴ If this is replotted with the cross direction in the center of the projection, as in Fig 17, it becomes apparent that, in a rough approximation, the major component of this texture may be considered as an

FIG 13—(100) pole figure for deformation texture (dotted lines), and for components *A* and *B* of recrystallization texture obtained by Burgers in rolled aluminum crystal of commercial purity.

Arrows indicate [112] rotations, as given by Burgers.

FIG 14—(100) pole figure for the data given in Fig 13, with one component of the deformation texture in standard position.

Arrows indicate [111] rotations of 27° for *A*, and 33° for *B*.

incomplete [111] fiber texture, with the cross direction as the fiber axis. Consequently, the often noted fact that the rolling texture of polycrystalline aluminum is fairly well retained upon recrystallization,⁴ may be visualized as described above for the fiber texture, even though the agreement cannot be expected to be as good as it is in the case of drawn aluminum. According to this interpretation, the "active" [111] axes in the various grains are all nearly parallel to the cross direction, in agreement with what was found above for rolled single crystals.

The behavior of rolled polycrystalline copper (with not more than about 80 pct reduction of area) is apparently very similar to that just described for aluminum. But it has been reported that the recrystallization texture of rolled silver²¹ and of certain face centered cubic copper alloys,²² such as brass, has mainly a (113) [112] position, even though the [111] fiber texture of cold drawn brass is apparently retained upon recrystallization.⁷ These conditions are not as yet clearly understood, and they are now being investigated at this laboratory.

It is known that certain body centered cubic metals have a [110] fiber texture, and that this is retained in recrystallization.²³ In analogy to the behavior of aluminum, it may be expected that in such metals the orientation relationship between a deformed grain and the recrystallized grains

growing in it may correspond to a rotation around a [110] direction. This expectation is also being tested at the present time.

Acknowledgments

The authors wish to express their appreciation to Mr. Philip R. Sperry for his conscientious and competent assistance with the experiments, and to the Aluminum Co. of America for

the grant of high purity aluminum. The continued interest and encouragement of Drs. A. R. Troiano, H. A. Dix, Jr., and A. J. Phillips is gratefully acknowledged. This work was supported by the office of Naval Research, U. S. Navy, Contract No. N6 ori-165, T.O. 1. The helpfulness of Messrs. I. R. Kramer, J. J. Harwood and James Bryson of the Materials and Mechanics Branch of the O.N.R. was of great value.

Conclusions

1. The orientation of the recrystallized grains growing in a rolled or compressed aluminum single crystal is related to the main orientation of the deformed crystal by rotation around a [111] direction. The extent of rotation varies between about 30 and 50°. The orientation relationship for recrystallization does not appear to be affected by impurities present in commercial aluminum.

2. Since the axis of the rotation, which may be used to describe the orientation relationship between deformation texture and recrystallization texture for aluminum single crystals, is identical with the axis of the fiber texture of cold drawn polycrystalline aluminum, the retention of the [111] fiber texture in the recrystallization of this material is explained.

3. The orientation of the coarse grains growing in a matrix of fine grained recrystallized high purity aluminum with sharply defined texture is related to the main orientation of the matrix by rotation around a [111] direction. The extent of rotation may vary over wide limits, but it is usually about 30 to 50°. Important components of the coarsening texture may strongly deviate from the deformation texture. Consequently there is no reason to assume that the coarse grains are "nucleated" by remnants of the deformed material.

4. The orientation of coarse grains growing in a matrix of fine grained recrystallized high purity aluminum with sharply defined texture, from points where recrystallized grains with a large

variety of orientations are available (sawed edges) is the same as that of the coarse grains formed elsewhere. This indicates that the coarsening texture is determined by the orientation dependence of the rate of growth, rather than by "oriented nucleation."

Annealing Twins in Copper and 70-30 Alpha Brass*

WALTER R. HIBBARD, JR.,† Junior Member, YOU-CHAO LIU,† and STANLEY F. REITER,† Student Associates AIME

Cyril Stanley Smith in his classic 1948 Institute of Metals Lecture¹ noted in the case of annealing twins that: "It is well known that approximately the same number of twins per grain and the same general geometry are maintained in large grains as in small ones, a fact that certainly suggests a mechanism such as the above where boundaries and twins grow proportionately together. If this view is correct, a spherical grain should have no mechanism for keeping its twins." Such a constancy of twins per grain would be of particular interest as a tool for the study of the origin of annealing twins. It has been proposed by Mathewson² and later by Barrett³ that in face-centered cubic metals slip occurs in the {111} plane by $\langle 112 \rangle$ shears which combine in pairs to produce the macroscopically observed $\langle 110 \rangle$ movement. This proposal is schematically inviting since $\langle 112 \rangle$ slip permits the atoms of one plane to move along the interatomic valleys of its neighbor rather than up the hills across the atom sites. There is strong experimental evidence⁴ that annealing twins result from the growth of nuclei in the form of "twin faults" produced by single $\langle 112 \rangle$ shears.

It is possible that more twin faults would form at low deformation temperatures than at high ones, because the more rigid lattice may increase the tendency to "freeze" the twin faults

and prevent their dissipation in slip. This is suggested by (1) the greater resistance to slip at low temperatures and (2) greater tendency toward mechanical type twinning at low temperatures (a summary of these factors is presented by Seigl  and Brick⁵). These considerations would suggest the following:

- Constant twin/grain ratio for specimens deformed constant amounts at a constant temperature, but annealed at various temperatures above the recrystallization temperature.
- Larger twin/grain ratios for recrystallized specimens previously deformed constant amounts at lower temperatures.

The purpose of this investigation is to test these considerations.

Experimental Procedure and Results

One half in. rods of phosphorous deoxidized electrolytic copper and 70-30 alpha brass (68.36 pct Cu, 0.005 pct Pb, 0.01 pct Fe, 31.62 pct Zn remainder) were rolled to a thickness of 0.350 in., milled to specimens $0.350 \times 0.437 \times 2$ in., and annealed at 700°C to an average grain size of 0.065 and 0.090 mm, respectively. These specimens of each metal were then rolled 50 pct reduction in thickness and annealed one hour under conditions which were all combinations of the following:

| Rolling Temperatures, °C | Annealing Temperatures, °C |
|--------------------------------|----------------------------------|
| -70 | 400 |
| 25 | 500 |
| 200 | 600 |

Standard metallographic techniques⁶ were used to prepare specimens. By the method of lineal analysis⁷ using a minimum of ten samples of fifty grains each for each specimen, the ratios of twins* per total grains, twins per twinned grain, twin families* per total grains and twins per twin family were determined. Recrystallized grain size was determined by A.S.T.M. comparison methods.⁸ All observations were made on the rolling plane.

The results are tabulated in Table 1.

* Twins were counted as the number of distinguishable twins on the polished surface even though many of them were parallel. Twin families were counted as the number of different twin directions in a grain, a maximum of four.

Discussion of Results

From Table 1 the following observations are apparent:

1. Under similar conditions of rolling and annealing, more annealing twins are found in 70-30 alpha brass than in copper, both from the standpoint of total number of twins and number of twin families.

2. In the case of copper, the various twin ratios are essentially independent of the annealing temperature as suggested by Smith.¹

3. In the case of 70-30 alpha brass, significantly fewer twins were formed at the highest annealing temperature under all rolling conditions. However, it was noted that a large number of nearly spherical grains survived at this temperature, again in accordance with the suggestions of Smith.¹

The tendency toward forming annealing twins is slightly but probably not significantly less for lower temperatures of deformation.

4. In the case of copper, by comparing twins per total grains with twins per twinned grains, it appears that after the 600°C anneal there were about the same number of twins per grain but significantly more twin-free grains than after the 400 and 500°C anneals. In the case of brass there were significantly fewer twins per grain but about the same number of twin-free grains at 600°C.

Observation (1) suggests that twin 70-30 alpha brass has greater tend-

faults form more readily in 70-30 alpha brass than in copper. Thus the tendency to form annealing twins is a direct function of the elastic anisotropy of the metal (that is, brass is more anisotropic than copper). This can be extrapolated to aluminum, which is nearly isotropic and in which annealing twins possibly have not been observed. It suggests that twin faults form more readily if the elastic modulus normal to the slip plane is significantly larger than that parallel to it.

Observations (2) and (4) suggest that in copper there is a tendency for twin-free grains to grow at the expense of grains containing twins, particularly those with few twins. Observations (3) and (4) suggest that in alpha brass many twins form at lower annealing temperatures (as reported by Maddigan and Blank,⁹ but that the twins coalesce within the grains at higher temperatures (600°C). This coalescence apparently starts when the grains have grown sufficiently to approach a spherical shape.

While more twin faults may have formed at lower deformation temperatures, in these experiments a proportionately larger number of them did not grow to annealing twins. Possibly the increased activity of the atoms at the annealing temperature permitted most of the twin faults to be absorbed.

Summary

encies toward annealing twin formation than copper. The twins per grain ratio is essentially constant for copper and 70-30 alpha brass over a wide range of deformation temperatures and annealing temperatures, except for the alpha brass at 600°C where an appreciable reduction in this ratio was found.

Acknowledgment

The interest, encouragement and counsel of Professor C. H. Mathewson are gratefully acknowledged. The phosphorous deoxidized electrolytic copper was furnished by the Scovill Manufacturing Co., Waterbury, Conn., and the 70-30 alpha brass rod by the American Brass Co., Torrington, Conn. Dr. Robert Maddin read and criticized the manuscript.

The Yielding and Strain-aging of Carburized and Nitrided Single Crystals of Iron

HARRY SCHWARTZBART,* Junior Member, and JOHN R. LOW, JR.,† Member AIME

Introduction

Annealed, polycrystalline, low carbon steel exhibits a phenomenon known as the "yield point." If such a steel is loaded in tension, the load increases steadily with elastic strain, drops suddenly, fluctuates about some constant load value for a time and then rises with further strain. The load at which the sudden drop occurs is called the "upper yield point"; the load at which deformation proceeds at constant load is known as the "lower yield point"; the amount of elongation at constant load is termed the "yield point elongation."

Deformation which occurs during the yield point elongation is heterogeneous in nature, deformed metal existing next to undeformed metal. The drop in load from the upper yield point is concurrent with the formation of a band of deformed metal which usually appears at a stress concentration such as a fillet and at an angle of approximately 45° with the direction of pull. As deformation proceeds during the yield point elongation, the deformed region grows until the entire specimen has been strained an amount equal to the strain in the first band.

A phenomenon very often associated with the yield point is that of strain aging. Aging in steels may be of two types: quench aging, or precipitation hardening, and strain-aging. Strain aging differs from precipitation hardening in that if the metal is merely strained instead of given a solution anneal and quenched, it then undergoes changes in properties similar to those

observed in quench aging.

The yield point effect and strain aging are most markedly exhibited by low carbon steel, but have been observed in other alloys. Numerous explanations for the mechanisms of both phenomena have been advanced, but the evidence for the acceptance of any of the hypotheses is incomplete. One of the explanations of the yield point phenomenon frequently proposed is that there exists a honeycomb of grain boundary material that supports the load above the yield strength of the ferrite and that when this network ruptures, the ferrite flows with no increase in load. This notion was first advanced by Dalby¹ in 1913 and has been since put forward in more concrete form by many investigators. The testing of this hypothesis was, in part, the object of the present investigation. Similarly, the mechanism by which

strain aging occurs remains to be explained. Presumably, it is a precipitation hardening phenomenon similar to quench aging, the precipitation being initiated by strain. However, it is not known whether the process is a solution and precipitation effect or a change in solubility due to strain.

One obvious method of determining whether or not the yield point is a grain boundary phenomenon is to determine if single crystals exhibit a yield point. Low and Gensamer² have shown that carbon and nitrogen are responsible for the yield point and aging in steel and that these effects can be eliminated by the removal of these elements through wet hydrogen purification. Single crystals that have been grown in wet hydrogen treated material must then be recarburized or re-nitrided in order to evaluate the effect of grain boundaries. In the present investigation, single crystals of iron which had been annealed in wet hydrogen to remove the carbon and nitrogen were cut into two specimens having the same orientation with respect to the tension axis. Of these, one specimen was pulled in tension in the wet hydrogen treated state and the other was carburized or nitrided and tested similarly. All the crystals were examined for a yield-point and strain aging.

The grain boundary hypothesis for the explanation of the yield point in steel has been tested only indirectly previously. Arrowsmith,³ Andrew and Lee,⁴ Edwards and Pfeil,⁵ Fell,⁶ Ludwik and Scheu,⁷ Winlock and Leiter⁸ and others found a decrease in proportional limit and yield point effect with an in-

FIG 1—Orientations of the single crystals.
Checks were made on Crystals 6 and 7.

crease in grain size. Edwards and Pfeil⁵ did not find a yield point in a single crystal of hydrogen purified mild steel, but the carbon and nitrogen were probably absent in their crystals. Single crystals of iron grown in wet hydrogen purified mild steel were tested under dead weight loading by Gensamer and Mehl⁹ who found that at stresses at which yielding occurs, the rate of elongation is initially low, then increases, and finally decreases to zero. They point out that this behavior will

be observed in material whose flow curve shows a drop in load at yielding. Gensamer¹⁰ tested similar crystals in a conventional tension testing machine; these crystals showed no drop in load but the initial plastic elongation took place at substantially constant load. These crystals had not had all of the carbon and/or nitrogen removed. Holden and Hollomon¹¹ in an investigation contemporaneous with the present one found no yield point in carburized or nitrided single crystals of iron. A point-by-point comparison of the experimental procedures used in the two investigations reveals the following principal differences:

1. Holden and Hollomon's crystals were made from aluminum killed stock while those of the present investigation were made from silicon killed material. The presence of an excess of aluminum might conceivably affect the behavior of nitrided single crystals by combining with the nitrogen but would not be expected to have a similar effect in the case of carburized crystals.

2. Holden and Hollomon used $\frac{1}{8}$ -in. ga. length SR-4 strain gauges for measuring strain while the present authors used 1-in. Tuckerman gauges. The shorter gauge length used by Holden and Hollomon would tend to obscure the "drop in load" feature of the yield point, but the "strain at constant load" portion should have been observed if present.

3. Holden and Hollomon's single crystals were slowly cooled following carburizing and nitriding, whereas the present authors' were air cooled. There is no apparent reason why this difference in cooling rate should lead to the reported differences in yielding behavior.

Up to the present time, no satisfactory explanation has been found for the differing results of the two investigations.

Experimental Procedure

The single crystals used in this investigation were prepared at Carnegie Institute of Technology by the strain-anneal method and are similar to the crystals which were used in the investigation of Gensamer and Mehl⁹ discussed earlier. Details of their fabrication can be obtained from their paper. The bar stock from which the crystals were grown contained 0.36 pct Mn, 0.010 pct P, 0.025 pct S and 0.09 pct Si and it is to be expected that the single crystals contained substantially the same amounts of these elements.

Six crystals were used in the present investigation, all of which were initially in the form of $\frac{3}{8}$ in. diam round bars. No X ray examination for crystal perfection was made; however, macroscopic examination after etching to develop etch-pits did not reveal any occluded crystallites or evidence of gross crystal imperfections.

The crystals were found to contain 0.003 pct carbon when analyzed by the low pressure vacuum fusion method; hence it was not known if they had been adequately decarburized to eliminate the yield point and strain aging since this amount of carbon lies near the limit found by Low and Gensamer for these two characteristics in polycrystalline specimens. Therefore, further wet hydrogen treatment was performed on the crystals after machining into tensile specimens for this investigation.

The orientations of all the crystals were determined and the orientations

FIG 2—Grips used in single crystal tension tests.

FIG 3—Stress-strain curves for polycrystalline specimens 11 and 23.
As wet hydrogen treated.

of the tension specimen axes are plotted in the stereographic triangle of Fig 1. The method used to determine orientations was similar to the etch pit technique described by Barrett and Levenson.¹² Since the success of this investigation depended on the fact that the specimens being compared were cut from the same single crystal and, therefore, had the same orientation it was not essential that the orientation be determined with a high degree of accuracy.

Each of the single crystal bars was sawed in half longitudinally and two halves ground flat to give two specimens having the same orientation with respect to the tension axis. The specimens consisted of simple rectangular prisms with no reduced section. The dimensions of the specimens before testing varied from 0.1505 in. to 0.3036 in. wide by 0.0416 in. to 0.0578 in. thick. The length of the specimens between the grips varied from 1 $\frac{5}{16}$ in. to approximately 2 $\frac{1}{2}$ in.; the distance between grips was the same for all specimens from a single crystal. All of the specimens were composed of a single crystal between the grips except the specimens of Crystal 2 which had a grain boundary about $\frac{3}{4}$ in. from one grip. In this case the knife edges of the extensometer did not contain the grain boundary between them but were placed entirely on one crystal at least $\frac{1}{4}$ in. away from the grain boundary. The results obtained on Crystal 2 are consistent with those for the other crystals.

After machining, the specimens were heated to 720°C in tank hydrogen, then held for the amounts of time shown in Table 1 in an atmosphere of hydrogen containing water vapor in the percentages noted in the same table, and air cooled. The flow rate of gas through the furnace was 2 cfhr which is equivalent to a linear flow rate of 0.037 fps. The specimens after cooling in air were coated with a thin oxide film; this was removed in 10 pct HNO₃. In some cases there was a layer of fine crystals on the specimens caused by recrystallization of the machined (cold worked) surfaces. These fine crystals were removed by alternately etching in 10 pct HNO₃ and grinding, using extremely light passes.

It can be seen in Table 1 that not all the crystals received identical wet hydrogen treatments. Since it was observed in the cases of Crystals 2, 3 and 4 that a slight yield point indication was obtained on the uncarburized

FIG 4—Composite stress-strain curves for polycrystalline specimens 11 and 23. As wet hydrogen treated.

| Temp.—720°C; linear flow rate—0.037 fps | | |
|---|--|---|
| Crystal No. | Time of Treatment, Hr | Vol. Pct H ₂ O |
| 2, 3, and 4 | 6 $\frac{3}{4}$ 8 $\frac{1}{2}$ | 10 (saturator at 46°C) 3 (saturator at room temperature) |
| 5 and 7 | 8 $\frac{1}{2}$ + 11 $\frac{3}{4}$ | 3 (saturator at room temperature) 10 (saturator at 46°C) |

specimen in the test after aging it was desirable to learn if longer treatments would reduce the carbon and/or nitrogen to the level of complete elimination of yield point indications either before

or after aging. The treatment in which the saturator was at room temperature was a mistake. The furnaces used for all the heat treating were of the nichrome wound electric resistance type with a Sillimanite tube as the heating chamber.

One of the specimens cut from Crystals 2, 3, and 4 was heated to 700°C in tank hydrogen, then held for 10 min. in an atmosphere of hydrogen saturated with normal heptane at 22°C (this will yield a mixture containing about 5 pct heptane), and air cooled. These conditions and short carburizing time were chosen to prevent the introduction of a second phase in the crys-

* The specimens cut from this crystal were given insufficient wet hydrogen purification.

tals. The flow rate of gas through the furnace was 1.5 cfhr or 0.028 fps.

To make certain the carburization was effective, control specimens of wet hydrogen purified polycrystalline low carbon rimmed steel (ASTM grain size 8) were treated with the single crystals. The control specimens had been cut from 0.036 in. sheets previously wet hydrogen purified at 720°C for 4 hr and known to be free of either a yield point or aging. Specimens adjacent to the control specimens in the original wet hydrogen treated sheet were tested in tension and examined for yield point and strain aging. From the stress-strain curves reproduced in Fig 3, 4, and 5, it is evident that the control specimens had received sufficient purification to eliminate the yield point and strain aging and that if they exhibited these effects after carburization they were due to that carburization. The polycrystalline specimens were standard ASTM sheet specimens. Air cooling after carburization produced a scale on the specimens which was removed with 10 pct HNO₃. No recrystallization, due to carburizing, could be observed on the etched specimens.

The train used for nitriding was as follows: Tank hydrogen → CaCl₂ → empty Erlenmeyer flask at liquid air temperature → activated charcoal at liquid air temperature → liquid NH₃ saturator at -77°C → nitriding furnace. The CaCl₂ and liquid air trap were driers; the activated charcoal at -190°C was necessary for the removal of hydrocarbons present in tank hydrogen;² the ammonia saturator was maintained at -77°C to keep the concentration of ammonia in the hydrogen low enough (6 pct) to prevent the formation of iron nitrides.¹³ A venturi type flow meter between the hydrogen tank and the CaCl₂ drier indicated the flow rate which was maintained at 1.5 cfhr or 0.127 fps. The nitriding procedure was as follows: The single crystal specimens and, as in the case of carburization, the polycrystalline control specimens were placed in the cold furnace; dried ammonia vapor was introduced into the saturator where enough was condensed for one run; the specimens were heated to 500°C in hydrogen passing through the above train but by-passing the ammonia saturator; once at temperature the saturator was cut into the system by a suitable arrangement of glass T's and pinchcocks. Nitriding proceeded for 3 hr at 500°C after which the specimens were air cooled. This produced a light scale

which was removed in 10 pct HNO_3 . No recrystallization, due to nitriding, could be observed on the etched specimens.

Tensile tests were made on a Baldwin-Southwark 60,000 lb hydraulic machine with an Emery weighing system. Load readings were taken on the 1200 lb range dial of the machine to the nearest pound. The rate of head movement on all tests was approximately 0.0022 in. per min. Elongations up to about 1.6 pct were measured with a Tuckerman optical extensometer on a 1 in. ga length with a precision of 2×10^{-6} in. per in. Light punch marks were placed 1 in. apart on the single crystals and 2 in. apart on the polycrystalline specimens; elongations greater than 1.6 pct were then measured to the nearest 0.01 in., using dividers.

Axiality of loading was achieved through the use of modified Robertson shackles wherein the load is applied at the point of contact between a hardened steel plane and a steel ball. That part of the shackle which contained the threaded end of the specimen, adapter or grip could be shifted in relation to the stress axis by means of positioning screws thus correcting for any eccentricity in the system. A test for axiality is the requirement that upon a change in load in the elastic range all four sides of the specimen elongate or contract the same amount. In this investigation the specimens were aligned to the extent that, upon a change in load in the elastic range, the changes in length of any two opposite sides were within 6 pct of each other.

The polycrystalline specimens were gripped in Templin sheet grips. A special set of grips was used for the single crystals; these are illustrated in Fig 2. The specimen was fastened in the grips with the latter out of the tensile machine; the complete assembly as shown in Fig 2 was then transferred to the testing machine, with great care being exercised to avoid bending of the specimen.

The single crystals before testing had all been etched in 10 pct HNO_3 . The only difference in treatment of the two specimens cut from any single crystal was the carburization or nitriding treatment. All crystals were strained 5.0 pct, the load removed and the specimen (still in the grip assembly) was placed immediately in an oven at 200°C for 3 hr after which they were pulled again and examined for strain

FIG 8—Composite stress-strain curves for polycrystalline nitrided specimens 14 and 22.

FIG 9—Stress-strain curves for single crystal 2.

aging and yield point.* The polycrystalline specimens, with one exception, were strained 10 pct before aging. In all cases, the amount of strain applied before aging was sufficient to pass through the yield point; that is, the load-elongation curve was rising steadily at the time the load was released. The amount by which the curve is raised by the aging treatment is a measure of the extent of strain aging. This was expressed as a percentage determined as follows:

$$\text{Pct strain aging} = \frac{A - B}{B} \times 100$$

where A is the yield strength in the test

* Davenport and Bain¹⁴ and Kenyon and Burns¹⁵ have shown that a marked increase in hardness occurs at this temperature in not too long an interval of time; further, that the curve of hardness vs. time has a flat maximum so that some variation in time of aging will not appreciably influence the results.

after aging and B is the stress at the time the load was released in the initial test. An exception was made in the case of the polycrystalline specimens as wet hydrogen treated. The yield strength in the test after aging was actually lower than the stress at which the load was released before aging. This was due to recovery during aging. These specimens are indicated in the results as having shown "zero" per cent strain aging. The yield strength was defined as the stress at which extensive plastic flow began; where a drop in load or constant load elongation was exhibited the stress at the lower yield point or at the level of constant load elongation was taken as the yield strength. As an arbitrary measure of the height of the flow curve after some strain, the stress at 4 pct strain was used. The ef-

FIG 10—Composite stress-strain curves for single crystal 2.

FIG 11—Stress-strain curves for single crystal 3.

fect of carburization or nitriding on the load-elongation curve is expressed as the percentage by which the treatment raised the stress at 4 pct strain. In the foregoing definition of terms the stress was computed to the nearest 500 psi based on the initial cross-sectional area. Microscopic examination of carburized and nitrided single crystals showed no evidence of a second phase.

Experimental Results

Stress-strain curves for the polycrystalline specimens are reproduced in Fig 3 to 8 and for the single crystals in Fig 9 to 20.

Some of the data derived from the stress-strain curves as well as carbon

and nitrogen analyses are tabulated in Table 2.

Discussion of Data

Examination of the stress-strain curves for the polycrystalline specimens (Fig 3 to 8) reveals results consistent with those found by Low and Gensamer.² Wet hydrogen purified material exhibited no yield point either in the initial stress-strain curve or in the test following aging. Further, no strain aging was observed. Carburizing at 700°C for 10 min. in hydrogen bearing 5 pct of normal heptane was sufficient to restore the upper yield point and some 3 pct constant load elongation at the lower yield point. The specimens

exhibited 17 pct strain aging and pronounced upper yield points in the test after aging. Nitriding at 500°C for 3 hr in hydrogen bearing 6 pct of ammonia had similar effects. These specimens exhibited upper yield points and approximately 2 pct constant load elongation. About 17 pct strain aging is observed and in the test following aging there is a constant load elongation of 2 pct; one specimen also exhibited an upper yield point in this test.

Specimens from three single crystals, 2, 3 and 4, were carburized. The uncarburized specimens from Crystals 2, 3 and 4 in every instance exhibited the following behavior: no upper yield point in the initial test nor in the test after aging; practically no constant load elongation in the initial test but 0.5 pct constant load elongation in the test after aging; no strain aging. The 0.5 pct of constant load elongation in the test after aging is consistent with the information reported by Edwards, Jones and Walters¹⁶ and Edwards, Phillips and Liu¹⁷ that low carbon steels given prolonged wet hydrogen treatment followed by slow cooling gave no yield point indication; the same samples after straining and aging gave a pronounced yield point. It was this information plus similar data for nickel, silver and copper age hardening alloys that led them to conclude that the yield point is caused by precipitation of a solute on slip planes.

Examination of the stress-strain curves of the carburized specimens of Crystals 2, 3 and 4 reveals the following information: strain aging is exhibited in every instance; Crystals 3 and 4 show a drop in load in the initial curve and Crystal 2 shows a drop in load in the test after aging; in the initial part of the curve obtained in the test after aging Crystals 3 and 4 show a low slope which rises as the test proceeds.

In summary, the uncarburized specimens of Crystals 2, 3 and 4 exhibit neither strain aging nor yield point phenomena except in the tests after aging where a slight constant load elongation was observed; the carburized specimens all show yield point indications in the initial loading as well as strain aging. Every specimen showed greater yield point indications in the test after aging than before aging.

Specimens from single Crystals 5, 6 and 7 were nitrided and the yield point and strain aging characteristics compared to non-nitrided specimens from the same crystals. It should be noted in Table 1 that the specimens cut from

Crystal 6 received insufficient wet hydrogen purification; this is evident from the yield strength and the stress level of the flow curve of the non-nitrided specimen. The non-nitrided specimens of Crystals 5 and 7 exhibited behavior similar to the non-carburized specimens of Crystals 2, 3 and 4 except for a drop in load in the initial test of Crystal 5. Examination of the stress-strain curves for the nitrided specimens reveals the following information: strain aging is exhibited in all instances, a greater amount of strain aging being observed in the nitrided specimen of Crystal 6 than in the non-nitrided specimen; a pronounced drop in load is observed in the test of Crystal 5 after aging; some constant load elongation is exhibited in most of the tests, the test of Crystal 6 after aging showing a gradually decreasing load for some 4 pct elongation after which the load rises with strain.

In summary, with the exceptions of the specimens cut from Crystal 6 which received insufficient wet hydrogen purification and a slight drop in load in the initial test of Crystal 5, the non-nitrided specimens showed no strain aging and no yield point effects while the nitrided specimens exhibit both phenomena. In the case of the exceptions noted more strain aging and yield point effect were observed in the nitrided specimens than in the non-nitrided. With one exception, greater indication of yield point behavior was exhibited in the test after aging than in the test before aging.

Addition of carbon or nitrogen had the same action, that is, to produce yield point effects and strain aging in single crystals of iron where they did not previously exist or increase these effects where they had previously existed. Aging a strained specimen, whether in the wet hydrogen purified state or carburized or nitrided, gave a greater yield point effect than in the original test.

There appeared to be no correlation between orientation and yield point behavior. A satisfactory examination of such a correlation would require a much larger number of specimens than was used in this investigation.

Microscopic evidence showed no evidence of a second phase either in the carburized or nitrided crystals. The carburized crystals contained 0.005 pct carbon and the nitrided crystals 0.007 pct nitrogen (see Table 2). The higher carbon and nitrogen contents (0.010 pct and 0.014 pct respectively) of the

FIG 12—Composite stress-strain curves for single crystal 3.

FIG 13—Stress-strain curves for single crystal 4.

FIG 14—Composite stress-strain curves for single crystal 4.

carburized and nitrided polycrystalline specimens result from the fact that these specimens were 0.036 in. thick

while the single crystals were somewhat thicker (over 0.050 in. for the carburized crystals and about 0.043 in.

FIG 15—Stress-strain curves for single crystal 5.

FIG 16—Composite stress-strain curves for single crystal 5.

FIG 17—Stress-strain curves for single crystal 6.

for the nitrided crystals). The nitrogen analyses indicate that the polycrystalline specimens may have had higher nitrogen contents as purified than the single crystals. The presence of grain boundaries may have influenced the diffusion coefficient of carbon or nitro-

gen in alpha-iron; whether they do or to what extent is not known.¹⁸

In the light of the present data the grain boundary hypothesis as stated previously for the explanation of yield point behavior becomes untenable. Definite yield point effects have been

observed in single crystals. These effects are not as marked in the single crystals as they are in the polycrystalline specimens. Further, it has been demonstrated that single crystals which have been strained and aged show greater yield point indications after aging than before aging. This observation supports the hypothesis of Edwards, Phillips and Liu¹⁷ that the yield point is due to precipitation of solute on slip planes. Further evidence in favor of this hypothesis is the fact that mild steel as quenched exhibits no yield point but will do so if allowed to age at room temperature.^{7,19} It is suggested by the present authors that the material responsible for the yield point is in either one of two states: first, a transition state between solution and discrete second phase or, second, has just precipitated in a fine dispersion and has not had sufficient time to agglomerate. The first possibility is analogous to the transition phase which causes maximum hardness in quench aging. The second possibility was suggested by Edwards et al.

The observation is cited above that the single crystals did not exhibit yield point behavior to as great a degree as the polycrystalline specimens. It is possible that, as in quench aging, precipitation takes place preferentially at slip planes and/or grain boundaries, the latter being the more powerful in promoting yield point behavior. This would explain an increasing yield point effect with decreasing grain size as found by numerous investigators.

Conclusions

1. A yield point (drop in load and elongation at constant load) has been found in single crystals of iron containing small amounts of carbon or nitrogen. The yield point in polycrystalline iron is therefore not due to the presence of a grain boundary film as has been frequently suggested.

2. Strain aging is observed in single crystals of iron containing small amounts of carbon or nitrogen. The yield point effect is increased by strain aging in single crystals just as it is in polycrystalline irons.

Acknowledgments

The authors wish to thank Mr. F. Garofalo for his stimulating discussion and suggestions, the use of the specially

designed grips and much material assistance.

Messrs. H. F. Shannon and W. J. Frederick of the Carnegie-Illinois Steel Corporation arranged for the chemical analyses reported and their kind assistance is gratefully acknowledged.

The Effect of Oxygen, Nitrogen, and Hydrogen on Iodide Refined Titanium*

ROBERT I. JAFFEE,† Member AIME, and I. E. CAMPBELL†

Oxygen, nitrogen, and hydrogen are known to be absorbed by titanium at elevated temperatures. Ehrlich¹ reports that about 30 at. pct oxygen can be dissolved in solid solution by alpha-titanium. Nitrogen also has a solid solubility in alpha-titanium, but there is no information as to its extent. The solid solubility of hydrogen in titanium also is high. Kirshfeld and Sieverts² report 50 at. pct soluble, while Hägg³ reports about 33 at. pct hydrogen to be soluble in alpha-titanium.

General statements are made in the literature that oxygen, nitrogen, and hydrogen embrittle titanium, but no quantitative measurements have been made of the effect of these gases on the mechanical properties of the metal. One reason for this is the lack of a source of titanium pure enough to be considered a suitable starting material. Iodide-refined titanium, made by thermal decomposition of titanium iodide vapor on an incandescent wire,⁴ contains small amounts of carbon, silicon, iron, and aluminum, but is very low in oxygen, nitrogen, and hydrogen content, and, therefore, was used in this work.

A further reason for the lack of quantitative information on the effect of these gases, particularly oxygen, is the difficulty of carrying out accurate analytical determinations at the low concentrations of interest in this work.

For this reason, the oxygen, nitrogen, and hydrogen were added in measured amounts as gases, and diffused into the titanium, to avoid the necessity of chemical analysis.

The purpose of the work reported here was to isolate and measure the effects of oxygen, nitrogen, and hydrogen on titanium of the highest purity available at the time. The concentrations studied were 0.25, 0.5, and 1 at. pct in each case.

Experimental Work

One-half of a 24-in. hairpin of iodide-refined titanium was available for this work. The rod was approximately

0.25-in. in diam and had a 0.003-in. tungsten core. From chemical and spectrographic analyses, the purity of the sample was estimated to be between 99.80 and 99.95 wt pct. The chief impurities (aside from the tungsten core) were iron (0.04 pct), silicon (0.01–0.1 pct), aluminum (0.05 pct), carbon (0.03 pct). The tungsten core constituted 0.05 pct by weight of the sample. Although some alloying undoubtedly took place between the tungsten and the titanium during the deposition reaction, the core remained substantially intact in the deposited metal.

The initial average hardness of the titanium as deposited was 105 Vickers (10-kg load). The maximum hardness was 116 Vickers and the minimum 91 Vickers. The metal was somewhat harder than that currently being obtained by the iodide process, that is, 75–90 Vickers.

The rod was cold swaged to 1/4-in. diam and then cold rolled in diamond shaped rolls to about 0.080-in. square, using reductions of 15 pct in area per pass. The 0.080-in.-square wire was cut into 6-in. lengths for the preparation of the alloys by the gaseous absorption and diffusion method.

ADDITION OF OXYGEN, NITROGEN, AND HYDROGEN TO TITANIUM

A modified Sieverts' absorption apparatus, shown in Fig 1, was used in

Cleveland Meeting, October 1949.

FIG 1—Gas-absorption and diffusion apparatus for producing alloys of iodide titanium with oxygen, nitrogen, and hydrogen.

adding each of the gases to the titanium samples.

Measured quantities of gas at known temperature and pressure were added to the evacuated system in each case, and the desired alloys were prepared by absorption and diffusion of the gas in the heated metal.

The samples were pickled for about 5 min. in hot, 10 pct sulphuric acid, then washed, dried, and rinsed successively in carbon tetrachloride, absolute alcohol, and acetone.

The samples were weighed to ± 0.0001 g and then suspended in an induction furnace. A No. 34 B and S ga. platinum wire was used to hold the sample.

The gas burette was flushed thoroughly with the gas to be used and then filled. Pure oxygen was obtained by slowly heating a 4:1 (by weight) mixture of C.P. potassium chlorate and manganese dioxide. The oxygen was passed through ascarite to remove traces of carbon dioxide, and then

through a dry-ice alcohol trap and magnesium perchlorate to remove water vapor. Tank nitrogen (99 pct) and tank hydrogen (99+ pct) were used as sources of those gases. Both were purified by being passed over copper turnings at 700°C and then dried in the same manner as the oxygen.

After the sample was sealed in place, the apparatus was evacuated, filled with argon, and re-evacuated. This process was repeated, but the sample tube was flamed during the final evacuation to remove occluded gas. The required volume of gas (calculated from the sample weight, barometric pressure, and temperature) was then admitted to the system from the burette and the pressure within the system redetermined. The induction-heating coil was energized, and the sample maintained at the desired temperature until the gas was completely absorbed. Additional "soaking" periods were used to obtain uniform distribution of the gas through the sample.

Data on the thermal treatment of the samples are summarized in Table 1. The oxygen was absorbed at 1000°C (observed temperature). Absorption was quite rapid and was virtually complete in 5–10 min. The samples were maintained at 1000°C for 60–80 min., however, to obtain uniform distribution of the oxygen throughout the sample.

The nitrogen was also absorbed at 1000°C but the absorption rate was much slower, 1.5–2 hr being required for complete absorption at the higher concentrations. These samples were removed as soon as absorption was complete, and given separate diffusion treatments at 1075–1100°C in vacuo.

Hydrogen, unlike nitrogen and oxygen, is absorbed reversibly, and at the higher concentrations, absorption takes place more rapidly at lower temperatures. At 650–700°C, concentrations up to one atomic per cent were completely absorbed in 2–4 min. Additional "soaking" periods were used as indi-

* This comprises only the diffusion treatment for the Ti-N specimens, and does not include the absorption treatment.

† Specimen No. 1 was harder than either Specimen 12 or 13, and, therefore, may not be considered as pure as those specimens. The values of 47.7 and 47.8 microhm-cm probably are better values for iodide-refined titanium.

cated in Table 1 to insure complete diffusion.

DISCUSSION OF ABSORPTION

When large amounts of oxygen or nitrogen are admitted to the absorption chamber, oxide or nitride films are formed, which act as barriers that retard the absorption process. Slow continuous addition of these gases at low pressures, therefore, gives higher overall absorption rates than step-wise additions at higher pressures. In the case of nitrogen, which is absorbed slowly, the last traces of gas may be only adsorbed, rather than absorbed, but if the sample is maintained at temperature for a few minutes, the adsorbed gas will diffuse into the metal.

Hydrogen, unlike nitrogen and oxygen, is best absorbed at higher pressures, and, for higher concentrations than those reported here, the procedure should be modified to the extent that a measured fraction of this gas should be absorbed, rather than the entire addition. At higher hydrogen concentrations, an appreciable equilibrium pressure of hydrogen is developed at temperatures where the absorption is quite rapid, and to take advantage of the rapid absorption at the higher temperatures, the hydrogen should be added at pressures up to one atmosphere and the extent of the hydrogen absorption regulated by controlling the absorption time.

FIG 2—Effect of oxygen, nitrogen, and hydrogen on the electrical resistivity of iodide titanium.

The absorption technique used in this work provides an accurate method for adding precise quantities of hydrogen, nitrogen, and oxygen to titanium, and where the limits of solid solubility are not exceeded, homogeneous alloys can be obtained in reasonable diffusion times. Weight changes obtained upon addition of these gases to the titanium check well with the calculated weights of the gases added.

Since the amounts of gases added in this work were small, the evaporation of titanium did not introduce a significant error. The loss of titanium was insignificant in itself, and for short

absorption times the absorption of gases by titanium vapor and volatilized titanium can be neglected.

The specimens prepared were 6 in. long and approximately 0.080-in. square. Their compositions and physical condition are summarized in Table 1. For convenience, in the rest of this report the nominal compositions, 0.25, 0.5, and 1 at. pct, will be referred to, rather than the actual composition.

From each 6-in. specimen, a length 4.25 in. long was cut for determination of density, cross-section, and electrical conductivity. This was then cut into two pieces, one 3 in. long for a tensile test, and the other about 1 in. long for a cold-rolling test. The remainder of the original specimen was reserved for microscopic examination.

DENSITY, RESISTIVITY

Density at room temperature was measured by determining the displacement of the specimen, 4.25 in. long, in distilled water at a known temperature.

Results of density measurements are tabulated in Table 1. The cross-sections of the specimens were determined by calculation from the weight, length, and density of the specimens. Resistance of a 3.5-in. length of the specimen was determined at 25.6°C (78°F) by means of a Kelvin bridge. Values of the electrical resistivity were calculated from the resistance, cross-section, and length, and are given in Table 1

FIG 3—Unalloyed titanium. Unetched. 1000 X. FIG 4—Unalloyed titanium. Annealed at 1000°C. 250 X.

 FIG 7—1 at. pct oxygen. Annealed at 1000°C. 250 \times .
 Figures reduced one-seventh in reproduction.

There is no significant change in the density of the alloys containing oxygen and nitrogen with alloy content. There may be a change in density with hydrogen content, as indicated by the high value for the 0.25 at. pct H alloy in Table 1, but this is rather doubtful. Most of the densities fall between 4.51 and 4.53, which are in excellent agreement with the values reported in the literature.

A plot of the electrical resistivity data is shown in Fig 2. Both oxygen and nitrogen raise the resistivity of titanium to the same extent per atomic per cent, the increase in resistivity being almost linear. This is in agreement with the reported solid solubilities of these elements in alpha-titanium. Hydrogen to one atomic per cent does not appear to affect the electrical resistivity.

The values of 47.8×10^{-6} ohm-cm and 47.7×10^{-6} ohm-cm found for the electrical resistivity at 25.6°C are in fair agreement with the value of 47.5×10^{-6} ohm-cm at 20°C reported by van Arkel.⁵ Using the value of the temperature coefficient of resistance given by van Arkel, 0.00425 per °C, the two experimental values become 46.7×10^{-6} ohm-cm and 46.6×10^{-6} ohm-cm at 20°C. Magnesium-reduced

titanium has an electrical resistivity at 20°C of 56×10^{-6} ohm-cm, according to Dean, Long, Wartman, and Anderson,⁶ and 55.4×10^{-6} ohm-cm according to Greiner and Ellis.⁷ This higher resistivity is undoubtedly caused in part by dissolved oxygen and nitrogen, as indicated here by the potent effect of these elements on the electrical resistivity.

MICROSTRUCTURE

Cross-sections and longitudinal sections of each of the specimens were examined metallographically. No apparent lack of homogeneity was observed in the cross-sectional structure of any of the alloys, apart from the diffusion area around the tungsten core.

Polishing was done on wool laps

using 0-2-micron diamond abrasive suspended in carbon tetrachloride. In order to bring out a true structure on the titanium specimen and the softer of the alloys, it was necessary to polish and etch alternately three or four times to eliminate the worked surface. Etching was done by swabbing for 5-10 sec with an etchant containing 3 pct concentrated HNO_3 , 1.5 pct con-

concentrated HF, balance water (volume percentages).

In the as-polished condition, all of the specimens showed a number of gray inclusions. Fig 3 shows a typical field of these inclusions at 1000 × magnification. The identity of these inclusions is not known. It is suspected that they may be titanium silicide.

Unalloyed titanium in the condition as cooled from 1000°C has the

structure shown at 250 × in Fig 4. It consists of large plates of alpha-titanium arranged in a somewhat Widmanstättenic manner; the alpha plates probably formed along the octahedral planes of the high-temperature cubic phase on cooling through the transformation temperature.

The structures of alloys with 0.25, 0.5, and 1 at. pct oxygen are shown in Fig 5, 6, and 7, respectively. The

general effect of oxygen seems to be to refine the structure, making the plates of the alpha-titanium smaller, and the Widmanstätten arrangement more regular.

The structures of the nitrogen-bearing alloys are shown in Fig 8, 9, and 10. The effect of nitrogen on the microstructure is to promote the formation of needles of alpha titanium. This is a most interesting observation, be-

FIG 14—Average cross-sectional hardness values for alloys of iodide titanium with oxygen, nitrogen, and hydrogen.

cause this needle-like Widmanstätten structure is characteristic of most magnesium-reduced titanium that has been annealed above the alpha-beta transformation temperature. The conclusion may be drawn that the needle-like structure found in most less pure kinds of titanium is caused by nitrogen in solid solution.

The structures of the hydrogen alloys are shown in Fig 11, 12, and 13. The alloys containing 0.25 and 0.5 at. pct of hydrogen are not materially different from unalloyed titanium. They show large Widmanstätten plates of alpha-titanium. Origin of the markings shown inside the grains in Fig 12 is not known. They may be transitional structures developed by the grinding and polishing-etching operations. Fig 13, for the one atomic per cent hydrogen alloy, shows an arrangement of line markings which resembles a Widmanstätten precipitate. The origin of these marks is not known. It is doubtful that they are a second phase based on hydrogen, because one atomic per cent is very far from the accepted solid solubility of hydrogen. Another peculiar thing about them is that they cross over grain boundaries in some cases. A

possibility is that they are a kind of deformation twin, originating in the preparation of the specimen for metallographic examination.

MECHANICAL PROPERTIES

Hardnesses were taken on a cross-section of each of the specimens to see whether there was any difference in hardness between the surface and center. The only specimen for which this condition existed was No. 6, 0.5 at. pct nitrogen. Here the surface had a hardness of 245 Vickers, and the center had a hardness of 170 Vickers. This may be associated with its shorter diffusion time of 47 min. at 1075°C. Specimen No. 5, one atomic per cent nitrogen, was diffused 90 min., at 1080°C, and was uniform from center to surface.

A plot of the average cross-sectional hardness of the specimens versus their compositions is shown in Fig 14.

Tensile tests were run on 3-in. lengths of each specimen, observations being made of ultimate tensile strength and per cent elongation in one inch. Results of these tests are shown in Fig 15.

The hardness data for oxygen and nitrogen alloys are somewhat erratic, but indicate that oxygen and nitrogen

FIG 15—Tensile strength and elongation of alloys of iodide, titanium with oxygen, nitrogen, and hydrogen.

FIG 16—Work-hardening curves of iodide titanium and titanium-oxygen, titanium-nitrogen, and titanium-hydrogen alloys.

Table 2 . . . Cold Reductions Causing Edge Cracking

| Specimen No. | Composition, Atomic Per Cent | Initial Hardness, Vickers (10-kg load) | Rolled to, Inch | Per Cent Reduction | Edge Cracked |
|--------------|------------------------------|--|-----------------|--------------------|--------------|
| 12 | 100 Ti | 116 | 0.004 | 95 | No |
| 2 | 0.25 O | 164 | 0.004 | 95 | No |
| 3 | 0.5 O | 214 | 0.024 | 70 | Yes |
| 4 | 1 O | 242 | 0.032 | 60 | Yes |
| 7 | 0.25 N | 184 | 0.040 | 50 | Yes |
| 6 | 0.5 N | 202 | 0.032 | 60 | Yes |
| 5 | 1 N | 262 | 0.046-0.048 | 30-40 | Yes |
| 10 | 0.25 H | 110 | 0.004 | 95 | No |
| 9 | 0.5 H | 109 | 0.004 | 95 | No |
| 8 | 1 H | 107 | 0.004 | 95 | No |

harden titanium to about the same extent, with nitrogen possibly having a greater effect. The positions of oxygen and nitrogen are reversed at the 0.5 at. pct composition, and it is believed that this is not the actual case. As was pointed out in previous discussion, the 0.5 at. pct nitrogen alloy was incompletely diffused, and the soft center probably was given too much weight in the straight arithmetic average taken of the cross-sectional hardnesses.

Hydrogen up to one atomic per cent does not increase the hardness of iodide titanium, and actually appears to decrease it slightly, although the apparent decrease may have been caused by hardness variations in the

iodide titanium rod itself.

Nitrogen has a considerably greater strengthening effect on titanium than oxygen when added in concentrations of up to one atomic per cent, and correspondingly decreases the ductility to a greater extent. The hydrogen alloys appear to be slightly stronger and more ductile than the titanium control specimens. Since the elongation of pure titanium is generally found to be closer to 40 pct in one inch, rather than the 30 pct average found with the control specimens, the high ductilities of the hydrogen-containing specimens are more likely the result of specimen variation rather than any interaction of hydrogen with the impurities in the

titanium. Thermodynamic considerations indicate that reactions between hydrogen and the residual oxygen, nitrogen, or carbon in the titanium would not proceed to an appreciable extent under the conditions of preparation of the hydrogen-containing alloys.

COLD ROLLING CHARACTERISTICS

One-inch lengths of each of the 0.080-in.-square specimens were cold rolled at 0.001 in. per pass until edge cracking started, or to the minimum thickness the mill could roll, which was 0.004 in. Surface Vickers hardnesses (10-kg load) were taken at steps of 10

pct reduction in thickness to 70 or 80 pct reduction if the cold rolling could be carried that far.

The reductions at which edge cracking became apparent are shown in Table 2 for the various specimens.

Pure titanium and the Ti-H alloys all were very soft initially and cold rolled to 0.004 in. or 94 pct reduction without edge cracking. The 0.25 at. pct oxygen alloy, which was 164 Vickers initially, also could be rolled to 95 pct reduction without edge cracking. A completely different result was found with the 0.25 at. pct nitrogen alloy, which was 184 Vickers originally, only slightly higher than the oxygen alloy. It could be rolled only to 50 pct reduction before edge cracking. This indicates that nitrogen content is more deleterious to cold rollability than oxygen content of either the same amount or the same hardness. This adverse effect of nitrogen compared to oxygen on cold rollability shows up also in the edge-cracking limits at the 0.5- and 1-at. pct levels.

WORK-HARDENING CURVES

The work-hardening curves found for the various alloys are plotted in Fig 16.

The work-hardening curve of the unalloyed titanium (Specimen No. 1) is approximately a straight line. An 80 pct reduction about doubles the original hardness. The strip was rolled to 95 pct reduction, but determinations of hardness values were stopped at 80 pct.

Oxygen alloys had work-hardening curves very similar to the unalloyed titanium, apart from the different hardness levels from which the alloys start. This means that the relative ratios of hardness to the Ti-O alloys to titanium are unaffected by cold working.

The work-hardening data of the Ti-N alloys had some peculiarities. First, there was an initial decrease in the hardness, which was followed by

a normal increase in hardness on further cold working. This anomalous decrease in hardness may have been caused by a hard surface shell of nitrogen-rich material, which, once thinned out by a cold reduction, permitted the hardness indenter to penetrate to the softer core. The second peculiarity of the work-hardening curves of the Ti-N alloys is the closeness of the curves for the 0.5 at. pct and 1 at. pct nitrogen alloys. This does not seem to be in line with the results of the tensile tests. Actually, since the 1 at. pct nitrogen alloy only had 3 pct elongation and showed signs of edge cracking at 30 pct reduction, there probably were not enough data obtained on sound metal from which to draw conclusions. The normal part of the curve for the 0.25 at. pct nitrogen alloy shows about the same characteristics as unalloyed titanium, with the hardness level about 15 Vickers points above the curve for the 0.25 at. pct oxygen alloy.

The work-hardening data for the titanium hydrogen alloys were so similar to unalloyed titanium that no attempt was made to separate them in Fig 16.

Summary

Oxygen and nitrogen up to one atomic per cent increase the electrical resistivity at 25.6°C linearly from 48 to 56 micro-ohm-cm, while hydrogen in the same concentration has no effect.

Dissolved nitrogen changes the microstructure of annealed titanium from large Widmanstätten plates to long, narrow Widmanstätten needles. Oxygen refines and makes the Widmanstätten arrangement of the alpha-Ti plates more regular. Hydrogen does not change the microstructure of titanium at 0.25 at. pct concentration, but at higher concentrations, some markings of unknown origin appear.

Nitrogen has a more potent hardening and strengthening effect than oxygen and decreases the ductility to a greater extent. Hydrogen, when added

to one atomic per cent either does not affect the mechanical properties, or slightly improves both the strength and ductility.

Unalloyed titanium, the titanium-hydrogen alloys, and the 0.25 at. pct oxygen alloy could be cold rolled to 95 pct reduction without edge cracking. The higher oxygen alloys edge cracked at 60-70 pct reductions, while the nitrogen-containing alloys had considerably less capability for cold rolling without edge cracking. Work-hardening curves were determined for the various specimens.

The Origin of Annealing Twins in Brass

ROBERT MADDIN,* Junior Member, C. H. MATHEWSON,† Member, and WALTER R. HIBBARD, JR.† Junior Member AIME

According to conventional crystal mechanics, a face-centered cubic single crystal slips on the system $\{111\} \langle 110 \rangle$ which receives the highest shear stress in terms of the stated orientation of the stress axis of the crystal.¹ However, in brass, the slip process is never as simple as this conventional analysis indicates. There is always a second cooperating plane which contains the same slip direction as the primary plane.^{2,3} There is still another cooperating slip system commonly called the conjugate system³ previously observed to function with considerable lag only after the rotation due to the action of the first plane had produced a symmetrical condition of equal shear stress on the two systems.

In the 1943 Campbell Lecture,⁴ a slip mechanism was outlined in which the $\{111\}$ planes moved step-wise in two adjacent $\langle 112 \rangle$ directions integrating into the $\langle 110 \rangle$ slip direction. "... the slipping process would be visualized as a succession of steps 30° to the right and left of the resultant, microscopically observed, slip direction; a first step setting up the twinned configuration in the single spacing involved and an ensuing slip returning the atoms to the untwinned configuration while completing a fully integrated $\langle 110 \rangle$ movement."⁴ This process is shown diagrammatically in Fig 1 which shows two close packed layers of atoms at a slip site. A movement of the full circles through the "valleys" into the adjacent sites would produce a twin configuration with respect to the open circles. The term, "twin fault," seems most appropriate to define this faulted condition of the lattice.

Annealing twins in face-centered cubic metals may arise from preformed nuclei which could be described as twin faults produced by the first movement of this two stage slip process.

FIG 1—Hypothetical mechanical twin formation by deviation of slip from "foothills" into "valleys" of close-packed face-centered cubic structure.

(Mathewson⁴)

However, it is clear that this kind of slip does not take place so as to embrace a measurable number of adjacent planes because careful X ray examination has not conclusively shown the existence of ponderable twin lamellae (as in the case of Neumann bands in the body-centered ferrite).

In view of the imponderable character of these hypothetical twin faults, the search for evidence of their existence seems restricted to indirect methods.

The most obvious experimental technique serving this purpose is the determination by micrographic and X ray methods of the alignment of the composition planes of annealing twins with

the former slip planes in axially strained and recrystallized single crystals. In previous attempts of this sort not all of the annealing twins could be traced to slip planes known to be operative in the conventional sense and hence evidence appeared negative or inconclusive. With the discovery of additional slip systems^{2,3} operating in conjunction with the major system of highest resolved shear stress in axially strained brass it became apparent that the simple technique outlined above might be re-employed with more gratifying results.

If, on annealing single crystals of alpha brass previously strained in tension, twins are found with their composition planes parallel to all three operative slip planes and with no participation of the fourth plane there is good evidence in favor of the existence of twin faults and of the two stage slip process.

Experimental Procedure and Results

Single crystals of alpha brass of the 70-30 composition were grown by solidification from the molten state.

FIG 2—Stress-elongation curves for three tapered single crystals.

After a long homogenization treatment (24 hr at 800°C), central sections, about 3 in. long, were carefully tapered in a lathe to provide a linear decrease in diameter from 0.5 to 0.32 in. along the gauge length. Etching in 1:1 aqueous nitric acid solution removed the cold work, and subsequent electrolytic polishing² provided a smooth metallographic surface. Back-reflection Laue photograms were made at four different radial positions to insure that all cold work had been removed and to determine the orientation of the crystals. Fine black lines were painted on each specimen at one-quarter inch intervals; these intervals were carefully measured on a Zeiss metallograph at a magnification of X77.

The crystals were extended with a constant rate of loading until slip lines became visible within one-half inch of the large end of the gauge length. The average of repeated measurements of the gauge intervals using the same magnification gave the elongation per one-quarter inch interval. Stress values were derived from the maximum load to which the crystals were extended and the areas of the specimen after extension. A series of four back-reflection Laue photograms per gauge interval gave reorientation values in terms of λ and χ , where λ is the angle between the specimen axis and the primary slip direction and χ is the angle between the specimen axis and the primary slip plane. These values were used to calculate the elongation in the usual manner,⁵ viz.

$$\frac{l_1}{l_0} = \frac{\sin \chi_0}{\sin \chi_1} \quad [1]$$

where χ_0 and χ_1 are the original and final angles, and l_0 and l_1 are the original and final gauge lengths. The data relating stress to the measured and

calculated elongation are plotted in Fig 2. In the case of Specimen BR-4-T only measured values are shown because the reorientation was too small to yield reliable calculations.

Using the values of λ and χ determined by means of X rays, shear stress resolved in the primary $\langle 110 \rangle$ direction of slip and on the primary plane of slip was calculated by means of the usual formula.⁵

$$S = \frac{P}{A} \sin \chi \cos \lambda \quad [2]$$

where P is the load; A , the area; S , the resolved shear stress; and χ and λ , as previously designated. The shear was calculated from the two expressions;

$$t = \frac{\cos \lambda_1}{\sin \chi_1} - \frac{\cos \lambda_0}{\sin \chi_0} \quad [3]$$

and

$$t = \frac{1}{\sin \chi_0} \left(\sqrt{\left(\frac{l_1}{l_0} \right)^2 - \sin^2 \lambda_0} - \cos \lambda_0 \right) \quad [4]$$

Formulas 2 and 3 gave resolved shear stress-shear values from the X ray data and formulas 1, 2 and 4 gave resolved shear stress-shear values from the measured data. These resulting shear strengthening curves are shown in Fig 3.

The rotations of the lattice, Fig 4, are plotted from the back reflection X ray determinations of the orientations along the tapered gauge length.

These tapered specimens afforded an excellent opportunity to study the progressive formation of slip lines because of the increasing amount of deformation from zero per cent at one end to beyond 24 pct at the other. A series of representative micrographs of slip lines in Spec. Br-2-T is shown in Fig 5-16 together with the approximate extension at the respective position on the tapered specimen.

The first observable slip line, Fig 5, appeared very thin at X500. Even at this initial stage, slip on the conjugate plane is evident. Cross-slip, although not shown in Fig 5, was nevertheless present in the first group of slip lines at a different point of observation (cf Fig 17) and is shown in Fig 10 after an

FIG 3—Resolved shear stress-shear curves for tapered single crystals.

FIG 4—Stereographic projection showing the axes rotations of the tapered single crystals pulled in tension.

elongation of 4 pct. With increasing deformation, new slip lines appear adjacent to former lines, in such locations as to widen the original band, and produce the familiar clustered appearance.

At about 4 pct elongation (Fig 10) the clusters are sensibly wide and at the higher deformations, perhaps beginning with about 16 pct elongation, the clusters have overlapped to form a continuous bundle of lines which have lost their sharpness because of the proximity of many lines in and out of sharp focus.

The specimens were next wrapped loosely in thin, dead soft, brass foil of the same composition and annealed for

one hour at 800°C. After furnace cooling, they were etched in nitric acid solution followed by ferric chloride. Microscopic examination revealed that the composition planes of the many twins were nearly parallel to one of three different slip planes of the parent lattice. This structure is shown in Fig 18 and 19. The genesis of the twins was proven by X ray examination in which the X ray beam was positioned partly on the twin and partly on the adjacent material. Crystallographic analysis of the resulting double set of Laue spots gave the stereographic plot shown in Fig 20 which is typical of many such analyses made to establish the twin

relationships.

In all three specimens, recrystallization was found to extend to the location representing a minimum value of shear of about 0.22 (see Fig 3). The amount of recrystallization observed in Spec. Br-3-T was small in comparison detected in the other two specimens. Nevertheless, grains in all three specimens were large and replete with annealing twins, all of which produced boundary traces which corresponded to one of three composition planes.

From close examination of Fig 19, it may be seen that the twins seem to grow along the former slip lines.

By repolishing the specimens and

* Angles determined from stereographic analyses

† Angles measured on metallograph

FIG 5-10—Slip lines in Specimen BR-2-T corresponding to various amounts of extension.

Except in the case of Fig 5, all micrographs were taken at a position around the conical surface of the specimen which would lie in a plane perpendicular to the plane containing the specimen axis and the primary slip direction. Stress axis vertical. Reduced one fifth in reproduction. $\times 500$

again straining in tension, slip lines were made to reappear in the unrecrystallized structure at the head of the taper and in the new grains. By aligning the composition planes of the twins with the slip lines in the parent lattice, that is, by moving the field from twin to original lattice along the axis of the specimen, these composition planes were identified as approximately parallel to former primary slip lines, cross-slip lines and conjugate slip lines. Several cases of close alignment are shown in Fig 21-26. In other cases, misalignments amounting to as much as 11° were found. Attempts were made to locate twins close to the unrecrys-

tallized structure so as to avoid misalignments due to the rotation of the lattice during the plastic extension preceding recrystallization. Since this was not always possible, stereographic analysis was used to correct the cases of misalignment by plotting the angles at the point of observation between the slip lines and the stress axis before and after straining. A typical construction is shown in Fig 27 from which the angles between the axis and the reoriented primary and cross slip planes respectively shown in column 3 of Table 1 were derived.

If observations of slip lines are made in the plane AP , then the trace of the

slip plane (primary) in the plane of observation is at the intersection of the two planes, viz., at P , and the angle AP , equal to 40° , is the measured angle between the axis and the trace of the slip plane.

If twins arising from this slip plane are observed in a part of the specimen in which the change of orientation during this extension is represented by moving the axis from A to A' , the angle $A'P$, equal to 24° will now represent the angle between the axis and their composition plane provided the latter occupies the new position of the slip plane with respect to the axis. In the case of the cross-slip plane, the

FIG 11-16—Slip lines in Specimen BR-2-T.

Positions similar to those represented in Fig 6-10. Stress axis vertical. Reduced one fifth in reproduction. $\times 500$

angle of its trace to the axis in the plane of observation AC , is equal to 10° and is practically unaltered in the new position $A'C$ after rotation. This is about 6° less than the measured angle between the axis and the twin composition plane. Similar constructions were made for the conjugate plane in this specimen and for all twinning planes in the other two specimens, BR-3-T and BR-4-T, as reported in Table 1.

The maximum error in alignment shown in Table 1 is 11° . There are four recognized sources of error in the technique used; (1) a possible 2° error in the X ray determinations from which changing positions of the stress axis were ascertained, (2) a possible 6° error introduced by the taper of the speci-

mens, (3) a possible error associated with the translation of the specimen on the microscope from the position of annealing twin to the position of the corresponding slip lines, and (4) an undetermined error in measuring the trace of the cross-slip lines because of their minute lengths. One or all of these possible errors may explain the observed deviations from perfect alignment.

Finally, the orientations of a number of grains in each specimen were determined by the Laue back-reflection technique. One group of these orientations together with the orientation of the parent lattice are shown in stereographic projection in Fig 28. These projections were drawn with the X ray beam at B , the center of the diagram,

that is, normal to the exposed grain surfaces. In the diagram, P refers to the parent lattice and the numbers refer to the specific grains outlined in Fig 29. In all of these recrystallized grains, there was an octahedral pole close to one of the octahedral poles of the parent lattice (ringed in the projection) as observed in the strained and annealed condition and in the neighborhood of the recrystallized grain, viz., at position 2 in Fig 29. It is doubtful if the term "recovered lattice" can be used in this connection since subsequent experiments have shown that the upper (least strained) part of a tapered specimen which showed no recrystallization at 800°C may recrystallize if annealed at a still higher temperature (900°C). In spite of the difference of

FIG 17—Appearance of first slip lines in Specimen BR-2-T.

orientation, which may amount to as much as 12° , between this octahedral plane as observed in the parent lattice and in the recrystallized grain, it is believed to be a common plane in the sense that it constituted the nucleus in the parent strained crystal from which the new grain grew, with a certain adjustment of orientation to the environment of strain, by a rotational process either identical with or akin to the one recently described by Kronberg and Wilson.⁶

The subsequent analytical technique was simply to perform the small rotation of the projection which was necessary to bring the so-called "common" octahedral pole in the recrystallized grain into exact coincidence with its position in the unrecrystallized structure, followed by the substantial rotation around this "common" pole which brought about complete coincidence of the two structures.

The results are shown in Table 2.

While this subject cannot be regarded as closed in view of the present meager understanding of lattice strain

in relation to recrystallization, the present experiments permit the following conclusions:

The recrystallized structure after substantial plastic deformation contains an octahedral plane obviously derived from a similar plane in the parent lattice.

The new grain does not grow out into the matrix without change of orientation or as an unreoriented twin. Its structure may be derived from the original structure by a rotation around the polar axis of the common octahedral plane.

Many of these rotations approximate the 22° and 38° rotations found by Kronberg and Wilson⁶ in their analysis of annealing twins in the secondary recrystallization of copper.

The rotation is presumably the response of the crystal to an activating strain which seems to be generally associated with twin faulting.

The Kronberg and Wilson analysis shows how a gross rotation of the lattice around an octahedral pole, for example, may be attained by small

coincidental movements of the atoms chiefly around sites which have retained their identity after the specific gross rotation. It is possible in this way to start with a twin fault and by thus moving the atoms around coincidence sites in neighboring planes on one side of the fault, to grow a new crystal whose octahedral planes are rotated 22° with respect to those of the original crystal, while growth on the other side of the fault by a similar process produces a twin structure whose poles are rotated 38° in the opposite direction around the composition plane. Other rotational possibilities are pointed out by Kronberg and Wilson. The present experiments are not wholly consistent with this crystal-geometrical pattern but offer strong evidence that the annealing twins in brass grow from twin faults parallel to the active slip planes by some rotational process of reorientation determined by the condition of strain in the plastically deformed crystal.

Inherent in the theory of two stage slip is the consideration that movement of the atoms in an octahedral slip plane determined by an active component of stress along the close packed strings of atoms $\langle 110 \rangle$ if forced to deviate into the interatomic valleys $\langle 112 \rangle$, (as shown by the arrows in Fig 1) which are assumed to be the paths of least resistance, would introduce a condition of residual stress in the hypothetical twin fault directing its alignment with the active component of shear stress. Thus the twin-faulted regions could be focal points of activation for a rotational process of atomic rearrangement and the observed annealing twins would be reoriented according to some pattern generally consistent with the reported observations.

Discussion of Results

Previous observations^{2,3,7,8,9} of lack of strain hardening in 70-30 brass single crystals during the early stages of deformation, are not in agreement with the present observations of strain hardening summarized in Fig 3. However, an explanation for these phenomena may be sought in the method of straining. In most of the experiments cited,^{2,3,7,8} the authors strained their crystals repeatedly but released the load after each individual extension. In the present investigation, the crystals attained their total extension

under one application of load. This points to the possibility that a recovery process may be responsible for the lack of strain hardening previously observed and that under continuous loading, the normal process of strain hardening occurs.

A significant observation from the resolved shear stress-shear curves of Fig 3 is the constant rate of strain hardening in all three orientations investigated, up to a value of shear of about 0.22. Beyond this strain the rate of hardening appears to be a function of orientation. And this value of shear was the minimum one at which recrystallization occurred at the selected annealing temperature (800°C). The exact significance of this shear value (0.22), that is, whether or not it is constant for all orientations at all temperatures of deformation and recrystallization must be determined by further study.

The composition planes of the annealing twins formed on recrystallization of the axially strained tapered crystals of 70-30 brass were always approximately parallel to one of the active slip systems. The orientation of a new grain or part of a twin could be derived from the orientation of the parent crystal in the strained condition by rotation around their "common"

FIG 20—Stereographic plot of two sets of Laue spots showing the twin relation between the spots.

The twinning pole is labeled as *P* and its plane is shown as the arc in the plot.

octahedral pole, derived from the primary, cross or conjugate slip plane, but a certain small angular adjustment was necessary to bring the "common" pole into exact coincidence.

An attempt was made to rationalize the rotational reorientation by postulating a condition of residual stress at a twin fault due to the nature of the slip process. According to this view, the twin-fault is a preformed nucleus which activates a crystal-geometrical process of atom regrouping by rota-

tional shearing movements similar to those already reported by Kronberg and Wilson.⁶

In order to distinguish between the failure of the tapered specimens to recrystallize at 800°C in the regions which had been slightly deformed and their copious recrystallization in the severely strained regions, the following suggestions are offered on the basis of a two-stage slip process. Here a twin fault is produced in the first stage and a return to the original structure in the second stage (always accompanied by a certain configuration of residual stress).

In the early stage of slip, the atoms may be considered to move freely into their appropriate positions so as to complete the two $\langle 112 \rangle$ movements and result in an essentially unchanged lattice. However, during the later stages of the slip process, apparently beginning at about 0.22 shear, the lattice may be so strained or fragmented by the action of the three cooperating slip systems that the primary configuration can no longer be attained.

Summary

1. In the tensile straining of tapered 70-30 brass single crystals, variable de-

Stress axis vertical. Reduced one fifth in reproduction. $\times 500$

formation along the specimen axis afforded the opportunity to record micrographically the progress of formation of slip lines.

2. Calculated resolved shear stress-shear curves show that there is slight strain hardening up to a value of shear amounting to about 0.22. At this point there is a marked rise in the rate of strain hardening which now appears to be a function of orientation.

3. Recrystallization on annealing at 800°C begins at a minimum value of shear of about 0.22.

4. Annealing twins are formed with composition planes parallel to the former operative primary, cross and conjugate slip planes, with no other relationships observable.

5. Recrystallized grains are found to

be related to the former parent lattice as reoriented after straining by a rotation about the pole of an operative primary, cross or conjugate slip plane. The variable amount and direction of rotation are apparently due to the difference in the strain configuration throughout the specimen.

These observations are interpreted as strong evidence in favor of coordinated $\langle 112 \rangle$ slip.

Acknowledgments

The authors' thanks are due to the New Jersey Zinc Co. of Pennsylvania for financial support which made this investigation possible and to the American Brass Co. for supplying the brass

from which the single crystals were grown.

Some Observations on the Rate of Secondary Recrystallization in High Purity Copper

ANNA M. TURKALO* and DAVID TURNBULL †

It is well known that if copper that has been severely cold-worked by rolling (70-98 pct) is heated to high temperatures a small number of large grains are formed at the expense of the fine grained structure that appears upon primary recrystallization.

Dahl and Pawlek,¹ Cook and MacQuarie,² Ward,³ and Boas and Bowles⁴ have studied this phenomenon in copper. It has been reported as taking place with measurable velocities in the temperature range 700–1080°. Boas and Bowles have reported that the time necessary for the transformation is of the order of days at 700°C. According to Ward³ the number of secondary grains which appear in OFHC

copper decrease with increasing perfection of cubical alignment after primary recrystallization; also the perfection of cubical alignment increases with decreasing grain size prior to the final reduction.

In this investigation two heats, *A* and *B*, of especially high purity copper (99.999 pct) supplied by the American Smelting and Refining Co., were used. The behavior of samples prepared from

the two heats was qualitatively very similar providing that the grain sizes established prior to the final reduction were about the same.

We observed that in specimens prepared from bars which were relatively coarse grained prior to final reduction secondary recrystallization took place at a rapid rate at temperatures as low as 500°C. This is about 200–300°C lower than the temperature necessary to obtain fairly rapid transformation in OFHC copper. A 0.22 in. thick rectangular bar of lot *B* was cold-reduced 60 pct by straight rolling and given a penultimate annealing treatment at 250°C. Following this it was cold-reduced 90 pct and heated to various temperatures in the range 450–1040°C. The specimens were about 8 mils thick

and $\frac{1}{2}$ sq. in. in area. They were placed in quartz specimen holders and heat treated in a hydrogen atmosphere. In general the secondary transformation was completed after about $\frac{1}{2}$ hr at 550° and in most specimens was partially complete after 6 hr at 500°C. From this it may be inferred that the linear growth rate in the transformation is at least 5×10^{-5} cm per sec at 500°C. Fig 1 shows photographs of typical specimens after heating for various times at the specified temperatures. Transformation is complete in all excepting those heated at 500°C. It is evident that the final grain size markedly increases with decreasing temperature so that at the lowest temperature only one grain appears per specimen.

Decreasing the penultimate reduction and increasing the penultimate annealing temperature tend to lower the temperature at which secondary recrystallization takes place rapidly. A sample of *B* given a penultimate reduction of 50 pct, penultimately annealed at 350°C, and cold-reduced 90 pct, exhibited complete recrystallization to several grains after 6 hr at 500°C.

In agreement with work on OFHC copper our results indicate that the tendency of secondary grains to form decreases with increasing perfection of cubical alignment. However, we have observed that the rate of appearance of secondary grains in specimens having a high degree of cubical alignment is greatly accelerated by very small strains. Specimens were prepared from heat *A* as follows: a 0.164 in. thick rectangular bar was cross-rolled to a reduction of 50 pct and annealed at 400°C for 3 hr. Because of the smaller initial grain size the grain size resulting from this treatment was much less than that obtained in lot *B* after the penultimate annealing treatments described above. The bar was cold-reduced 90 pct by straight rolling and cut into specimens having the same size as those from lot *B*. Rapid heating of these specimens to 1040°C and holding for 4 hr produced complete secondary recrystallization to 1 or 2 grains per sq. in. However, specimens recrystallized by heating at 500°C for one hour or heated slowly (200°C per hr) showed no evidence of beginning secondary recrystallization after periods of 16 to 20 hr at 1040°C provided that care was taken not to strain the specimens after primary recrystallization. If the specimens were strained by small amounts after primary recrystallization

FIG 1—Copper samples annealed at various temperatures after 90 pct reduction.

a. 500°C—1 hr. b. 750°C—1 hr. c. 500°C—6 hr. d. 900°C—1 hr. e. 550°C— $\frac{1}{2}$ hr. f. 1040°C—1 hr. g. 600°C—5 min.

the secondary transformation was complete in nearly all specimens after 4–6 hr at 1040°C. Strains as small as 0.085 pct maximum, produced by bending the specimen over cylinders of a given radius of curvature, were sufficient to cause this effect. These results are in agreement with those obtained independently by Kronberg and Wilson⁵ on OFHC copper although they apparently used much larger strains to accelerate the secondary transformation.

The orientations of the secondary crystals which we observe are in fair agreement with those reported for copper by Boas and Bowles.

Our results demonstrate that the rate of the secondary transformation is much more rapid in high purity copper than in OFHC copper. At 500°C the rate of growth of secondary grains in high purity copper is at least 10^5 times greater than the value obtained for OFHC copper by extrapolation of Ward's results. Also it may be concluded that the secondary transforma-

tion takes place very slowly if at all in specimens exhibiting a high degree of perfection in cubical alignment. Secondary transformation is accelerated (or perhaps initiated) in the latter specimens by strains as small as 0.085 pct. The orientation of the grains thus obtained is very near that of the grains appearing in the secondary transformation of samples rapidly heated to the transformation temperature from the cold-rolled state. These results will be reported more completely in a subsequent paper.

Optical Temperature Scale and Emissivity of Liquid Iron

MINU N. DASTUR* and NEV. A. GOKCEN†

In metallurgical process industries a knowledge of true melting and casting temperatures is very essential for increasing the operating efficiency as well as improving the quality of the finished product. Optical pyrometers are widely used for the purpose because of their cheapness and ease of operation. It is an unfortunate fact, however, that this mode of measuring temperature entails a source of severe error inasmuch as with all non-black bodies, the temperature observed is always below the true temperature owing to deficient emissive power. Hence, the need for emissivity correction arises.

In 1913 Bidwell¹ obtained emissivity values of 0.36–0.48 for a temperature range of 1520–1800°C. He measured the true temperature of molten iron by sighting into a carbon cavity immersed in the iron under an atmosphere of hydrogen. In 1914 Burgess² determined the emissivity of a smooth surface of liquid iron free from oxide to be 0.37 under an atmosphere of hydrogen. He claimed to have attained an accuracy of within 5°C at 1500°C with an optical pyrometer using monochromatic light. He reported that no difference appeared to exist between the emissivities of pure iron and of steels containing considerable percentages of carbon, nickel or manganese; nor was there any appreciable variation of emissivity with temperature from 1530 to 1571°C. Wensel and Roeser³ found an emissivity value of 0.4 for temperatures above 1375°C for cast iron.

The average emissivity value for carbon steels reported by Leiber,⁴ Todd,⁵ Hase⁶ and Umino⁷ range from 0.4 to 0.45.

Knowles and Sarjant⁸ made an extensive study of emissivity of molten iron and steel over a wide range of workshop and laboratory conditions. Observations of true temperature were made with immersion thermocouples, and correlated with apparent temperatures indicated by optical pyrometer readings taken on the pouring stream

as it passed over the lip of the crucible. The emissivity of Armco iron was shown to be of the order of 0.4, rising slightly with increasing temperature. But for plain carbon steels containing up to 1.0 pct carbon the emissivity was shown to fall slightly with increasing temperatures. The results of their investigation are in agreement with those of Guthmann,⁹ Naeser,¹⁰ Spencer,¹¹ Todd⁵ and Hase⁶ in regard to the relation between emissivity and temperature for plain carbon steels. However,

Goller¹² has found a rise of emissivity with increasing temperature for the same steels. Results of several investigations are given in Fig 1.

Measurement of True and Apparent Temperatures

The necessity for an accurate optical temperature scale for liquid iron in studies of gas-metal equilibria led to this investigation. Experimental measurements were carried out in the induction furnace used by Dastur and Chipman¹³ in their studies of the reaction of hydrogen with oxygen in liquid iron. The furnace as modified for this work is shown in Fig 2. The atmosphere of the furnace was a mixture of purified argon with hydrogen containing a small controlled amount of water vapor. Gases were preheated by means of a platinum-10 pct rhodium resistance coil. The stream of hydrogen sweeping across the surface of molten iron vir-

FIG 2—Furnace set-up for the determination of the true temperature scale and emissivity of liquid iron.

tually eliminates errors resulting from the presence of iron vapor except at temperatures approaching or above 1900°C. The charge consisting of about 90 g of pure iron was melted in a pure beryllia crucible especially designed for this purpose as shown in Fig 2.

Two sets of simultaneous temperature readings were obtained: (1) Optical top temperature reading by a sensitive optical pyrometer and bottom reading from a properly assembled thermocouple touching the top of the crucible cavity (see Fig 2A). (2) Top and bottom optical temperature readings by using the crucible cavity as a perfect black body for the bottom optical pyrometer (see Fig 2B).

After the charge was molten both the optical pyrometer and the thermocouple were frequently checked against the melting point of electrolytic iron in hydrogen which was taken as 1535°C. Thermocouples were also rechecked after each experimental run.

Optical temperature readings were taken when the gas preheating coil was hot and cold, and it was observed that the coil temperature has no effect upon temperature readings.

Each pair of simultaneous readings was taken when a constant and steady

temperature had been obtained by adjusting the power input from a high-frequency source. Temperature measurements obtained by stepwise heating were in agreement with those of stepwise cooling, indicating the absence of temperature gradient between the molten metal and thermocouple.

THERMOCOUPLES

Calibrated platinum-platinum rhodium and tungsten-molybdenum thermocouples were used in this investigation for establishing the true temperature of liquid iron. Platinum-platinum rhodium thermocouples were used only up to 1660°C and tungsten-molybdenum thermocouples were used from 1650 to 1900°C.

Schulze¹⁴ found that tungsten, molybdenum and tantalum were well suited for measuring high temperatures when the couples had been annealed at a higher temperature to assure constant thermal powers. The use of these thermocouples in liquid steel has been described by Taylor and Chipman.¹⁵

Schofield and Grace¹⁶ in using platinum-platinum rhodium thermocouples reported that no effect was noticed in the thermocouple output from the field

present in the induction furnace. The tungsten molybdenum thermocouples used in this investigation were from a batch calibrated and used by Potter¹⁷ and were rechecked against the melting point of pure iron.

OPTICAL MEASUREMENTS

The optical systems at the top and bottom of the furnace contained identical sight glasses and prisms and two optical pyrometers which had previously been calibrated against a standard instrument from the Bureau of Standards. No temperature difference was observed upon interchanging pyrometers or sight glasses and prisms. Since the hollow tip in the center of the crucible was more than three times longer than its diameter, it presented a perfect black body condition for the measurement of the true temperature of melt, corrected for absorption and reflection from the intervening optical system and the gas column. After checking the melting point of iron, temperatures as high as 1900°C were recorded by taking simultaneous readings with optical pyrometers from top and bottom.

Results

The results of true and apparent (optical) temperature readings are plotted in Fig 3 which gives a calibration for the given experimental conditions. Such scales may lend themselves to the evaluation of transmissivity and emissivity values, as will be shown presently.

Transmissivity correction is obtained from the optical bottom temperature reading when emissivity is unity. For this purpose the melting point of electrolytic iron (1535°C) was used as reference temperature and the transmissivity evaluated by the Wien-Planck equation:

$$\ln(E\alpha) = \frac{c_2}{\lambda} \left(\frac{1}{T_i} - \frac{1}{T_a} \right)$$

E = Emissivity

α = Transmissivity

c_2 = Fundamental constant of Planck equation, 14,330 micron-degrees

λ = Wavelength of light used (0.65 micron)

T_i = True temperature °K

T_a = Apparent temperature °K

In the special case of the melting point of iron versus bottom optical reading the apparent temperature was 1748°K and the true melting point was

FIG 3—True temperature vs. observed (optical) temperature.

1808°K as measured by the platinum-rhodium couple. These values lead to a transmissivity of 0.65 which is considered constant within a temperature range of 1500–1900°C.

Once the transmissivity of the intervening optical system (sight glass and prism) was determined, the emissivity of liquid iron was calculated from observed top temperatures by the Wien-Planck equation using the experimental true and observed temperatures plotted in Fig 3. The scattering of the points in the emissivity plot of Fig 4 is of no great significance because even a slight error in the measurement of true or observed temperature will cause a relatively large change in the emissivity, since the logarithm of the emissivity is proportional to the difference in the reciprocal of the temperatures. An accuracy of $\pm 5^\circ\text{C}$ in observed temperature is equivalent to a change of ± 0.017 in emissivity values at 1600°C. Variation of the effective wavelength (λ) with temperature introduces a negligible error in emissivity values.

The total change in the emissivity of liquid iron over the temperature range of 1540–1900°C is from 0.42 to 0.50. The result of this investigation is presented graphically with the results of previous investigators in Fig 1 showing the inconsistency of the reported emissivity values. Variation of the emissivity of steels with temperature, investigated under plant conditions and reported by Sosman¹⁸ as 0.39 at 1425° and 0.50 at about 1650° agrees qualitatively with the present results.

Any correlation between the plant data and the emissivity is often much less accurate because of the presence of atmospheric disturbing factors as investigated by Hall¹⁹ and the surface condition of metal.²⁰

The emissivity of molten iron also varies with the addition of alloying elements. The effects of several elements have been reported rather inconsistently in the available literature. The only such element investigated here was vanadium which was found to have no effect upon the emissivity at concentrations up to 2 pct.

Acknowledgments

The authors wish to thank Professor John Chipman for suggesting the experimental method, Mrs. Virginia Mahaday for making the beryllia crucibles and Hans Elvander for assistance in the temperature measurements. This investigation forms a part of a study of the physical chemistry of steelmaking sponsored by the Office of Naval Research under contract N5 or-07816, Task Order XVI, NR-031-186.

Size Effects in Quenching High-purity, Precipitation-hardenable Alloys*

WALTER L. FINLAY,† Member AIME

Introduction

Size effects in quenching steel are particularly prominent and well recognized because of the existence of a critical cooling rate separating nucleation and growth transformations, as exemplified by the formation of pearlite, from the shear type of transformation characterizing the martensite reaction. The absence of a similar, sharply demarcating cooling rate is characteristic of precipitation hardening systems and size effects in these are correspondingly less prominent. This paper is concerned with a size effect in high-purity, precipitation-hardenable alloys which appears not to have been recognized previously. This effect is believed to result from the thermal fluctuations which inevitably occur in quenching a specimen of finite size into a cooling liquid rather than from the existence of a critical cooling rate.

QUENCHING "ANOMALIES"

The precipitation hardening literature contains many references to so-called anomalous quenching and aging results. By "anomalous", investigators usually meant that their alloys did not consistently harden on aging after quenching according to some anticipated pattern; not infrequently virtually no age hardening occurred with compositions known to be precipitation-hardenable.

Perhaps the most prominent series of anomalies was reported over a 15-year

period by Gayler and coworkers on aluminum-copper.^{1,2,3,4} Working with silver-rich copper alloy, Cohen⁵ secured some very interesting Rockwell F hardness changes of from 1-5 Rockwell points between the first peak and valley. Fink and Smith borrowed one of

Cohen's specimens and, following his heat treatment and quenching practice to the letter, secured⁶ very different results in which only one peak was obtained and in which the hardness level at the aging time of Cohen's first peak was 20 Rockwell F points higher.

Fink and Van Horn⁷ encountered serious deviations in age-hardening high purity aluminum-zinc alloys. They stated that "the discrepancies were larger than might be expected from possible experimental errors in the Brinell readings."

Geisler, Barrett and Mehl⁸ likewise encountered anomalous hardening results in aluminum-silver alloys, securing quite different age-hardening curves from two identical specimens. They stated that "the treatments of these samples had been the same, so that the different behaviors could be attributed only to accidental variations in the quenching practice."

FIG 1—12 pct Al-Zn age hardening and retrogression. Longitudinal specimens with 0.1 × 0.5 in. cross-section. 2 hr at 475°C; 10°C water jet quench. Each point the average of five determinations.

Cleveland Meeting, October 1949.

TP 2694 E. Discussion of this paper (2 copies) may be sent to *Transactions AIME* before December 1, 1949. Discussion is tentatively scheduled for publication in May 1950.

Manuscript received April 29, 1949; revision received July 5, 1949.

Interior center hardness.

The present paper presents the view that these anomalies may be associated with retrogression effected by the thermal fluctuations accompanying quenching. Accordingly, the retrogression characteristics of the 12 pct aluminum-zinc alloy used in the investigation

being reported are outlined in the following section.

RETROGRESSION

Retrogression is a term which has been applied⁹ to the curious behavior of

certain age-hardening alloys according to which a quenched alloy partially or completely aged at a lower temperature, at first softens appreciably before slowly hardening again at a higher temperature. Masling suggested¹⁰ that the smaller of the precipitation particles which were stable at the lower temperature went back into solution at the higher temperature before additional precipitation could occur so that the observed weakening occurred. This explanation now appears to be generally accepted as valid.

A marked retrogression has been reported¹¹ for binary aluminum-rich aluminum-zinc alloys. The dashed curve in Fig 1 is a reproduction from Ref 11 for the 100°C retrogression of 12 pct aluminum-zinc; the 90 and 120°C retrogression curves also plotted in this figure present new data.

The 12 pct aluminum-zinc alloy was employed for a large part of the present investigation. Its pertinent behavior may, in terms of Rockwell 15T hardness, be summarized as follows: 1. It

quenches to a hardness of 50–55. 2. At room temperature it ages to 76–78 in 0.1–0.2 hr, and stays unchanged at that level for at least 2 yr. 3. Retrogression from its room temperature peak of 76–78 has been shown from 70°C up to at least 120°C, and doubtless this behavior is even more marked at higher temperatures. Within the temperature range investigated, the bottom of the retrogression valley is reached in 1–10 hr, and extends to depths of 56–72, the higher the temperature the shorter the time to the valley and the greater its depth. As is characteristic of the retrogression reaction, the rise from the valley is much slower than the rate of initial precipitation hardening at room temperature even though the latter is lower.

The retrogression behavior of binary aluminum-copper alloys has been studied extensively and, in principle, is not dissimilar from that of aluminum-zinc, although it differs in details, principally in that longer times or higher temperatures are required for corresponding aging effects.

Commercially pure aluminum-base alloys also retrogress and industrial use is made of this.¹⁷ In general, however, commercially pure alloys retrogress more reluctantly than their high purity counterparts.

Experimental Work

The following materials were employed in the investigation:

1. High purity 12 pct aluminum-zinc
2. High purity 4 pct aluminum-copper
3. Commercial purity 24S aluminum alloy
4. Commercial purity 75S aluminum alloy.

The preparation of the first two is described in Ref 11; the last two were purchased in the form of $\frac{1}{8}$ in. diam rod from Alcoa.

QUENCHING DIFFICULTIES

Age-hardening anomalies of the kind mentioned in the introduction were encountered in attempting to precipitation-harden high-purity, 4 pct aluminum-copper and 12 pct aluminum-zinc creep specimens having a 0.4 in. diam by 7 in. gauge length, whereas $\frac{1}{8}$ in. thick discs cut from these specimens and solution heat-treated and quenched together with the creep specimens gave consistent room temperature aging

results. With the aluminum-zinc alloy, for example, a series of 10 individual Rockwell 15T hardnesses of 77 ± 1 were common with the $\frac{1}{8}$ in. thick discs. But individual Rockwell 15T hardnesses on either the surface or cross-section of 0.4 in. round specimens were almost always low and very erratic, a typical sequence of readings being 50–38–48–22–46.

Several different quenching procedures were tried in uniformly unsuccessful attempts to secure, in the 0.4 in. round specimens of 12 pct aluminum-zinc, the 76–78 Rockwell 15T hardness level very readily attained in $\frac{1}{8}$ in. thick discs of the same material merely by dropping them into water. A special quenching unit was then built as the ultimate in quenching effectiveness. This quenching apparatus consisted of two parts: a vertical tube furnace for solution heat treating; and, axially aligned with the tube, a vertical quenching fixture into which the specimen dropped directly by gravity. A single specimen was suspended in the central portion of the vertical tube furnace by means of a wire. After a sufficient period of solution heat treating, the wire was cut and the specimen plunged directly into the jet quenching fixture. The latter consisted of a 1 in. id brass tube 10 in. long with approximately 200 holes 0.050 in. in diameter drilled into it in a uniform pattern with centers $\frac{3}{8}$ in. apart and extending from one end of the fixture to the other. Water pressure of 60 psi gave rise to 200-odd jets which symmetrically struck the specimen as it dropped through the fixture. Jets were employed both submerged and not submerged.

The result of this ultimate effort in quenching 0.4 in. diam 12 pct aluminum-zinc was a Rockwell 15T hardness averaging in the neighborhood of 50—something of an improvement over air cooling, but still far short of the hardness obtained on thin disc specimens.

Several 0.4 in. diam, 4 pct aluminum-copper rounds and $\frac{1}{8}$ in. thick discs were then jet quenched with similar results to those obtained on 12 pct aluminum-zinc, although, in the case of the 4 pct aluminum-copper, the rounds were not so markedly inferior to the discs.

The foregoing results definitely indicated a size effect. As a practical measure, therefore, all subsequent work on 12 pct aluminum-zinc and 4 pct aluminum-copper was done on specimens with a maximum thickness of 0.1

in. In order to gain some insight into the phenomena, however, a series of partial immersion quenching tests was conducted.

PARTIAL IMMERSION QUENCHING

Two rectangular bars, one with a square cross-section, 0.4 in. on a side, and another with a rectangular cross-section 0.1 in. thick and 0.4 in. wide, were employed in these tests. The specimens were solution heat treated in the standard manner and then were rapidly transferred to the quench where, in a vertical position their lower ends were immersed in the quenching medium. These experimental conditions were set up in order to secure, in one specimen, a wide range of both thermal gradients and a wide diversity of thermal fluctuations, since it was felt that the explanation for the puzzling phenomena encountered must be associated with failure, in a given region of the specimen, to maintain a uniform rate of temperature decrease during quenching.

The square cross-section bar, $0.4 \times 0.4 \times 5.0$ in., was carefully machined with its bases precisely normal to the longitudinal axis. All surfaces were flat and were polished through No. 000 paper. A hole was then drilled through one end which thereafter became the top of the vertically-quenched specimen. Three specimens were made in this manner: one from high-purity 12 pct aluminum-zinc; one from commercial 75S; and one from commercial 24S. Each was individually placed in the vertical tube furnace and solution heat treated for 2 hr. It was then quickly placed vertically in quiet 10°C water with the lower end immersed until the entire specimen had cooled to a few degrees below room temperature. One hour after quenching, pencil lines were drawn on one side of the bar as shown in Fig 2A and hardnesses were determined at 0.1 in. intervals from bottom to top of the specimen at “edge” positions (0.1 in. in from the bar edge) and at the “midpoint” position (0.2 in. in from the bar edge). The specimen was then stored for 24 hr after quenching to 25°C and hardnesses were similarly determined on an adjacent side. The hardness patterns shown in Fig 2A and 2B were thereby obtained. Because of the care with which the specimen had been machined, it was possible to determine hardnesses on the bottom of the specimen in the nine positions sketched in Fig 2A.

FIG 3—100°C aging of Fig 2 specimen.

After quenching as detailed on Fig 2, aged at 100°C. Each point the average of 10 determinations on the surface in the region bracketed.

FIG 5—100°C aging of Fig 4 specimens.

After quenching as detailed on Fig 4, aged at 100°C. It was found, regardless of quenching medium and location on specimen, that after 24 hr at 100°C all hardness values were within 3 Rockwell 15T points of each other.

FIG 4—12 pct Al-Zn partial immersion quenching.

0.1 × 0.4 × 5 in. specimens; 2 hr at 475°C; quickly placed vertically for quenching—

○ Lower 1.6 in. in quiet 10°C water.

● Lower 1.6 in. in quiet 10°C oil.

○ Entire specimen in still 25°C air.

Each point a single hardness determination.

Hardnesses throughout the interior of the bar were then obtained by the following procedure: the specimen was clamped gently into a small vise; a line was scratched 0.1 or 0.2 in. from the end; the vise and specimen were immersed in 10°C water; by slow sawing with a fine jeweler's hack saw, a 0.1 or 0.2 in. thick specimen was cut from the end of the bar; by means of slow strokes from a clean, sharp, small-toothed file, the end of the bar specimen was squared up with the longitudinal axis; and, finally, the specimen and vise were removed from the water, the specimen was removed and hardnesses were again determined at the nine locations sketched in Fig 2A. The results of this investigation are shown in Fig 2C, 2D, and 2E. There is an excellent general correlation between the surface and interior hardnesses indicating that the necessary machining operations to secure the interior hardnesses were

carried out so that virtually no change in the actual hardnesses was effected by the machining operations. On the other hand, there are significant differences between the interior and surface hardnesses which fall into a consistent pattern when the data are analyzed from the standpoint of thermal-fluctuation-actuated retrogression and/or overaging.

The foregoing somewhat laborious procedure was carried out only on the 12 pct aluminum-zinc specimen since, as shown in Fig 6, the commercial aluminum alloys, 24S and 75S, were far less sensitive to whatever quenching variables were introduced by the test procedure and it was assumed that their interior hardnesses were the same as their surface hardnesses.

The data plotted in Fig 6 were determined one hour after quenching. Similar hardness determinations were made at intervals up to 500 hr after

quenching, resulting—in the case of both 24S and 75S—in a hardness increase of approximately 5 Rockwell 15T points uniformly along the length of the bar. Subsequent elevated temperature aging (10 hr at 190°C for 24S and 24 hr at 120°C for 75S) likewise raised the hardness uniformly along the entire length of the bar.

In order to distinguish between the effect of thick and thin specimens, the series of partial immersion quench tests graphed in Fig 4 was run on 0.1 × 0.4 × 5.0 in. specimens of 12 pct aluminum-zinc.

SUBSEQUENT AGING OF PARTIAL-IMMERSION-QUENCHED SPECIMENS

There are very few investigating means available to determine, in a polycrystalline specimen during the early stages of precipitation hardening, at just what stage is a particular region in the course of age hardening, particularly when, as in the case under discussion, the thermal history is both widely variable within the specimen and known in only a speculative way. The simplest procedure which occurred to the writer was to age the various pieces of the Fig 2 specimen, as well as the Fig 4 specimens, at 100°C, since a very large background of data had been built up on the behavior of 12 pct aluminum-zinc aged at this temperature. Results of this aging analysis are plotted in Fig 3 and 5.

Discussion of Results

The outstanding feature of the results obtained from the partial immersion quenching test is the hardness of the region just above the quenching

liquid level relative to the hardnesses of the other regions of the bar. From Fig 2, 4, and 6 the following broad details can be observed:

1. The high purity 12 pct aluminum-zinc shows a very sharp dip in hardness just above the quenching water level in the 0.4 in. square cross-section bar and the absence of any such dip in the 0.1 × 0.4 in. rectangular cross-section bar quenched in either oil or water.
2. The commercial purity 0.4 in. square cross-section bars of 24S and 75S show no dip.

The foregoing findings are the chief contribution which this paper offers to the experimental knowledge of the quenching operation. Unfortunately, time was not available to extend the investigation to other high purity systems than aluminum-zinc; but the previously-mentioned difficulties with 0.4 in. diam specimens of both high purity 4 pct aluminum-copper and 12 pct aluminum-zinc and the known lack of similar difficulties with commercial precipitation hardening aluminum alloys suggested that, in contrast to commercially pure alloys, high purity alloys may be vulnerable to unavoidable variables in even the best quenching practice. Among the possible explanations for this vulnerability and perhaps the most evident are:

1. *Critical cooling rate.* It might be assumed that a critical cooling rate exists, faster than that at which full hardening on aging subsequent to quenching is obtained and slower than that at which substantially full hardening during quenching to the temperature of the coolant is obtained. On this basis it might be argued that, after 0.1 hr at room temperature, 12 pct aluminum-zinc specimens cooled both above and below the critical cooling rate would be at approximately the same high hardness level; at about the critical cooling rate, such specimens would be soft, since very little precipitation would have occurred, yet room temperature precipitation could be very slow because the lattice defects present in volently quenched specimens would not be present to promote nucleation, despite the appreciable supersaturation.
2. *Quenching stresses.* Phillips and Brick suggested¹² that "quenching stresses are an important factor in accelerating and, perhaps, actually causing, age hardening."
3. *Thermal fluctuations.* Throughout the present paper the term "thermal fluctuations" is defined to comprise the momentary fluctuation which it is assumed would be observed if a continuous, instantaneous record could be kept of representative isotherms in a

FIG 6—Commercial aluminum alloy partial immersion quenching. 24S and 75S bars with the same dimensions and heat treatment as Fig 2A. Each point the average of three determinations across the width of the specimen made one hour after quenching.

* Average through the range 750–550°F.

specimen being quenched. Such fluctuations would mean that, in a given small region affected (that is, a volume element several hundred atoms in diameter and larger), the temperature would first fall and then, momentarily, would rise before again falling. With slow, uniform cooling presumably an isotherm would contract uniformly without appreciable fluctuations occurring. With submerged jet-quenching of thin sections, perhaps such fluctuations would be minimized. With more massive specimens, however, the combination of fluctuating vapor zone surrounding the specimen being quenched, coolant convection currents, and an appreciable quantity of heat to be removed from the interior of the specimen, is assumed to give rise to thermal fluctuations of sufficient magnitude to cause the anomalous hardening results which have been reported.

In considering the critical cooling rate possibility, the excellent experimental work of Fink and Willey¹³ is quite useful. These investigators established a "C" curve for 75ST, plotting as a function of time at isothermal quenching temperatures, the percentages of full 75ST properties attained. This work, in common with other published data by Fink and his collaborators on the precipitation hardening of high purity aluminum-copper and including the classic paper on double

aging peaks,⁶ was done with 0.064 in. thick specimens and thus, according to the findings of the present investigation, were quenched entirely satisfactorily. Fink and Willey also published¹³ extensive quenching rates for 75S, a few pertinent data being given in Table 1.

From this tabulation it can be observed that, in aluminum alloys, air cooling is negligibly slow relative to the cooling effected by conduction through the aluminum to a water quenched surface. Additional pertinent information on quenching rates in aluminum alloys has also been given by Loring, Baer, and Carlton,¹⁴ who employed a modified Jominy quench test specimen for their investigation. Extrapolating the Fink and Willey cooling rate data to the partial immersion quenching of the 0.1 and 0.4 in. thick specimens of the present investigation, one can conclude that, if a critical rate were of controlling importance, both these specimen thicknesses would have exhibited a sharp hardness dip if one did. The high purity 12 pct aluminum-zinc alloy showed a marked hardness dip in the 0.4 in. thickness but not in the 0.1 in. thickness. Hence it is concluded that the existence of a critical cooling rate does not explain the findings.

In developing their quenching stress thesis with high purity aluminum-copper alloys, Phillips and Brick used specimens from 0.0025 in. diam (filings) to 1.5 in. diam rod. Their many ingenious experiments established a very consistent trend in increasingly anomalous behavior with increasing specimen diameter. They concluded that the anomalies were related to and perhaps originated in the solution heat treatment and quench. It is perhaps

significant, in light of the data reported by the present paper, that Phillips and Brick secured quite uniform results up to a specimen thickness of 0.125 in., but that from the next greater thickness (0.25 in.) investigated, results were increasingly anomalous. In a very worthwhile discussion of the Phillips and Brick investigation, Barrett estimated the magnitude of the quenching stresses existing on a radial element near to the surface of the specimens and concluded that they reached a maximum compressive stress of about 15,000 psi. More recent work by Finlay and Hibbard¹¹ investigated the effect of 100,000 psi hydrostatic pressure on the precipitation hardening of the 12 pct aluminum-zinc alloy. This hydrostatic pressure aging is of course a different situation from that obtaining in a quenched cylinder which has tangential tensile stress and radial compressive stress present. The hydrostatic pressure aging indicated that precipitation hardening was both accelerated and intensified relative to atmospheric-pressure-aged specimens, but the differences were by no means great enough to account for those shown by the present investigation. In any case, both the region of the sharp hardness dip and the region of the high hardness plateau at the upper end of the 0.4 in. thick, 12 pct aluminum-zinc specimen were above the water level and, therefore, were in locations where quenching stresses were much less than in the region below the water level and presumably were quite low. Accordingly, it does not appear that quenching stresses can explain the results obtained.

In considering the possible action of thermal fluctuations on a precipitation hardening system, one is led to the thought that they may—under proper combinations of time, temperature, and composition—effect retrogression. From Fig 3 and 4 it is seen that the various regions of the 12 pct aluminum-zinc alloy, whether of the 0.4 in. square or 0.1×0.4 in. rectangular cross-sections, and whether water, oil, or air quenched, do indeed exhibit a 100°C aging behavior which is consistent with the hypothesis that each has been retrogressed to a different degree depending upon the kind of thermal fluctuations to which it was subjected.

The element of retrogression which appears rather definitely to be present in the hardness dip region of the 0.4 in. square aluminum-zinc specimen is the existence of a supersaturated

solid solution which is much less unstable than the same structure freshly quenched. This is evidenced by the relatively quite slow hardening rates at 100°C shown in Fig 3 compared to the much faster room temperature aging of the freshly quenched specimens shown in Fig 1. Similarly slow hardening rates are assumed in Fig 5, as shown by the dashed lines, since, unfortunately, data were not taken earlier than 22 hr on the 100°C aging of the Fig 5 specimens. Guinier's explanation¹⁵ for the reduced hardening rate of the retrogressed structure assumes that the as-quenched matrix lattice is subjected to high internal stresses and, accordingly, has many lattice defects which promote nucleation of precipitate particles. Both the initial aging at room temperature and subsequent retrogression "anneal" at 100°C given the aluminum-zinc specimen tend to diffuse these defects away, so that the nucleation rate is reduced and, with it, the rate of hardening.

Evidence for the presence of the other element of retrogression—resolution of coherent precipitate particles—is not clear from the data obtained. It seems possible that both re-solution and overaging (that is, breaking away from coherency with the matrix) of precipitate particles are involved. Thus, in the case of the air quenched specimen of Fig 4, some precipitation must have occurred during the period of relatively slow cooling and subsequent room temperature aging of one hour's duration. The low hardness can be interpreted to indicate that some of the larger precipitate particles had broken away from coherency. Upon subsequent 100°C aging, some of these noncoherent particles may have redissolved in the aluminum matrix; others may have remained noncoherent; and possibly a number of coherent precipitate particles redissolved. In any case, the typical retrogression feature of a more perfect lattice and, consequently, a lower rate of nucleation are believed to have obtained and resulted in a reduced rate of hardening to the retrogression peak. This point of view is employed in the following paragraphs to examine the details of Fig 2 and 3:

1. The Fig 2 data show generally falling hardness from the bottom of the specimen to the water line. Below the latter it is pictured that the thermal fluctuations are quickly quieted by the rapid water quenching, the more rapid and effective the quenching (as in the bottom and edges) the less the thermal

fluctuations. Thermal fluctuations, arising from heat coming from the interior, tend to begin to retrogress the outer portions so that they exhibit somewhat less than the expected room temperature hardness peak of 75–80 Rockwell 15T. Consistent with this, Fig 3 shows that on subsequent 100°C aging, retrogression continued and then recovery set in until the retrogression peak was attained. This viewpoint is consistent with the additional observations that: (a) the surface midpoint exhibits lower hardnesses than the surface edges; and (b) the surface has lower hardnesses than the interior.

2. Between the water line and 0.8 in. above the water line it is observed that (a) surface hardness is very low and does not change appreciably with distance but there is a noticeable tendency for the surface midpoints to become harder than the surface edges, and (b) like the surface, the interior hardness reaches a decided low at about the water line but, unlike the surface, the interior hardness recovers to higher values very quickly as the distance increases from the water line.

It is envisioned that because of the slower cooling just above the water line relative to that below the water line there are sufficient degree and duration of thermal fluctuations to soften the matrix to the retrogression valley. Fig 3 shows that subsequent 100°C aging raises this region out of the valley up to the retrogression peak. The interior is believed not to be subjected to as severe retrogression as the surface except at the water level and so it is generally harder but nevertheless at the retrogression valley.

3. Beyond approximately 1 in. above the water level, the hardnesses of all regions are at the highest levels attained and are matched only by the hardness at the very bottom of the specimen where presumably quenching was best. It is hypothesized that at the still slower cooling rate of this region, relative to that just above the water level, there is a longer period of severe thermal fluctuations capable of retrogressing the structure so that this region is retrogressed to the retrogression peak. Accordingly, on subsequent 100°C aging, as shown in Fig 3, the hardness falls off very slowly due to overaging.

4. From 0.8 to 1.8 in. above the water line it is observed that the surface midpoint is harder than the surface edge. This is just the opposite from the situation below the water line. Never-

theless, the thermal fluctuation retrogression theory gives a consistent explanation of the happenings. From its viewpoint it is believed that the edges both in the region under discussion and also below the water line are not retrogressed as much as the midpoints but, since in this case the hardness of the region is climbing out of the retrogression valley, the midpoints have reached the retrogression peak and are therefore harder than the edges which have not yet attained it. In the case of the region below the water the midpoints have also retrogressed more than the edges but there its advanced state meant that it had descended farther into the retrogression valley and hence was softer than the edges.

Fig 4 and 5 give the results of 0.1 in. thick bars as contrasted to the 0.4 in. thick bars of Fig 2 and 3. Similar, though less marked, results are shown in Fig 4 and 5 to those portrayed in Fig 2 and 3. The explanation for the data is also believed to be similar. No significant difference was found between the midpoints and the edges since there was not a sufficient thermal reservoir in the interior to give rise to it. For the same reason, a pronounced hardness valley was not developed just above the water line. The air-cooled specimen was discussed earlier. Subsequent aging of these specimens at 100°C resulted in the remarkably uniform hardness level characteristic of 12 pct aluminum-zinc overaging slowly from the retrogression peak.

Unlike the high-purity 12 pct aluminum-zinc, the commercial 75S and 24S bars with an 0.4 in. square cross-section did not exhibit a vulnerability to poor quenching practice. This is believed to be due to the fact that the commercial alloys have relatively very stable precipitates which resist retrogression and, indeed, this feature would appear to be a prerequisite to industrial use. As shown in Fig 6, the hardness curves, after partial immersion quenching of 75S and 24S, show no tendency whatever towards the hardness valley which is such a pronounced feature of the comparable 12 pct aluminum-zinc bar.

Summary and Conclusions

The high purity, binary, aluminum-zinc alloy containing 12 pct zinc was shown to exhibit marked retrogression at quite moderate temperatures. By means of a special testing technique, termed partial immersion quenching

and aging, it was established that this alloy was quite vulnerable to the variables encountered during quenching, and this was ascribed to its ready retrogression, possibly in concert with overaging, as effected by thermal fluctuations; further, that this vulnerability dropped to negligible proportions when the specimen thickness was not greater than 0.1 in.; and, finally, that commercial purity alloys 24S and 75S are not at all similarly vulnerable. Smaller scale tests indicated that high purity 4 pct aluminum-copper exhibited a quenching and aging behavior similar to that of the high purity 12 pct aluminum-zinc alloy.

A selection from the extensive literature on the "anomalous" quenching and aging behavior shown by high purity, binary, precipitation hardening alloys was presented. Examination of these references shows the use of specimen thicknesses considerably greater than 0.1 in. The thicknesses employed included $\frac{3}{16}$ in. for silver-aluminum;⁵ $\frac{1}{4}$ in. for aluminum-zinc;⁷ $\frac{1}{4}$ in. for aluminum-silver;⁸ $\frac{5}{32}$ in. for aluminum-copper;^{1,2,3,4} and, quite recently, $\frac{1}{2}$ in. for aluminum-copper.¹⁶ The majority, and perhaps all, of these anomalies are perhaps explicable on the basis of the size effect postulated by this paper. Additional evidence supporting this view is given in Ref. 3 wherein, when some of the anomalous-hardening $\frac{5}{32}$ in. thick specimens were forged to $\frac{1}{8}$ in. thickness, good and consistent age hardening results were obtained.

Based on the foregoing, the generalization is tentatively put forward that many precipitation hardening systems, particularly those comprising high purity binary alloys, may, because of ready retrogression and overaging, exhibit quite erratic quenching and age hardening behavior when the specimen thickness exceeds some maximum in the neighborhood of 0.1 in., since greater thicknesses inevitably give rise to excessive thermal fluctuations upon being quenched into a liquid. Commercial precipitation hardening alloys are believed not to be subject to such retrogression and overaging, since considerable tolerance to a relatively wide range of quenching conditions is presumably one of the essential prerequisites determining the suitability of an alloy for industrial use. It would appear, therefore, that the research worker dealing with noncommercial alloys should consider the possibility of a significant size effect in many precipi-

tation hardening systems and should employ some procedure such as the partial immersion quench test to insure that his quenching practice does not contain any uncontrolled variable which may invalidate his data, particularly in the early stages of aging.

The Ternary System, Copper-manganese-zinc

T. R. GRAHAM,* J. R. LONG,† C. E. ARMANTROUT,† and A. H. ROBERSON‡

Introduction

The preparation and fabrication of copper-manganese-zinc alloys and the evaluation of their engineering properties have for some time been an integral part of a research program of the Federal Bureau of Mines. In this project, the use of electrolytic manganese, along with high purity copper and zinc, has permitted the preparation of alloys which contain a minimum of impurities which are capable of producing detectable effects in the properties studied. The initial work on the physical properties of wrought alpha solid solution alloys and a general outline of the alpha solid solution area for alloys containing up to 40 pct manganese have been presented in previous reports.^{1,2,3,4,5} The evidence accumulated in these investigations clearly showed that additions of manganese to the copper-zinc alloys improve the strength properties of the brasses without seriously reducing their characteristic ductility and that considerable quantities of manganese could be added to the copper-zinc alloys without exceeding the mutual solubilities of manganese and zinc in copper. In continuation of these studies, additional data have been obtained in a more extensive investigation of the phase relationships of the copper-manganese-zinc ternary system. The present report delineates the solid phase boundaries of the ternary system from the copper-zinc binary to the manganese-zinc binary for alloys containing up to 50 pct zinc.

Summary

The alloys used in this investigation were conditioned by working schedules designed to homogenize the structures prior to heat treatments required for

FIG 1—Condition of the alloys prior to thermal treatments used in this investigation.

the equilibrium phase study. The treated alloys were examined by metallographic methods including hardness and X ray data for confirmation.

The composite data of the investigation are summarily presented in a series of isothermal sections of the ternary system at 1100, 1200, 1300, 1400, and 1500°F. The salient features of the system as outlined by these data are: (1) the continuous alpha solid solution

which extends across the diagram to the gamma-manganese phase of the manganese-zinc system at temperatures of 1200°F and higher, (2) the beta phase of the copper-zinc system similarly forms a continuous solid solution with its counterpart the beta field of the manganese-zinc binary, (3) at 1100°F (593°C) these alpha and beta fields are greatly restricted by complications arising from the allotropic transitions of manganese and the decreasing solubility of manganese in the alpha solid solution. The alpha + beta fields intersect the alpha + alpha manganese field to produce the beta + alpha manganese field and two adjacent three phase fields consisting of alpha + beta + alpha manganese and gamma + beta + alpha manganese.

Typical microstructures representative of the various phase areas at each temperature are also presented.

Review of Previous Work

The copper-manganese-zinc alloys have periodically been the subject of numerous investigations of both prac-

tical and theoretical significance.⁶ In a large measure, these studies have been concerned with the duplex, $\alpha + \beta$, alloys which constitute a commercially important group of engineering materials normally referred to as manganese bronzes. The actual manganese content of these alloys seldom exceeds 4 to 5 pct, and frequently is less than the total iron, nickel, tin and lead contents. Other investigations of the higher manganese compositions by Heusler,⁷ Bauer and Hansen,⁸ Guillet,⁹ and Hieke and Ledebur¹⁰ have been somewhat more extensive but are of limited value since their results were based on relatively impure alloys under admittedly nonequilibrium conditions. Reports by members of the Bureau's staff,^{4,5} have discussed the characteristics of a large group of the copper-manganese-zinc alloys, but did not include alloys containing more than 40 pct manganese.

The binary systems involved have been thoroughly examined in numerous studies and the principal phase boundaries are well established. The copper-zinc system has recently been reviewed by Phillips and Brick.¹¹ The copper-manganese system was thoroughly examined in the early part of the Bureau's work on alloys of electrolytic manganese.¹² Potter and Huber¹³ using powder metallurgy methods for the preparation of the alloys have determined the phase relationships of the manganese-zinc system for alloys containing up to 50 pct zinc by X ray diffraction and thermal analysis methods.

Experimental Materials and Methods

The alloys used in this investigation were prepared from electrolytic manganese, wire bar grade copper and 99.99+ zinc in substantially the same manner as described in the previous reports on these and similar alloys. It is perhaps also unnecessary to list the individual analyses for the 145 alloys examined but sufficient to point out that they were selected from some 500 heats of copper-manganese-zinc alloys which were made for a variety of experimental studies. These alloys were chosen on the basis of their suitability with due regard to their relative position in the ternary system and their low impurity content. The principal impurities present in the alloys are iron, silicon, and aluminum. Only four of the alloys contained greater than 0.020 pct iron and these contained less than 0.040 pct iron. The silicon

content of all the alloys was reported as less than 0.005 pct. The residual aluminum from the intentionally added deoxidizer did not exceed 0.04 pct and in 96 of the alloys the aluminum content was less than 0.02 pct.

Since cast alloys are not ideally suited for the determination of phase relationship because of their inherent characteristics of segregation, porosity, tendency for grain boundary constituents, persistence of agglomerated precipitates, and others, efforts were made to give the alloys a substantial amount of working before the final thermal treatments. However, this was not possible in all cases and a fixed processing schedule which would suit all the alloys could not be devised.

In this investigation one group of the copper rich alloys has been hot and then cold worked. Another group containing higher manganese and zinc was hot worked only and still other compositions were examined in the as-cast condition. The metallurgical condition and composition of the individual alloys prior to heat treatment are denoted in Fig 1. Contrary to the general tradition that high manganese alloys are normally quite brittle and unworkable, this chart shows that a substantial proportion of the alloys was hot rolled or forged. With proper adjustment of temperature in accordance with the phase boundaries subsequently developed, no doubt many of the other compositions could have been hot and cold worked. In fact, in some later work, many of the alloys containing more than 50 pct manganese with 10 to 15 pct zinc were cold rolled 60 pct reduction in thickness after quenching from 1400°F (760°C) without difficulty.

The high copper alloys which were finished by cold working, Fig 1, had, in addition to some hot reduction, three anneals with cold reductions averaging 50 to 60 pct between anneals. The hot worked alloys were reduced approximately 80 pct from the as-cast size with intermittent soaking at 1200 or 1400°F (648 or 760°C). Examination of the hot worked alloys showed the cast structures were entirely destroyed and that homogeneous or uniform structures were produced.

Several of the alloys were not worked prior to heat treatment. These alloys were primarily those highest in zinc or manganese. The castings, which were chill cast in 1¼-in. diam ingots, were quite uniform and clearly defined in structure and without serious

segregation.

Specimens of the individual alloys were heat treated for periods of 4, 8, 24, and 48 hr at 1300, 1400, and 1500°F (704, 760, and 815°C) and for 24, 48, and 200 hr at 1100 and 1200°F (593 and 648°C) in an atmosphere of helium, then quenched. In some of the highest manganese alloys slight demanganization occurred but seldom penetrated more than a few thousandths of an inch deep. All heat treated specimens were bisected so that an internal surface of one section could be used for metallographic study and the other was reserved for incidental hardness checks and X ray diffraction patterns as required for confirmation.

Approach to equilibrium conditions was determined by comparison of the structures obtained by various time periods at the same temperature. In general the structures differed but slightly and these differences were usually in amount of phases present. In a few instances, a phase was found to disappear in borderline compositions with longer heating periods. Structure of specimens held 24 and 48 hr at 1300, 1400, and 1500°F (704, 760, and 815°C) were unchanged by the longer time at temperature. Similarly structures of materials treated for 48 and 200 hr at 1100 and 1200°F (593 and 648°C) exhibit no change with the longer soaking time at temperature. The final observations from which the isothermal diagrams were drawn are based on the 48-hr treatment for 1300, 1400, and 1500°F (704, 760, and 815°C), while the 1100 and 1200°F (593 and 648°C) sections were based on 200-hr specimens.

Discussion of Results

The results of the investigation are graphically represented in Fig 2, 3, 4, 5, and 6 in which the isothermal sections for the ternary copper-manganese-zinc system at 1500, 1400, 1300, 1200, and 1100°F (815, 760, 704, 648, and 593°C) temperature levels have been drawn. In these drawings, the various phase boundaries have been extrapolated to the solubility values taken from the established copper-zinc, manganese-zinc, and copper-manganese diagrams. Where experimental observations permitted positive placement of the phase boundaries, solid lines have been drawn. Where the data are too incomplete for accurate placement of the phase boundary, but the trend of the field was known, dashed lines were used for the extension of the

FIG 2—The isothermal section of the copper-manganese-zinc system at 1500°F (815°C).

FIG 3—The isothermal section of the copper-manganese-zinc system at 1400°F (760°C).

FIG 4—The isothermal section of the copper-manganese-zinc system at 1300°F (704°C).

FIG 5—The isothermal section of the copper-manganese-zinc system at 1200°F (648°C).

FIG 6—The isothermal section of the copper-manganese-zinc system at 1100°F (593°C).

boundary. In each of the isothermal sections, certain of the phase fields were not defined by the data but because they are necessary construction imposed by the binaries or by data in subsequent sections, dashed lines have been used to approximate their position.

At 1500°F (815°C), Fig 2, the alpha and beta solid solutions of the copper-zinc system extend uninterrupted to the manganese-zinc binary although the solubility of zinc in these phases decreases to a minimum at approximately 40 pct manganese then increases with larger amounts of manganese reaching a maximum solubility at the manganese-zinc binary. Some restriction in the alpha solid solution occurs near the manganese corner and a two phase field of alpha solid solution plus

beta manganese has been estimated on the basis of the solubility data of the manganese-copper and manganese-zinc system. The solidus line which has been incorporated in the 1500°F (815°C) isotherm is not intended as an exact solidus but has been drawn primarily to differentiate between those alloys which showed evidence of melting and those which did not exhibit melting at this temperature.

Manganese decreases the solubility of zinc in the alpha phase of the copper-zinc system. The alpha and beta solubility lines are substantially parallel to one another and parallel to the lines of constant copper up to 15 to 20 pct manganese. In general, manganese and zinc act as equivalents. The present data show slightly less solubility of

zinc in the alpha and beta phases in the range of 20 to 40 pct manganese than were previously recorded in work on the alpha solubility limits. Calculations by Hume-Rothery¹⁴ on the earlier data, showed that manganese in small amounts affected the alpha-beta equilibrium as though it were a divalent element but departed from this simple relationship at rather low manganese contents. The solubility line of the present investigation indicates the solubility curves are comparable to the theoretical curve up to 15 to 20 pct manganese if equilibrium were determined by electron concentration alone and manganese possessed a valency of 2. As the concentration of manganese increases beyond 20 pct the alpha + beta phase field tends to widen and

becomes more or less parallel to the copper-manganese binary at approximately 40 pct manganese. With larger amounts of manganese, the alpha + beta field continues to widen and the solubility of zinc in both the alpha and beta phases increases. These solubility curves are extrapolated from the 15 pct copper line to the manganese-zinc binary and decrease considerably in width with decreasing copper to correspond with the extent of this phase field in the binary system.

Similar trends of the alpha/alpha + beta and beta/alpha + beta solubility lines for the ternary system are shown in the 1400°F (760°C) isothermal section in Fig 3, although these curves are displaced to higher zinc concentrations. The solidus shifts rapidly as the temperature decreases from 1500 to 1400°F (815 to 760°C) and a rather large beta area is formed at the lower temperature. The projections of the beta + gamma field of the copper-zinc system and the beta + epsilon field of the man-

ganese-zinc system are also introduced at 1400°F (760°C).

At 1300°F (704°C), Fig 4, the general shape and contour of the alpha and beta boundaries remain substantially the same as indicated for the higher temperatures. The alpha/alpha + beta and beta/alpha + beta lines are approximately parallel giving the field a spread of 5 to 6 pct as measured on lines of constant manganese for all compositions up to about 40 pct manganese. With increasing manganese the two phase field widens to a maximum at 60 pct manganese then decreases to the manganese-zinc binary values.

The metallographic structures of specimens treated at 1300, 1400, and 1500°F (704, 760, and 815°C) are in general quite similar to the characteristic alpha and beta structures of the copper-zinc system and are readily identified. Some exceptions, however, were encountered in the beta alloys which were immediately adjacent to the beta/alpha + beta boundary.

These alloys, particularly in the low manganese range, often transform bodily to the alpha phase during the quench making it difficult to be positive of the high temperature structure. Characteristic micrographs of these structures as well as structures of the alpha and beta phases for alloys containing less than 30 pct manganese were presented in the report on the alpha solubility limits.⁴ Phillips¹⁵ has also described the mass transformation reactions for the binary copper-zinc alloys.

Representative structures for alloys containing more than 40 pct manganese and falling within the alpha + beta and beta fields are illustrated in Fig 7 to 11, inclusive. In these structures the beta phase appears as the dark or acicular constituent. In general, increasing manganese tends to stabilize the beta phase, but varying degrees of decomposition depending on composition and temperature were found to occur.

Fig 7 and 10 are characteristic alpha + beta structures obtained when there is little tendency for the beta phase to decompose. The formation of grain boundary and acicular alpha within the beta grain, Fig 8, occurs during the quench. Fig 9 illustrates an alpha + beta structure in which the beta phase is almost completely transformed during the cooling. In the micrograph of Fig 11, designated as an alpha + beta structure, it is quite probable that most of the alpha present was formed during the quench and that the beta/alpha + beta boundary could be lowered slightly at this point. However, evidence from the near-by compositions and the trends shown in pseudo-binary sections for higher and lower temperatures point to the position of the solubility line given.

The alpha + beta manganese structure is shown in Fig 12 for one of the alloys which falls within this field at 1300°F (704°C). The microstructure in Fig 13 is typical of the low manganese high zinc alloys in the beta + gamma

field and are similar to the structures of beta + gamma brasses.

The beta solid solution field is slightly reduced by the beta + gamma and beta + epsilon fields at 1200°F (648°C), Fig 5, and the alpha + beta boundary has shifted to higher zinc concentrations. The eutectoid decomposition of the beta phase in the manganese-zinc system requires the formation of the three phase field alpha + beta + epsilon and the alpha + epsilon field which have been tentatively positioned in the isothermal section for this temperature.

The contour of the alpha solubility line has a decided bulge at 60 pct manganese and 20 pct zinc but the field of complete miscibility remains with a narrow corridor between the manganese solubility curve and the alpha/alpha + beta line. Since the gamma manganese phase of the manganese-zinc system, which has been treated as the alpha solid solution phase of the ternary system up to this point, remains stable at this temperature and none of the beta

or alpha + beta alloys was found to contain manganese, it was assumed that these two boundaries have not joined at this temperature. It must be admitted, however, that only a limited number of alloys are positioned in this area. If a junction of the two lines did occur, it would necessarily be in the neighborhood of compositions containing less than 10 to 12 pct copper and alloys in the adjacent fields would contain precipitated manganese.

A new three phase field is introduced in the manganese rich corner of the diagram at 1200°F (648°C) based on the alpha to beta transition of manganese. Here again, the exact position of the alpha + alpha manganese + beta manganese field has been estimated, since all of the experimental compositions were found to contain only the alpha manganese phase. The beta manganese phase of the manganese-zinc system is stable at this temperature, therefore the three phase area must be placed at some intermediate position.

various phase fields at 1200°F (648°C) are shown in Fig 14 to 17, inclusive. Structures containing alpha and beta phases are shown in Fig 14 and 15. At this temperature, the high manganese beta phases are usually retained in the quench and do not transform or decompose. In Fig 14, the alpha phase is present in very minor amounts and the large grains of beta are restrained by the alpha. The alpha and beta structure in Fig 15 is representative of alloys which are more or less equidistant from the respective solubility limits. Fig 16 illustrates the alpha solid solution + alpha manganese alloys. Typical beta + epsilon structure is shown in Fig 17.

Sweeping changes occur in the copper-manganese-zinc ternary system as the temperature decreases to 1100°F (593°C). The construction given in Fig 6 is a complicated and radical departure from that of the isothermal section of Fig 5. The new fields are, however, dictated by positive metallographic and X ray evidence of the co-existence

of the indicated phases in these areas. The absence of beta manganese in all experimental alloys at 1100°F (593°C) and 1200°F (648°C) and the negligible solubility of copper in both alpha and beta manganese ties these fields to the manganese corner.

The zinc content of the alpha + beta field has shifted to still higher values as the temperature decreased from 1200 to 1100°F (648 to 593°C), but the respective solubility lines of this field remain essentially parallel from the copper-zinc binary to the limit of this field at approximately 36 pct manganese.

Intersection of the alpha + alpha manganese and the alpha + beta fields creates a four phase invariant plane which at 1100°F (593°C) produces the two phase field, beta + alpha manganese, and the two adjacent three phase fields, alpha + beta + alpha manganese and gamma + beta + alpha manganese. Principal evidence to support this construction is the complete absence of beta manganese in any

of the experimental alloys and the co-existence of only the beta and gamma phases without either alpha or beta manganese. The absence of beta manganese in the alloys indicates that the alpha manganese + beta manganese + alpha tentatively placed in Fig 5 must sweep toward the manganese-zinc binary before the alpha corridor is closed by the junction of the alpha + beta and alpha + alpha manganese fields. Were it otherwise, beta manganese and beta brass would be found to co-exist and this is not the case.

Representative microstructures for the two phase beta + gamma brasses are illustrated in Fig 18 and 19. Fig 18 shows the presence of a small amount of the gamma phase associated with retained beta. Transformed or decomposed beta and the gamma phase are present in Fig 19.

The microstructures observed for several of the ternary alloys containing less than 30 pct zinc annealed at 1100°F, (593°C) are reproduced in

FIG 25—Beta (dark) and gamma of the manganese-zinc system (light) in the 52.6 Mn 26.3 Zn alloy quenched from 1100°F.

× 250. ASTM zinc etchant No. 4.

FIG 26—Alpha solid solution (light) and alpha manganese (dark) in the 55.4 Mn 13.0 Zn alloy quenched from 1100°F.

× 250. Unetched.

Fig 20 to 26. The copper rich alpha solid solution with traces of the beta phase is illustrated in Fig 20. The structure of Fig 21 is somewhat more complicated by the presence of alpha manganese along with the alpha and beta solid solution phases. With such structures relief polishing affords a rapid method for positive identification of the manganese constituent and subsequent etching reveals the beta and alpha phases, along with the manganese. Another characteristic of these alloys is the comparatively small grain size resulting from the presence of manganese which inhibits normal grain growth. The constituents in all specimens within this three phase area were also confirmed by X ray diffraction data. The precipitation of alpha manganese within the beta phase is shown in Fig 22. Only one specimen was found to fall within the narrow three phase field beta + gamma + alpha manganese. The microstructure of this alloy annealed at 1100°F (593°C) is given in Fig 23. Representative structures of alloys containing only the beta and gamma phases at 1100°F (593°C) are reproduced in Fig 24 and 25. These two micrographs clearly demonstrate the absence of a manganese phase. The presence of the gamma and beta constituents was confirmed by X ray diffraction. Fig 26 is characteristic of the alpha solid solution plus manganese

alloys. The formation of alpha manganese in the grain boundaries and certain crystallographic planes within the grains is quite characteristic of alloys in this area.

Acknowledgments

The authors express appreciation for the valuable assistance of the various members of the metallurgical staff of the Bureau of Mines. Particular acknowledgment is due to the group at the Salt Lake City Laboratory where the experimental work of this investigation was conducted. The X ray investigations necessary for the identification of the various phases encountered in the microstructures were conducted by E. Vernon Potter and R. W. Huber of the Physics Section.

The final manuscript was prepared at the Rolla Station Laboratory at Rolla, Missouri.

Discontinuous Crack Propagation—Further Studies*

L. D. JAFFE,† Junior Member AIME, E. L. REED,† and H. C. MANN†

The authors have recently published¹ evidence that brittle transgranular fracture of polycrystalline metals does *not* originate at a point and propagate continuously across the material, but rather develops at numerous related points, leading to a series of microcracks which subsequently link up. Series of related microcracks were observed in steel specimens broken in fatigue—specifically, at the central portions which broke during the final sudden fracture.

Microcracks of the type mentioned have also been reported by Baeyertz, Craig and Bumps² in steel broken under impact.‡ Some micrographs published by Irwin³ may possibly be interpreted as showing discontinuous brittle cracks. This paper presents additional observations of the authors on discontinuous crack propagation under various conditions.

Impact Test Specimens

The impact test specimens were cut longitudinally from a steel forging containing:

| C | Mn | Si | P | S | Ni | V | Mo |
|------|------|------|-------|-------|------|------|------|
| 0.24 | 0.50 | 0.15 | 0.034 | 0.027 | 1.52 | 0.03 | 0.33 |

The heat treatment consisted of oil quenching in a heavy section from 1600°F and tempering at 1260°F. The resulting yield strength was 78,000 psi, tensile strength 100,000 psi, elongation 20.0 pct in 2 in., and reduction of area 55.0 pct. Standard V-notch Charpy specimens were broken in a 217 ft-lb machine at a striking velocity of 16.8 fps. Energy absorption and fracture

‡ Since preparing this article the authors have learned that Tipper¹² observed such microcracks near the fracture of mild steel plates. As the work of Baeyertz, Craig and Bumps was carried on simultaneously and independently of that of the authors, and apparently also without knowledge of Tipper's paper,¹² the microcracks have been found independently by three separate groups.

FIG 1—Impact transition curve. V-notch Charpy specimens.

appearance of this material in the V-notch Charpy test are plotted as functions of temperature in Fig 1. After test, fractured halves of specimens appearing 0, 40, 80, and 100 pct fibrous (to the unaided eye) were electroplated with nickel, sectioned longitudinally (perpendicular to the notch at its midpoint), polished and etched with Cohen-Hurlich-Jacobson (C-H-J) reagent (picric acid plus Zephiran chloride in ethyl ether)⁴ or with Vilella reagent (1 pct picric plus 5 pct hydrochloric acid in ethyl alcohol).⁵

Fig 2 and 3 show cracks near the path of final fracture in the specimen rated 0 pct fibrous. Many of the cracks terminate at the boundaries of ferrite grains, some at boundaries of pre-

existing austenite grains.* A crack often starts near the end of another. Cracks within the same ferrite grains are parallel or approximately parallel in several cases. A large percentage of the cracks are branched.†

Fig 4 illustrated a group of cracks in the 40 pct fibrous specimen. Branching and parallelism are well marked. No more than three directions of crack have been observed on the polished surface in one ferrite grain. This is consistent with the evidence⁶ that brittle fracture of ferrite takes place on the cube face crystallographic planes: the {100} planes. The appearance of some cracks suggests that they have passed around a projecting corner of a second ferrite grain by going outside the plane of polish.

In Fig 5 cracks in the 80 pct fibrous specimen may be observed. Some of

‡ References are at the end of the paper.

* By "ferrite" is not meant primary ferrite, but the body-centered cubic phase, within which carbide particles may or may not be dispersed.

† One of the cracks in Fig 3 seems to contain some particles. After lightly repolishing, without re-etching, hardly any of the particles could be found, but at higher magnification the edges of the crack appeared rough. It is thought that the particles are fragments torn from the edges and lodged in the crack during polishing.

Service Fracture

A fracture was examined in a steel casting of this analysis:

| C | Mn | S | P | Si | Cr | Mo | Ni |
|------|------|-------|-------|------|------|------|------|
| 0.33 | 1.02 | 0.033 | 0.041 | 0.26 | 0.05 | 0.43 | 0.02 |

The casting had been normalized and

FIG 2—Microcracks near final fracture of Charpy bar rated 0 pct fibrous. Broken at -57°C , energy absorption 15 ft-lb.

$\times 500$. Etched 1 min. in C-H-J reagent, re-polished $\frac{1}{2}$ min., re-etched 10 sec. Reduced approx. one half in reproduction

the cracks have a step-like path. In the area shown the final fracture appears transgranular and brittle ("crystalline"), with little if any evidence of deformation visible. The austenite and ferrite grains are equiaxed. Fig 6 shows an area where the final fracture appeared transgranular but ductile (fibrous), with evidence of local deformation near the break. The austenite and ferrite grains are not equiaxed and it appears that the material flowed in tension perpendicularly to the eventual path of fracture. No microcracks are evident in Fig 6. None was found near fibrous portions of the final fracture in the 40 pct or 80 pct fibrous specimens, or in any portion of the 100 pct fibrous bar. All cracks observed were within 0.01 in. of a brittle transgranular portion of a final fracture.

FIG 3—Microcracks very close to fracture in same Charpy bar as Fig 2.

$\times 500$. Etched 1 min. in C-H-J reagent, re-polished $\frac{1}{2}$ min., re-etched 10 sec. Reduced approx. one half in reproduction

FIG 4—Group of microcracks in crystalline area near final fracture of Charpy bar rated 40 pct fibrous. Broken at $+21\frac{1}{2}^{\circ}\text{C}$, energy absorption 52 ft-lb.

$\times 500$. Etched in Vilella's reagent. Reduced approx. one half in reproduction

drawn, giving a yield strength (0.1 pct offset) of 55–58,000 psi, tensile strength of 92–95,000 psi, 12–17 pct elongation in 2 in., and 13–28 pct reduction of area, in room temperature test. Sudden fracture occurred through a machined notch under service conditions of rapid loading at a temperature of -70°F . The fracture appeared to be almost completely brittle. It was prepared for examination in the same fashion as the impact test specimens, but a 4 pct picral etch was used.

The crack in Fig 7 is "stepped" within a ferrite grain, the "treads" and "risers" appearing to lie along two sets of parallel planes. Neumann bands (deformation twins) may be seen in several ferrite grains. These twins are plainer in Fig 8. Cracks were distinguished from Neumann bands by re-polishing the specimen lightly and examining without re-etching; cracks remained visible, the twins did not. Crack segments seem to be approximately parallel to Neumann bands within the same ferrite grain; some crack segments coincide with possible extensions of the bands. This suggests that microcracks have been nucleated at the stress concentrations surrounding the ends of twins, though the converse possibility that stress concentrations at the end of stopped cracks nucleated the twins cannot definitely be ruled out. Neumann bands in iron form along $\{112\}$ crystallographic planes and not along the $\{100\}$ planes.⁷

Fig 9 is of interest because it shows that microcracks within the metal parallel the path of the final complete fracture, when both are in the same ferrite grain. There is some evidence of this in Fig 4 also.

Micrographs discussed above have been at $500\times$ magnification. Fig 10 shows at $1500\times$ some of the cracks previously noted in Fig 9. A crack that might be thought "stepped" at the lower magnification is here seen to be discontinuous, at least in the plane of polish.

Fatigue Specimens

Fatigue specimens were cut transversely from a forging of the following composition:

| C | Mn | P | S | Si | Cr | Mo | V |
|------|------|-------|-------|------|------|------|------|
| 0.28 | 0.74 | 0.014 | 0.013 | 0.20 | 1.00 | 0.49 | 0.12 |

Heat treatment consisted of annealing

FIG 5—Some microcracks having a step-like path in crystalline area near final fracture of Charpy bar rated 80 pct fibrous. Broken at $+50^{\circ}\text{C}$, energy absorption 75 ft-lb.

$\times 500$. Etched in Vilella's reagent. Reduced approx. one half in reproduction.

from 1700°F , then holding 9 hr at 1675°F , water-quenching, holding 12 hr at 1150°F , and furnace-cooling. The material was heat-treated as a round approximately 8 in. in diam. The resulting yield strength (0.01 pct offset) was 105,000 psi, tensile strength 132,000 psi, elongation 15 pct, reduction of area 46 pct and V-notch Charpy impact energy 3-9 ft-lb at 70°F and 2 ft-lb at -40°F . The material was tested in rotating beam fatigue at 10,000 rpm as standard R. R. Moore specimens with 45° V-notch, having 0.015 in. radius at the base of the notch and a diameter across the notch of 0.220 in. All tests were at room temperature. The S-N curve is given as Fig 11.

Several specimens fractured at different stress levels were prepared for microexamination, as described for the impact bars. A micrograph of microcracks in a specimen broken under high stress has been published.¹ Fig 12 shows cracks in a specimen broken at the endurance limit: in 1,798,000 cycles at a nominal stress of 40,000 psi.* Microcracks were found in the fatigue specimens only near the path of final, complete, sudden fracture, where little or no evidence of deformation was observed, and never in the "battered" area where progressive fracture presumably took place over many cycles. No microcracks could be found below the notch in a specimen fatigued 40,880,000 cycles at 35,000 psi which did not fracture.

At the junction between the "battered" fracture and the final sudden

brittle fracture, there was always observed a projection that appeared to have been highly deformed in longitudinal tension. An example is shown in Fig 13. The significance of this projection, as well as of the microcracks, will be discussed in the next section.

Discussion of Results

Microcracks have to date been observed by the authors every time they have been looked for in areas adjacent to a brittle transgranular fracture. An explanation of the microcracks in terms of a theory of discontinuous crack propagation was given in Ref. 1. Briefly, it is suggested that a crack propagates along a crystallographic plane, in a brittle fashion, until it is stopped by a grain boundary or by a particle of a second phase. New cracks are likely to start in the zone of stress concentration at the end of the stopped crack. The

FIG 6—Local deformation in a fibrous area near final fracture of same Charpy bar as Fig 5.

$\times 500$. Etched in Vilella's reagent. Reduced approx. one half in reproduction

process then repeats, leading to discontinuous branching chains of microcracks. Cracks may also stop because

the elastic energy released by their further spread would not be sufficient to propagate the crack (to form the new surfaces). In this last case, new

cracks would have to be at orientations which would provide greater energy release.

The probability of further cracking

near the ends of and within chains of microcracks will be much greater than elsewhere. The size of continuous crack will therefore tend to increase. This increase in size raises still further the probability of additional cracking in adjacent areas. When one continuous crack has traversed the specimen, macroscopic fracture has occurred. The brittle fractures which represent final severance of specimens or parts are series of linked microcracks.

Observation of microcracks in impact test specimens demonstrates that they are not associated with the repetitive loading which characterizes fatigue, and that series of microcracks can develop very rapidly (in the time of fracturing a brittle Charpy specimen, of the order of 10^{-5} sec).

The microcracks visible in the micrographs and discussed above are not identical with the Griffith defects,⁸ sometimes also termed "microcracks," which are supposed to exist in the material prior to stressing.

The projection observed at the junction of the battered and the brittle regions in the fatigue specimens suggests that the material represented by the projection was deforming in tension while brittle cracking was occurring nearer the axis. The final brittle fracture presumably originated (a major series of brittle microcracks first developed) either close to the axis or a small distance below the tip of the progressively advancing "fatigue crack." Fracture originating close to the axis is analogous to fracture occurring in a tensile specimen after necking.⁹ Fracture originating a small distance below the tip of the fatigue crack is analogous¹⁰ to fracture originating a small distance below the tip of a machined notch, and might be expected, because the stress there is triaxial tension, whereas at the crack or notch tip itself only biaxial stress can exist. (The stress system ahead of a fatigue crack cannot differ much from that under a sharp machined notch.¹¹) In either case final fracture does not occur by propagation inward, in a brittle fashion, of the progressive fatigue crack.

Summary

Series of apparently discontinuous microcracks have been found adjacent to the path of final brittle failure in fatigue specimens, impact specimens, and a failed part, made from steel forgings and castings. These cracks

FIG 12—Microcracks near fracture of fatigue test specimen broken in 1,798,000 cycles at 40,000 psi.

White crack-like line indicated by arrow may be a crack which meets the surface outside the plane of polish and was partly filled with nickel electroplate. $\times 500$. Etched in Vilella's reagent.

FIG 13—Projection at the junction of the "battered" (right) and final fracture (left).

Same fatigue specimen as shown in Fig 12. $\times 500$. Etched in Vilella's reagent. Reduced approx. two-sevenths in reproduction.

have been observed every time they have been sought in areas close to a brittle transgranular fracture.

It is believed that the microcracks indicate that brittle transgranular fracture of polycrystalline metals does *not* originate at one point and propagate continuously across the material, but rather nucleates at numerous related points, leading to a series of microcracks which subsequently link up.

Microscopic evidence has also been found which is interpreted to mean that final fracture in a fatigue specimen does not occur by propagation inward, in a brittle fashion, of the progressive "fatigue crack." Rather, brittle fracture originates closer to the neutral axis and links with the fatigue crack subsequently.

The Free Energy Change Accompanying the Martensite Transformation in Steels

J. C. FISHER*

Martensite transformations in steels and other alloys are characterized in part by the absence of composition changes during the growth of a new phase. Transformation occurs rapidly, and there is insufficient time for long range diffusion or partition of alloying elements to take place; martensite reactions in alloys thus are similar to phase transformations in single component systems.

A fundamental understanding of martensite transformations in steels is impossible without knowledge of the free energy change upon transforming austenite (face centered cubic iron containing alloying elements) to ferrite (body centered cubic iron containing alloying elements) of the same chemical composition. The present paper assembles the best information available concerning the influence of temperature and composition on this free energy change. Most of the material has been taken from the work of Johansson,¹ Mehl and Wells,² Zener^{3,4} and Smith;⁵ and indirectly, through these authors, from the work of Austin.⁶

In agreement with the generally accepted viewpoint, martensite is assumed to be an ordered solution of carbon in ferrite of the same composition as the parent austenite; only at high temperatures and low carbon concentrations is the carbon in ferrite distributed at random. The properties of the disordered solution are estimated by extrapolating the known properties of iron-carbon solid solutions into the range of supersaturation, and the free energy change associated with ordering is estimated from the theory developed by Zener. By incorporating Smith's recent thermodynamic measurements and Zener's theory of ordering, the present analysis modifies previous estimates of the free energy change associ-

ated with martensite transformations.

Consider a two component system consisting of a solvent *A* and a solute *B*. Let N_A and N_B represent mol fractions of *A* and *B* respectively, let $a_A = \gamma_A N_A$ and $a_B = \gamma_B N_B$ represent activities, and let superscripts 1 and 2 refer to phases 1 and 2. The partial molal free energies of *A* and *B* in phases 1 and 2 can be summarized as follows:

| | free energy | standard state |
|--------------------------------|------------------|----------------------------|
| $\bar{F}_A^1 - \bar{F}_{A0}^1$ | $= RT \ln a_A^1$ | pure <i>A</i> ¹ |
| $\bar{F}_A^2 - \bar{F}_{A0}^2$ | $= RT \ln a_A^2$ | pure <i>A</i> ² |
| $\bar{F}_B^1 - \bar{F}_{B0}^1$ | $= RT \ln a_B^1$ | pure <i>B</i> |
| $\bar{F}_B^2 - \bar{F}_{B0}^2$ | $= RT \ln a_B^2$ | pure <i>B</i> . |

The free energy of a gram atom of phase 1 is*

$$\Delta F^1 = N_A^1 \bar{F}_A^1 + N_B^1 \bar{F}_B^1$$

and that of phase 2 is

$$\Delta F^2 = N_A^2 \bar{F}_A^2 + N_B^2 \bar{F}_B^2.$$

A martensite transformation from phase 1 to phase 2 requires

$$N_A^1 = N_A^2 = N_A \text{ and } N_B^1 = N_B^2 = N_B,$$

and the free energy change per gram atom accompanying transformation is

$$\begin{aligned} \Delta F^{1 \rightarrow 2} &= N_A (\bar{F}_A^2 - \bar{F}_A^1) \\ &\quad + N_B (\bar{F}_B^2 - \bar{F}_B^1) \\ &= N_A [RT \ln (a_A^2/a_A^1) \\ &\quad + \Delta F_{A^{1 \rightarrow 2}}] + N_B RT \ln \\ &\quad (a_B^2/a_B^1) \end{aligned}$$

* A gram atom of solution contains N_A gram atoms of component *A*, N_B gram atoms of component *B*, N_C gram atoms of component *C*, and so on.

Cleveland Meeting, October 1949.
TP 2704 E. Discussion of this paper (2 copies) may be sent to *Transactions AIME* before December 1, 1949. Discussion is tentatively scheduled for publication in May 1950

Manuscript received May 2, 1949.
* General Electric Co., Schenectady, N. Y.

¹ References are at the end of the paper.

$$\begin{aligned} &= N_A [RT \ln (\gamma_A^2/\gamma_A^1) \\ &\quad + \Delta F_{A^{1 \rightarrow 2}}] + N_B RT \ln \\ &\quad (\gamma_B^2/\gamma_B^1), \quad [1] \end{aligned}$$

where γ_A^2 , γ_A^1 , γ_B^2 , γ_B^1 are activity coefficients, and where $\Delta F_{A^{1 \rightarrow 2}}$ is the free energy change upon transforming a gram atom of pure *A* from phase 1 to phase 2 at the temperature in question.

For martensite transformations in plain carbon steels, *A* = iron (Fe), *B* = carbon (C), 1 = austenite (γ), 2 = ferrite (α), and Eq 1 is

$$\begin{aligned} \Delta F^{\gamma \rightarrow \alpha} &= N_{Fe} [RT \ln (\gamma_{Fe}^\alpha/\gamma_{Fe}^\gamma) \\ &\quad + \Delta F_{Fe}^{\gamma \rightarrow \alpha}] + N_C RT \ln (\gamma_C^\alpha/\gamma_C^\gamma). \quad [2] \end{aligned}$$

Nothing is known concerning the values of γ_{Fe}^α and γ_C^α for carbon concentrations in excess of 0.025 pct. However, the approximation

$$\gamma_{Fe}^\gamma = \gamma_{Fe}^\alpha = 1$$

cannot be appreciably in error for small carbon concentrations, and Eq 2 reduces to

$$\begin{aligned} \Delta F^{\gamma \rightarrow \alpha} &= N_{Fe} \Delta F_{Fe}^{\gamma \rightarrow \alpha} \\ &\quad + N_C RT \ln (\gamma_C^\alpha/\gamma_C^\gamma). \quad [3] \end{aligned}$$

Johansson¹ and Zener³ have calculated $\Delta F_{Fe}^{\gamma \rightarrow \alpha}$ from the specific heat measurements compiled by Austin.^{6*} Their calculated values agree closely, and are summarized in Table 1.

The activity coefficients relative to graphite for carbon dissolved in iron vary with temperature according to the relationships

$$\begin{aligned} d \ln \gamma_C^\gamma / d(1/T) &= \Delta H_C^\gamma / R \\ d \ln \gamma_C^\alpha / d(1/T) &= \Delta H_C^\alpha / R \end{aligned}$$

where ΔH_C^γ and ΔH_C^α are the heats of solution of graphite in γ and α iron. Assuming the values of ΔH to be independent of carbon concentration and temperature,

$$\begin{aligned} \ln \gamma_C^\gamma &= \Delta H_C^\gamma / RT + I_1 \\ \ln \gamma_C^\alpha &= \Delta H_C^\alpha / RT + I_2 \end{aligned}$$

* Johansson employed also specific heat measurements from several other sources.

where I_1 and I_2 are integration constants. The value of $RT \ln(\gamma_C^\alpha/\gamma_C^\gamma)$ reduces to

$$RT \ln(\gamma_C^\alpha/\gamma_C^\gamma) = \Delta H_C^\alpha - \Delta H_C^\gamma + RT \Delta I. \quad [4]$$

Smith⁵ has determined quite accurately the value $\Delta H_C^\gamma = 10,000$ cal per g atom. ΔH_C^α is less accurately known, Smith having obtained a value 20,000 cal per g atom from his own experimental data, and a value 26,000 cal per g atom by making use of earlier data concerning δ -iron. The value $\Delta H_C^\alpha = 20,000$ appears to be the more reliable, particularly for use at low temperatures. Moreover, according to a recent theory of austenite decomposition,¹⁰ $\Delta H_C^\alpha = 20,500$ cal per g atom gives the best agreement between calculated M_s temperatures and those determined by Lyman and Troiano⁷ for a series of 3 pct chromium steels of varying carbon content. Therefore the value $\Delta H_C^\alpha = 20,500$ cal per g atom is assumed, and

$$RT \ln(\gamma_C^\alpha/\gamma_C^\gamma) = 10,500 + RT \Delta I. \quad [5]$$

Consider the distribution of carbon at equilibrium in the two phase $\gamma + \alpha$ region. Then

$$\Delta \bar{F}_C^\gamma = \Delta \bar{F}_C^\alpha, \\ RT \ln \gamma_C^\gamma N_C^\gamma = RT \ln \gamma_C^\alpha N_C^\alpha$$

and

$$\gamma_C^\alpha/\gamma_C^\gamma = N_C^\gamma/N_C^\alpha.$$

From the equilibrium boundaries of the iron-carbon phase diagram as determined by Mehl and Wells² and by Smith⁵ the ratio N_C^γ/N_C^α is

$$N_C^\gamma/N_C^\alpha = 0.315/0.0128 = 24.6$$

at 800°C where the carbon concentrations are relatively low and both γ_C^γ and γ_C^α are practically independent of carbon concentration.⁵ Therefore, at 800°C,

$$RT \ln(\gamma_C^\alpha/\gamma_C^\gamma) = 6825. \quad [6]$$

It is assumed that γ_C^α and γ_C^γ vary similarly with carbon concentration, so that the ratio $\gamma_C^\alpha/\gamma_C^\gamma$ is independent of N_C .

According to Eq 4, 5, 6 the value of $N_C RT \ln(\gamma_C^\alpha/\gamma_C^\gamma)$ is

$$N_C RT \ln(\gamma_C^\alpha/\gamma_C^\gamma) = N_C(10,500 - 3.425 T) \quad [7]$$

decreasing linearly from 10,500 N_C at absolute zero to 6825 N_C at 800°C. However, Eq 7 was obtained by an extrapolation that effectively assumes the solution of carbon in ferrite to remain random at low temperatures. Zener⁴ has shown that spontaneous

FIG 1—Variation of $\Delta F^{\gamma \rightarrow \alpha}$ with temperature for several 3.5 pct chromium steels of differing carbon content, according to Eq 12.

FIG 2—Variation of $\Delta F^{\gamma \rightarrow \alpha}$ with temperature for several 1.0 pct carbon steels of differing chromium content, according to Eq 12.

ordering of the carbon in ferrite takes place below the temperature

$$T_C \cong 28,000 N_C \text{ (approximately)}$$

with a decrease in free energy that is not reflected in an extrapolation based upon high temperature properties; this free energy change must be added to the value of $N_C RT \ln (\gamma_C^\alpha / \gamma_C^\gamma)$ that is given by Eq 7.

The decrease in free energy per unit volume on ordering can be derived from Zener's analysis, and is given by the expression

$$\Delta f_* = -\frac{1}{2} \left(\frac{2}{3} n_1 \lambda z \right)^2 E + \frac{1}{3} n_1 k T [2(1-z) \ln(1-z) + (1+2z) \ln(1+2z)] \quad [8]$$

ergs per cc where

$$n_1 = 6.03 (10)^{23} N_C / N_S V_0 \text{ carbon atoms per cc}$$

N_S = sum of mol fractions of all substitutional elements

V_0 = volume corresponding to a mol of lattice sites

$$\lambda = 1.68 (10)^{-24} V_0 \text{ strain per carbon atom}$$

z = Zener's order parameter

$$E = 1.30 (10)^{12} \text{ dynes per cm}^2.$$

The value of the order parameter z depends only upon the temperature ratio T/T_C , as given in Table 2, where T_C is determined by the relationship

$$T_C = 3900 V_0 N_C / N_S. \quad [9]$$

When N_C is small, $N_S \cong 1$ and $V_0 \cong 7.2$, leading to the approximate relationship $T_C \cong 28,000 N_C$. Changing to the appropriate units, the free energy change on ordering is

$$\Delta F_* = 2.39 (10)^{-8} N_S V_0 \Delta f_* \quad [10]$$

calories per gram atom.*

*Zener's numerical values have been revised, following a more accurate calculation of the value of z at the critical temperature T_C (0.3772

Combining Eq 3 and 7, and adding ΔF_* to the right hand member of Eq 7, the free energy change on transforming austenite to ferrite of the same carbon content is

$$\Delta F^{\gamma \rightarrow \alpha} = N_{Fe} \Delta F_{Fe}^{\gamma \rightarrow \alpha} + N_C (10,500 - 3.425 T) + \Delta F_* \quad [11]$$

cal per g atom for plain carbon steels.

Addition of an alloying element alters the value of $\Delta F^{\gamma \rightarrow \alpha}$ given in Eq 11 by the amount

$$N_i RT \ln (\gamma_i^\alpha / \gamma_i^\gamma)$$

where the subscript i refers to a particular alloying element. Almost nothing is known concerning the ratio $\gamma_i^\alpha / \gamma_i^\gamma$ for alloying elements other than carbon; in the absence of adequate information, perhaps the simplest assumption that can be made is that $RT \ln (\gamma_i^\alpha / \gamma_i^\gamma)$ is constant:

$$RT \ln (\gamma_i^\alpha / \gamma_i^\gamma) = K_i.$$

With this assumption, Eq 11 becomes

$$\Delta F^{\gamma \rightarrow \alpha} = N_{Fe} \Delta F_{Fe}^{\gamma \rightarrow \alpha} + N_C (10,500 - 3.425 T) + \Delta F_* + \sum N_i RT \ln (\gamma_i^\alpha / \gamma_i^\gamma)$$

vs. 0.33 as given by him), and assuming a martensite tetragonality ratio $r = 1.053$ for a completely ordered steel containing 1.28 pct carbon, as determined by Lyman and Troiano.⁷ $r = 1.053$ falls between the values $r = 1.059$ and $r = 1.051$ determined by Honda and Nishiyama⁸ and by Kurdjumov and Kaminsky⁹ respectively. The strain corresponding to a tetragonality ratio r was assumed to be $e = (r - 1) / (1 + \nu)$ where $\nu = 0.3$ is Poisson's ratio. Assuming further that the density of iron is not altered by the addition of carbon, the volume of a gram atom of alloy is $V = N_3 V_0$ cc, and the number of carbon atoms per cc is $n_1 = 6.03 (10)^{23} N_C / N_3 V_0$.

Although it was not so stated in his analysis, there must be, according to Zener's theory, a temperature region near the "critical temperature" T_C where ordered and disordered phases of differing carbon content coexist at equilibrium. Failure to consider the two phase region leads to errors in the value of Δf_* . However, the errors are small, and they are not considered further.

$$\cong N_{Fe} \Delta F_{Fe}^{\gamma \rightarrow \alpha} + N_C (10,500 - 3.425 T) + \Delta F_* + \sum N_i K_i \quad [12]$$

cal per g atom for the martensite transformation in alloy steels. The summation includes all alloying elements other than carbon.

Eq 12 is an estimate of the free energy change upon transforming austenite to martensite, obtained by extrapolating the properties of disordered iron-carbon solutions into the supersaturated range, and employing the theory of ordering developed by Zener. $\Delta F^{\gamma \rightarrow \alpha}$ values calculated from Eq 12 are used by Fisher, Hollomon, and Turnbull¹⁰ in their analysis of austenite \rightarrow martensite transformation kinetics. They suggest a value $K_{Cr} = 1200$ cal per g atom for chromium, leading to variation of $\Delta F^{\gamma \rightarrow \alpha}$ with temperature as shown in Fig 1 and 2 for a number of chromium steels.

Kinetics of the Austenite → Martensite Transformation

J. C. FISHER,* J. H. HOLLOMON,* Junior Member AIME, and D. TURNBULL*

Application of the concepts of nucleation and growth to the analysis of experimental transformation data has led to valuable descriptions of phase transformations, an outstanding example being the transformation austenite → pearlite which has been examined with particular care by Mehl and co-workers.¹⁻⁵ In addition to the pearlite transformation, the proeutectoid ferrite and proeutectoid carbide transformations are known to proceed by nucleation and growth. Martensite, on the contrary, until recently was thought to form by a mechanism involving neither nucleation nor growth; however, extension of standard nucleation theory⁶ suggests that martensite, bainite, and the other products of austenite decomposition all grow from nuclei in the parent phase. The theory that martensite forms by nucleation and growth is strongly supported by recent experimental work of Kurdjumov and Maksimova.⁷

The concepts of nucleation and growth have been fruitful also in providing a sound basis for quantitative theoretical treatments of the kinetics of phase transformations. For example, Volmer and Weber⁸ and Becker and Döring⁹ developed the theory of nucleation from fundamental considerations to a point where excellent agreement was obtained with the results of experiments on the condensation of supercooled vapors. As a result of their analysis, the kinetics of vapor-liquid transformations now can be predicted. It seems probable that application of the theories of nucleation and growth to a quantitative study of austenite decomposition similarly will clarify the nature of the individual transformations involved, and will enable the calculation of austenite transformation kinetics.

In the present paper, the theories of nucleation and growth are applied to the austenite → martensite transformation in steels. The analysis begins with a discussion of nucleation in single component systems. Martensite appears to be coherent with the parent austenite, hence the nucleation theory is modified to include the effects of elastic distortion. Nucleation in the two component iron-carbon system then is discussed, for most steels are primarily alloys of these two elements. Finally, M_s temperatures and martensite transformation curves are calculated for each of several alloy steels of varying carbon and chromium content, and are compared with those determined experimentally by Lyman and Troiano¹⁰ and Harris and Cohen.¹¹

Nucleation Theory

NUCLEATION IN SINGLE COMPONENT SYSTEMS^{6,12-14}

The work required for reversible formation of a region of phase β within the parent α phase is expressed conveniently as the sum of two terms: $W_1 = A\sigma$, the product of the area of the interface and the interfacial free energy, and $W_2 = V\Delta f$, the product of the volume of the region and the free energy increase per unit volume associated with the transformation. The total work is therefore $W = A\sigma + V\Delta f$.

When α is more stable than β , Δf is positive and W increases without limit as the volume increases. The transformation $\alpha \rightarrow \beta$ does not occur. It is nevertheless true that small regions of phase β enjoy temporary existence here and there in the α . The equilibrium number of β regions of given size is proportional to $\exp(-W/kT)$ per unit volume of α , assuring that larger β regions occur with diminishing probability.

When α is less stable than β , Δf is negative and W passes through a maximum as V increases. Assuming for simplicity that regions of β are spherical, as is true when the interfacial tension is isotropic and there are no elastic strains,

$$W = 4\pi r^2\sigma + (4/3)\pi r^3\Delta f.$$

The maximum value of W is

$$W^* = 16\pi\sigma^3/3\Delta f^2 \quad [1]$$

for regions with radius

$$r^* = -2\sigma/\Delta f. \quad [2]$$

For single component condensed systems it has been shown¹⁴ that the steady rate of nucleation of β per unit volume of untransformed α is nearly proportional to $\exp[-(W^* + Q)/kT]$ where Q is the activation energy for the unit processes of adding or removing one atom from an embryo or nucleus. If T_0 is the temperature at which α and β are in equilibrium, the rate of nucleation is a maximum at a temperature $0 < T < T_0$ where $(W^* + Q)/kT$ is a minimum.

β regions smaller than critical size are called embryos; they tend to grow smaller and disappear, only exceptionally growing larger. Regions equal to or larger than critical size are called nuclei. A critical size nucleus may grow indefinitely large or may shrink back to α , either process decreasing the free energy of the region.

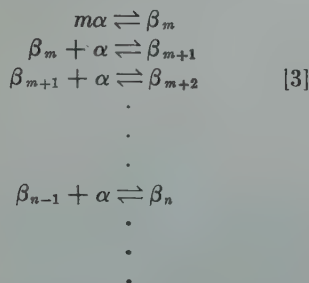

FIG 1—Growth of a martensite plate, schematic.

Arrows indicate direction of motion of parent phase.

It is important to recognize that embryos and nuclei do not suddenly appear full size in the parent phase.^{12,13} They grow larger and smaller by a series of essentially bimolecular reactions,

where α represents a single atom or molecule of phase α , and β_i represents an i -atom region of phase β . β_m , where $m \cong 10$ for metals, represents the smallest possible region having the structure of β . For β_i smaller than critical size, the specific rate of decomposition of β_i is greater than that of formation. For β_i larger than critical size the converse is true.

The unit processes of adding or removing α atoms have activation energies, and occur in finite time. If the temperature of a sample of α is changed rapidly from equilibrium at $T_1 > T_0$ where α is stable, to $T_{-1} < T_0$ where β is stable, the embryos at T_1

may be retained at the new temperature; with rapid quenching there may be insufficient time for the set of reactions $\beta_{i-1} + \alpha \rightleftharpoons \beta_i$ to lead to appreciable change toward establishment of the steady state β_i —distribution characteristic of T_{-1} .

If T_{-1} is sufficiently below T_0 , the larger embryos of β retained during quenching from T_1 will become nuclei during cooling as the critical size decreases. These nuclei then grow. The metamorphosis embryo \rightarrow nucleus that takes place during cooling is independent of thermal motion in the sense that no additional α atoms need be activated and added to the β region. For this reason nucleation resulting from the decrease in r^* with falling temperature has been termed athermal nucleation, in contrast to thermal nucleation which takes place isothermally.

It may happen that W^*/kT_{-1} is so large that the steady rate of nucleation at T_{-1} is negligible. Transformation $\alpha \rightarrow \beta$ then is initiated entirely by athermal nucleation. If the growth rate of β regions is rapid, and the size of a β grain is limited by changes in α grain boundaries, β will be observed to form only upon cooling of the α . If cooling ceases, athermal nucleation and therefore transformation also ceases. If the

cooling is continued, transformation continues.

Interrupted cooling can lead to “stabilization of the retained α ” when retained embryos of nearly critical size grow smaller and decrease in number as the steady state distribution characteristic of the holding temperature is approached. Subsequent cooling then produces fewer athermal nuclei than would have been produced by direct cooling to the final temperature.

NUCLEATION OF COHERENT PHASES

The elastic distortion accompanying transformations in solids frequently is so large that it cannot be neglected in calculating nucleation rates. Consider for example a transformation that occurs by the mechanism sketched in Fig 1. The phases are coherent in the sense that lines and planes of atoms are continuous across interfaces. The habit plane, or α plane that is parallel to the plate of β , is not necessarily rational. The transformation is evidently a “shear type” transformation; however the figure suggests that the final dimensions of a β plate are attained by growth, not by homogeneous shear or shears throughout the volume to be transformed.

The idea that “shear type” transformations are accomplished by homogeneous shears seems questionable in view of the very high activation energy associated with an entire β -plate in the partly-sheared condition. No such difficulty arises when the configuration between β -nucleus and full size β -plate is recognized to be a growing plate of intermediate size. It is suggested below that martensite is a coherent precipitate. Martensite plates are assumed therefore to form by the mechanism of Fig 1, successive layers of atoms being deposited one atom at a time as the parent phase moves relative to the plates.

Assume a coherent embryo or nucleus of radius r and of thickness δ at the center, the two surfaces of the plate being portions of spheres of large radius. The volume of the embryo is

$$V = \pi r^2 \delta / 2 \quad [4]$$

and its surface area is

$$A = 2\pi r^2 \quad [5]$$

to a good approximation when $\delta \ll r$. The formation of a coherent β embryo in α requires (1) formation of a coherent α - β interface, (2) transformation

of a volume of α to β , (3) concentration of elastic energy in the α (and to a lesser extent in the β).

Consider a sphere with center at the center of a thin coherent plate and with radius proportional to the radius of the plate. Select any point in the sphere (say on a line perpendicular to the plate at its center and at half the radius of the sphere). The elastic strain at the point is proportional to the ratio of the plate thickness to its radius,

$$e \sim \delta/r$$

as long as $\delta \ll r$. The strain energy per unit volume at the same location is proportional to the square of the strain,

$$E_v \sim (\delta/r)^2.$$

A similar proportionality holds at every point in the sphere; hence the total strain energy in the α is proportional to the product of $(\delta/r)^2$ and the volume of the sphere,

$$E = (3\theta/4) (\delta/r)^2 (4\pi r^3/3) = \theta\pi r\delta^2. \quad [6]$$

Here $3\theta/4$ is the proportionality constant.

The work associated with the reversible formation of an embryo of radius r and thickness δ is therefore

$$W = 2\pi r^2\sigma + \pi r^2\delta\Delta f/2 + \theta\pi r\delta^2. \quad [7]$$

The most probable shape for an embryo of volume V is that for which W is a minimum. Minimizing W with the condition $V = \text{constant}$ leads to the relationship

$$r = 3\theta\delta^2/4\sigma \quad [8]$$

which relates r and δ for minimum free energy embryos.

Most embryos are minimum free energy embryos. The work associated with the reversible formation of an embryo of thickness δ is therefore

$$W = 15\pi\theta^2\delta^4/8\sigma + 9\pi\theta^2\delta^5\Delta f/32\sigma^2. \quad [9]$$

W has a maximum

$$W^* = 8192\pi\theta^2\sigma^3/27\Delta f^4 \quad [10]$$

for nuclei with thickness

$$\delta^* = -16\sigma/3\Delta f \quad [11]$$

and volume

$$V^* = -32,768\pi\theta^2\sigma^3/27\Delta f^5. \quad [12]$$

Coherent nuclei grow as plates that finally are stopped at the edges by α grain boundaries, particles of a second phase, or other crystal discontinuities. Each plate thickens until the value of W associated with its formation from the α is a minimum. The plate then is

in equilibrium with the α and does not further thicken. Minimizing W at constant radius leads to the relationship

$$\delta/r = -\Delta f/4\theta \quad [13]$$

for full size coherent plates.

The ratio δ^*/r^* for coherent nuclei of critical size is also $\delta/r = -\Delta f/4\theta$ and experimental observation that $\delta \ll r$ for fully grown coherent plates justifies the assumption that $\delta \ll r$ for the corresponding nuclei and embryos.

Martensite

It is generally agreed that martensite is ferrite supersaturated with carbon of the same concentration as the parent austenite. Large amounts of dissolved carbon slightly distort the body-centered cubic structure of ordinary ferrite to a body-centered tetragonal structure. Martensite forms in thin lens-shaped plates that have definite orientation and habit relationships with the parent austenite. Transformation takes place primarily during cooling, and the growth of individual plates is very rapid.

These observations concerning martensite formation suggest the identification of martensite as supersaturated ferrite that forms by rapid coherent growth of athermal nuclei.

Martensite embryos come into being at the austenitizing temperature. Although a particular embryo has only transient existence, there is a definite equilibrium concentration of embryos of any given size. During quenching, the largest embryos find themselves supercritical for coherent growth, and they grow rapidly to full-size martensite plates.

Although both coherent and non-coherent embryos are present at the austenitizing temperature, only non-coherent embryos can be retained during quenching. Even at cooling rates as great as 10,000°C per sec, about 0.1 sec is required to reach the martensite start temperature from the austenitizing temperature. Individual martensite plates are observed to form in times of the order of 10^{-4} sec, indicating that the rate of coherent growth of martensite is very great. The life of coherent embryos therefore must be less than 10^{-4} sec, and during a time as long as 0.1 sec a given embryo will disappear; further, the largest embryos do not reform, for at lower temperatures the steady concentration of coherent embryos decreases in proportion to $\exp(-W/kT)$. Effectively,

coherent embryos always are present in the equilibrium or steady state concentration, while only noncoherent embryos, which require relatively long times to grow or shrink, can be retained during quenching.

A non-coherent α - β interface differs from a coherent interface in that non-coherent α and β structures get out of step occasionally, producing essentially a series of dislocations spaced along the interface. When β consumes α by non-coherent growth, existing dislocations move with the interface, and new dislocations appear where the interfacial area increases. However, it is possible also for β to consume α by coherent growth, leaving behind in the β the dislocations that initially were present at the α - β interface. Coherent growth of martensite from non-coherent ferrite nuclei therefore presents no contradiction.

Most martensite plates nucleate at embryos that have the minimum free energy of formation consistent with becoming nuclei at the low temperature, for these embryos are present in the greatest numbers. Let the critical size V^* for coherent growth of supersaturated ferrite (martensite) at a low temperature be as sketched in Fig 2A for a given iron-carbon alloy. Fig 2 suggests possible configurations for the embryos that are primarily responsible for martensite nucleation upon cooling to the low temperature in question.

Embryo (B) is a non-coherent ferrite region of size V^* , having the same carbon content as the austenite. Embryo (C) is a non-coherent ferrite region of the same size, but with the equilibrium amount of carbon for ferrite in contact with austenite.† The free energy of forming embryo (C) evidently is less than that of forming embryo (B), hence embryos similar to (B) do not contribute significantly to the martensite transformation.

Embryo (D) is a carbon-free austenite region of size V^* , containing a small non-coherent ferrite region just large enough to nucleate coherent growth in pure γ -iron at the low temperature. Upon quenching, the ferrite region in embryo (D) becomes a nucleus for coherent growth in carbon-free austenite; it grows to the boundary of the carbon-free region. Then, however, it is supercritical for growth in austenite of average carbon concentration, and it continues its coherent growth. The free energy of forming

† The equilibrium concentration of carbon is so low that it is assumed to be zero.

* P₁ pct manganese is counted as 2P₁ pct chromium, and P₂ pct silicon as P₂ pct iron.

embryo (D) is less than that of forming embryo (C), for embryo (C) requires a larger ferrite region with greater area of interface and greater volume of the unstable phase.

Although embryo (E), with carbon concentration increasing from zero at the boundary of the ferrite region to the average value at the boundary of the volume V^* has a free energy of formation somewhat smaller than does embryo (D), it is assumed, for ease of calculation in the following analysis, that martensite nucleates from embryos similar to embryo (D).

The free energy of formation of embryo (D) is the sum of two free energies; (1) that required to clear the carbon from a volume V^* , and (2) that associated with formation of the small ferrite region. It is assumed that the free energy required for formation of the small ferrite region is small in comparison with that required to clear the carbon from volume V^* .

The free energy change accompanying the reaction

corresponds to a transfer of all carbon from one gram atom of iron in austenite of initial carbon concentration N_C to a large reservoir of austenite of carbon concentration N_C . The activity constant for the reaction is

$$K = a_{\text{Fe}}/a_{\text{Fe}(C)} = 1/a_{\text{Fe}(C)}$$

taking the activity of pure iron as unity. The corresponding free energy change is

$$\Delta F - \Delta F_0 = RT \ln K = -RT \ln a_{\text{Fe}(C)}.$$

The standard free energy change ΔF_0 is zero, hence

$$\Delta F = -RT \ln a \quad [15]$$

cal per g atom of iron where the subscript has been dropped and $\ln a$ represents the logarithm of the activity of iron in an iron-carbon alloy.¹⁵

The activity of iron in austenite has been determined by Smith.¹⁶ He shows

that the relationship

$$-\ln a = N_C/N_s + [6.5 - 6 \exp(-1500/RT)] (N_C/N_s)^2 \quad [16]$$

gives satisfactory agreement with the experimental values over the entire temperature and composition range investigated. N_C is the mol fraction of carbon, and N_s is the mol fraction of iron. It is assumed in the following analysis that Eq 15 and 16 hold for steels of arbitrary composition when N_s is taken as the sum of the mol fractions of all substitutional elements.

The free energy change upon removing the carbon from a small region containing only n interstitial positions is

$$\Delta f_n = - (n/N) RT \ln a = -nkT \ln a. \quad [17]$$

The equilibrium number n_0 of carbon-free regions containing n lattice sites is proportional to $\exp(-\Delta f_n/kT) = \exp(n \ln a)$. Assuming ideal mixing of carbon-free regions and the remaining iron atoms the proportionality factor is N per mol of lattice sites,⁶ giving

$$n_0 = N \exp(n \ln a). \quad [18]$$

The number of regions larger than a critical size n^* is

$$n_r = \int_{n=n^*}^{\infty} n_0 dn = - (N/\ln a) \exp(n^* \ln a) \quad [19]$$

per mol of lattice sites.

CALCULATION OF M_s TEMPERATURES

Fisher¹⁷ has assembled information concerning the free energy change upon transforming austenite to martensite. The free energy change is

$$\Delta F_m' = N_{\text{Fe}} \Delta F_{\text{Fe}} + N_C (10,500 - 3.425T) + \Delta F_* + N_{\text{Cr}} RT \ln (\gamma_{\text{Cr}}^\alpha / \gamma_{\text{Cr}}^\gamma) \quad [20]$$

cal per g atom for iron-chromium-carbon alloys,[†] where the symbols have the following meanings:

$\Delta F_m'$ = free energy change upon transforming a gram atom of austenite to martensite (in the absence of elastic distortion associated with coherency).

ΔF_{Fe} = free energy change upon transforming a gram atom of γ -iron to α -iron.

ΔF_* = free energy change accom-

[†] A gram atom of iron-chromium-carbon alloy contains N_{Fe} , N_{Cr} and N_C mols of iron, chromium and carbon.

FIG 2—(A) Critical size for martensite growth. (B-E) Possible martensite embryos, schematic.

Dots represent carbon atoms.

panying the disordered-carbon \rightarrow ordered-carbon transformation in a gram atom of martensite.

N_{Fe} = mol fraction iron.

N_C = mol fraction carbon.

N_{Cr} = mol fraction chromium.

R = gas constant, 1.986 cal per mol $^{\circ}K$.

T = temperature, $^{\circ}K$.

γ_{Cr}^{α} = activity coefficient for chromium in α phase.

γ_{Cr}^{γ} = activity coefficient for chromium in γ phase.

As very little is known concerning γ_{Cr}^{α} and γ_{Cr}^{γ} , the approximation $RT \ln (\gamma_{Cr}^{\alpha}/\gamma_{Cr}^{\gamma}) = K_{Cr}$ is made, where K_{Cr} is a constant.¹⁷

Let N_s be the sum of the mol frac-

tions of all substitutional elements. The free energy change per mol of lattice sites is then

$$\Delta F_m = (N_{Fe}/N_s)\Delta F_{Fe} + (N_C/N_s)(10,500 - 3.425T) + \Delta F_{*}/N_s + (N_{Cr}/N_s)(1200). \quad [21]$$

The choice $K_{Cr} = 1200$ cal per g atom is justified in the following analysis. ΔF_m enters naturally into nucleation theory, for the free energy change per mol of lattice sites is very nearly proportional to the free energy change per unit volume. Table 1 gives values of ΔF_m vs. temperature for the 12 steels of interest in the present report.

It has been suggested that martensite nuclei form in carbon-poor austenite regions, and that the number of

martensite plates that form on cooling to a given temperature is equal to the number of carbon-free regions in the austenite that exceed the critical size for coherent growth of martensite nuclei in austenite of average carbon concentration.

According to this interpretation there is no sharply defined M_s temperature above which martensite does not form. However, there is a definite temperature, the experimental M_s temperature, at which the probability of finding a martensite plate during microscopic examination of a given specimen area is say 0.5. This temperature corresponds to a definite number of martensite plates per unit volume of iron. An equation for the experi-

FIG 3— M_s temperature for 3 pct chromium steels as a function of carbon content.

Experimental values determined by Lyman and Troiano,¹⁰ and (0.38 pct C only) by Klier and Lyman.²⁰ Curve calculated from Eq 25.

FIG 4— M_s temperature for 1 pct carbon steels as a function of chromium content.

Experimental values determined by Lyman and Troiano.¹⁰ Curve calculated from Eq 25.

mental M_s temperature can be obtained therefore by setting the expression for the number of martensite nuclei (that is, the number of carbon-free austenite regions as large or larger than the volume of a critical size martensite nucleus) per mol of lattice sites equal to a constant,

$$n_r = -(N/\ln a) \exp(n^* \ln a) = K_1. \quad [22]$$

Since the order of magnitude of $\ln a$ is the same for all steels for which M_s is determined, the above condition is practically equivalent to stating that the exponent $n^* \ln a$ is constant,

$$n^* \ln a = K_2. \quad [23]$$

The number n^* of lattice sites in a critical size martensite nucleus is proportional to its volume V^* which is in turn proportional to ΔF_m^{-5} (see Eq 12). Here $\Delta F_m \sim \Delta f$ is the free energy change in calories per mol of lattice sites for transformation to supersaturated ferrite. The equation for the M_s temperature is therefore

$$\Delta F_m = K_3(-\ln a)^{1/5} \quad [24]$$

or substituting the value $K_3 = -800$ which was found to give the best agreement with the data of Lyman and Troiano,¹⁰

$$\Delta F_m + 800(-\ln a)^{1/5} = 0. \quad [25]$$

M_s temperatures calculated from Eq 25 are compared in Fig 3 with the experimental values determined by Lyman and Troiano¹⁰ for seven 3 pct chromium steels containing from 0.08 to 1.28 pct carbon. Values of ΔF_m and $-\ln a$ required for the calculation are given in Table 1 and Eq 16.

M_s temperatures calculated for four 1 pct carbon steels of varying chromium content are compared with the experimental values of Lyman and Troiano¹⁸ in Fig 4. The value $K_{Gr} = 1200$ cal per g atom was selected to give agreement between Eq 25 and these experimental data.

MARTENSITE TRANSFORMATION CURVES

A martensite transformation curve gives the fraction of martensite, or the remaining fraction of untransformed austenite, as a function of quenching bath temperature for specimens cooled as rapidly as possible from the austenitizing temperature. The growth of individual martensite plates is stopped by austenite grain boundaries, previously formed martensite plates, and other crystal discontinuities that do

not allow coherent growth across an interface. The size of the first few martensite plates that form in a specimen of austenite containing no undissolved carbides is determined, therefore, by the austenite grain size. The size of later martensite plates is determined by the size of the pockets of untransformed austenite remaining among previously formed martensite plates. Calculation of martensite transformation curves requires an estimate of the size of these austenite pockets as a function of austenite grain size and number of martensite plates.

Let V_0 be the volume of a mol of lattice sites, let qV_0 be the volume of a single austenite grain, and let mqV_0 be the volume of an average martensite plate that forms near M_s .

After n plates have formed, the mol of lattice sites is cut up into chunks about $qV_0/(qn+1)$ cc in size. Let V_m be the volume of martensite formed. Slightly below M_s , $dV_m/dn = mqV_0/(qn+1)$ is the volume rate of transformation per martensite plate. A better approximation to dV_m/dn is

$$dV_m/dn = mq(V_0 - V_m)/(qn+1) \quad [26]$$

where V_0 has been replaced by $V_0 - V_m = V_a$, the remaining volume of untransformed austenite.

Integrating, $-\ln(V_0 - V_m) = m \ln [c(qn+1)]$ where c is the integration constant. $V_m = 0$ when $n = 0$, hence $-\ln V_0 = m \ln c$ and

$$1 - V_m/V_0 = V_a/V_0 = (qn+1)^{-m}. \quad [27]$$

Let n_0 be the number of martensite nuclei that would have appeared in the absence of nucleus growth. n , the actual number of martensite plates, is related to n_0 by the equation

$$dn/dn_0 = V_a/V_0 = (qn+1)^{-m}. \quad [28]$$

Integrating,

$$(qn+1)^{m+1}/(m+1) = qn_0 + c_2.$$

The value of c_2 is $1/(m+1)$, giving

$$(qn+1)^{m+1} = (m+1)qn_0 + 1$$

or

$$\begin{aligned} (qn+1)^{-m} &= [(m+1)qn_0 + 1]^{-m/(m+1)} \\ &\cong (qn_0 + 1)^{-m} \end{aligned} \quad [29]$$

since $m \ll 1$.

Therefore, the fraction of retained austenite is

$$V_a/V_0 = (qn_0 + 1)^{-m} \quad [30]$$

where

$$\begin{aligned} n_0 &= -(N/\ln a) \exp(n^* \ln a) \\ &= -(N/\ln a) \exp(V^* \ln a/v_0) \end{aligned} \quad [31]$$

is the number of martensite nuclei, q is the reciprocal of the number of austenite grains per mol of lattice sites, v_0 is the volume per lattice site, and $m \ll 1$ is a function of the shape of the martensite plate.

Let the ASTM grain size be g . There are then 2^{g-1} grains per sq in. visible at 100 diam, or 10^{4g-1} grains per sq in. The area of an average spherical grain cut at random is $A = 2\pi r_g^2/3$, hence the radius of a typical grain follows from the relationship

$$10^{4g-1}(2\pi r_g^2/3) = 1$$

giving

$$\begin{aligned} r_g &= 10^{-2g-2} \text{ in.} \\ &= 2.5(10)^{-2g-2} \text{ cm.} \end{aligned}$$

The volume per austenite grain is

$$V_1 = 4\pi r_g^3/3 = 65(10)^{-6g-3} \text{ cc,}$$

and the number of austenite grains per mol of lattice sites is V_0/V_1 where $V_0 = 7.2$ cc is the volume occupied by a gram atom of iron. The value of q is therefore

$$q = V_1/7.2 = 9.0(10)^{-6g-3g/2} \quad [32]$$

mol of lattice sites per austenite grain.

The volume of the average austenite grain is

$$4\pi r_g^3/3 = qV_0,$$

and the volume of the average martensite plate that forms in such a grain is

$$3(\delta/r)\pi^2 r_g^3/32 = mqV_0$$

where δ/r is the thickness to radius ratio for martensite plates. The ratio of plate volume to grain volume is

$$m = 9\pi(\delta/r)/128,$$

or

$$m = -9\pi\Delta f/512\theta = -\mu\Delta F_m \quad [33]$$

taking $\delta/r = -\Delta f/4\theta$ as given in Eq 13. μ is the constant of proportionality between m and ΔF_m .

Martensite transformation curves now can be calculated by means of Eq 30, where n_0 is given by Eq 31, q by Eq 32, and m by Eq 33. The coefficient μ in Eq 33 is the only unknown parameter. The best agreement between calculated transformation curves and those determined experimentally by Harris and Cohen¹¹ is obtained when

$$\mu = 7(10)^{-5}. \quad [34]$$

Fig 5 and 6 compare calculated and experimental curves for a 1.1 pct carbon steel and a 1.1 pct carbon, 1.5 pct

FIG 5—Martensite transformation curve for 1.1 pct carbon steel.

chromium steel.

Two important effects have been neglected in calculating martensite transformation curves. It is observed frequently that the growth of one martensite nucleus immediately sets off the growth of several others in the strained austenite adjacent to the first martensite plate. Elastic strains set up by the first plate presumably have altered the critical size for growth of otherwise subcritical nuclei, so that a few of them become supercritical and grow. Further, when a significant fraction of austenite is transformed, interaction of the stress fields around neighboring martensite plates allows them to thicken considerably in comparison with the equilibrium thickness for an isolated plate. Both the multiplication effect and the thickening effect lead to increased transformation over that given by Eq 30; the discrepancy becoming large when a significant amount of martensite is present.

Significance of the Agreement between Theory and Experiment

M_s temperatures and martensite transformation curves have been calculated from the basic assumptions that martensite and austenite are coherent, and that martensite grows by the mechanism sketched in Fig 1. Agreement between theory and experiment, summarized in Fig 3-6, is satisfactory, although it can be contended that the significance of this agreement is diminished by the arbitrary choice of values for the two parameters θ (the coefficient of the strain energy term in the equation for the work of forming

a coherent embryo) and σ (the coherent interfacial free energy).

Certainly, however, the significance of the agreement will be increased if it can be shown that the value of θ required for calculation of martensite transformation curves is that given by elasticity theory, and if it can be shown that the value of σ required for calculation of M_s temperatures is reasonable in comparison with known surface and interfacial free energies.

THE SHAPE OF A MARTENSITE PLATE

The strain energy associated with a martensite plate of thickness δ and radius r is $E = \theta\pi r\delta^2$ according to Eq 6. The value of the coefficient θ can be roughly estimated by assuming that the strain in the austenite surrounding a martensite plate is uniform throughout a circumscribed sphere of radius r . The shear strain is approximately $\gamma = \phi\delta/2r$ where ϕ is the "homogeneous shear" angle of the martensite. The energy per unit volume is

$$E_v = G\gamma^2/2 = \phi^2 G(\delta/r)^2/8$$

and the total strain energy is

$$E = (4/3)\pi r^3[\phi^2 G(\delta/r)^2/8] = (\pi/6)\phi^2 Gr\delta^2,$$

whence

$$\theta = \phi^2 G/6. \quad [35]$$

Taking $\phi = 0.34$ corresponding to the Nishiyama¹⁹ orientation relationship between martensite and austenite, and $G = 8(10)^{11}$ dynes per cm² (the value for ferrite) as an approximation for austenite, the value of θ is

$$\theta_1 = 1.54(10)^{10} \text{ dynes per cm}^2. \quad [36]$$

This approximate value of θ may be

compared with the value assumed in the analysis of martensite transformation curves. Eq 33 and 34 give

$$m = -9\pi\Delta f/512\theta = -7(10)^{-5}\Delta F_m$$

whence

$$\theta = 0.46(10)^{10} \text{ dynes per cm}^2, \quad [37]$$

in satisfactory agreement with θ_1 in view of the approximations in the elastic analysis and in the assumption that austenite pockets remaining in partially transformed steel are spherical.

The thickness to radius ratio δ/r for martensite plates can be calculated from the relationship

$$\delta/r = -\Delta f/4\theta = -3.2(10)^{-4}\Delta F_m. \quad [38]$$

At the M_s temperature, the ratio δ/r calculated for 3 pct chromium steels varies from 0.084 to 0.151 as the carbon content varies from 0.08 to 1.28 pct.

THE COHERENT α - γ INTERFACIAL FREE ENERGY

The experimental martensite start temperature corresponds to the presence of a definite number of martensite plates in a quenched sample of austenite of given grain size. A reasonable estimate of the number of plates needed to provide one visible plate per microscope field suggests that there are about 10^6 martensite plates per mol of lattice sites at the M_s temperature.

Substituting the value 10^6 for the number of martensite nuclei, Eq 22 becomes

$$10^6 = n_r = -(N/\ln a) \exp(n^* \ln a) = -(N/\ln a) \exp(V^* \ln a/v_0). \quad [39]$$

For ordinary values of N_c/N_s , Eq 39 fixes the value of $V^* \ln a/v_0$ to be

FIG 7—Calculated martensite transformation curves for 1 pct C, 3 pct Cr steel with ASTM grain sizes 0 and 7. Arrows indicate temperatures for 0.01 pct transformation.

FIG 8—Calculated martensite transformation curves for 3 pct chromium steels of differing carbon content. Arrows indicate temperatures for 0.01 pct transformation.

$$V^* \ln \cong a/v_0 - 45. \quad [40]$$

Substituting the value of V^* from Eq 12,

$$32,768 \pi \theta^2 \sigma^3 \ln a/27 v_0 \Delta f^5 = 45. \quad [41]$$

Taking $[-\ln a]^{1/5}/\Delta F_m = -1/800$ and $\theta = 0.46(10)^{10}$ from Eq 25 and 37, Eq 41 can be solved for the coherent α - γ interfacial free energy σ ,

$$\sigma = 24 \text{ ergs per cm}^2. \quad [42]$$

The value $\sigma = 24$ ergs per cm^2 that must be assumed in calculating M_s temperatures can be compared with the surface and interfacial free energies of solid copper, which should not differ markedly from those of iron:

$$\sigma_1 \cong 1400 \text{ ergs per cm}^2 \quad (\text{surface tension of copper}^{20})$$

$$\sigma_2 \cong 150 \text{ ergs per cm}^2 \quad (\text{non-coherent copper-copper interface}^{21})$$

$$\sigma_3 \cong 5 \text{ ergs per cm}^2, \text{ very approximately (twin boundary}^{21}).$$

It is encouraging to note that the coherent α - γ interfacial free energy and the twin boundary free energy in cop-

per agree as to order of magnitude.

It appears that the values of the parameters θ and σ , arbitrarily chosen to give agreement between theory and experiment, are close to the values expected from independent considerations. Within the error of an approximate calculation, θ is correctly given by a purely geometrical elastic analysis. The value of σ is reasonable in the light of what is known concerning coherent interfacial free energies of solids.

Influence of Austenite Grain Size and Other Variables

The M_s temperature and the extent of martensite transformation are dependent upon the austenitic grain size. Whenever nuclei form at random in the parent phase, and rapid growth of the new phase ceases at grain boundaries of the parent phase, each transformed particle is restricted to a single parent grain. The amount of transformation is the product of the number of nuclei and the size of each transformed region. The number of nuclei is independent of

grain size, and the volume of a typical transformed region is proportional to d^3 where d is the mean grain diameter, leading to the relationship

$$(\text{pct transformation}) \sim d^3 \quad [43]$$

during the early stages of transformation. A ten-fold decrease in grain diameter decreases the volume transformed to martensite by a factor of a thousand, thereby lowering the experimental M_s temperature.

Eq 30 gives the variation in the martensite transformation curve with grain size for all stages of transformation,

$$V_a/V_0 = (qn_0 + 1)^{-m},$$

where q is the number of mols of lattice sites per austenite grain. Fig 7 compares the calculated martensite transformation curves for two specimens of 1 pct C, 3 pct Cr steel with ASTM grain sizes 0 and 7, representing approximately a ten-fold change in grain diameter. The M_s temperature is 10–13°C lower (depending upon the method of measurement) in the fine grained material, and a comparable degree of transformation is achieved in a longer temperature interval.

INFLUENCE OF COMPOSITION ON THE SHAPE OF MARTENSITE TRANSFORMATION CURVES

Consider steels of varying chromium content and fixed carbon content. For these steels the free energy change ΔF_m on transforming austenite to martensite depends to a first approximation only upon the amount of subcooling below M_s . Hence n_0 and m in the relationship $V_a/V_0 = (qn_0 + 1)^{-m}$ are the same functions of the temperature interval below M_s for all steels of a particular carbon content, and the shape of the M_s transformation curve is independent of chromium content.

Steels with different carbon contents do not have quite the same shape, however, as shown in Fig 8 where calculated curves are compared for several 3 pct chromium steels of varying carbon content. The variation in shape with carbon content is in qualitative agreement with the observations of Grange and Stewart.²²

Although grain size and carbon content influence the shape of martensite transformation curves, examination of Fig 7 and 8 indicates that for the usual grain sizes and carbon contents that are employed in commercial steels, the shape of the martensite transformation curve is relatively insensitive to these

variables. The fraction of austenite transformed depends primarily upon the temperature interval below M_s , in agreement with the observations of Harris and Cohen.¹¹

EXTRAPOLATED M_s TEMPERATURES

The extrapolated M_s temperature is that at which the nearly linear portion of the martensite transformation curve intersects the axis of zero martensite. It lies a few degrees below the M_s temperature corresponding to the first plates visible during microscopic examination, as shown in Fig 9, where the shape of a calculated martensite transformation curve is given in detail near the M_s temperature.

Averaging data from 12 martensite transformation curves determined by Harris and Cohen¹¹ the extrapolated M_s temperature was found to lie about 6°C below the highest temperature of martensite observation for steels with M_s temperatures in the range $350 < M_s < 500^\circ\text{K}$. This value compares favorably with the calculated value of about 9°C.

STABILIZATION

Consider a specimen of austenite that transforms partially to martensite upon quenching to a temperature T_{-2} . It frequently is found that holding the specimen for a time at $T_{-1} > T_{-2}$ decreases the amount of martensite formed on subsequent cooling to T_{-2} , the maximum amount of martensite corresponding to direct quenching to T_{-2} .¹¹ This process is termed stabilization.

A mechanism for stabilization in single component systems has been described in the first section on nucleation. When embryos that would have become athermal nuclei upon further cooling are present in excess of their steady state concentration at a holding temperature T_{-1} , they decrease in number with time. Subsequent cooling to $T_{-2} < T_{-1}$ then produces fewer athermal nuclei and less additional transformation. In general, stabilization requires that subcritical embryos of the new phase somehow be eliminated while the specimen is held at T_{-1} . In single component systems, only embryos that grow smaller are eliminated. In the iron-carbon system, martensite embryos perhaps may be eliminated by processes that involve the diffusion of carbon.

Harris and Cohen¹¹ have shown that

FIG 9—Shape of calculated martensite transformation curve near M_s .

stabilization does not occur at temperatures above a critical temperature σ_s , dependent upon composition, and that the amount of stabilization increases as the holding temperature decreases below σ_s . The σ_s temperature has both theoretical and practical significance, and a complete analysis of austenite decomposition should provide means for explaining and predicting its existence. However, the mechanism of stabilization appears to be more complex than that of the austenite \rightarrow martensite transformation, and lies beyond the scope of the present analysis.

RATE OF GROWTH OF MARTENSITE PLATES

Coherent growth of martensite is very rapid, for each atom need move only about 0.34 of an atomic spacing to join the new lattice. The activation energy q^* for the unit process during this sort of "diffusion" is approximately $(0.34)^2$ times that for moving an atom a full atomic spacing. The latter value is estimated by Huntington and Seitz²³ to be about 0.36 times the activation energy for self-diffusion, the remaining 0.64 of the activation energy corresponding to the formation of a lattice vacancy. Birchenall and Mehl²⁴ report the activation energy for self-diffusion in γ -iron to be 48,000 cal per g atom, hence

$$q^* \cong 0.36 (0.34)^2 (48,000) = 2000 \text{ [44]}$$

cal per g atom (very approximately) is the activation energy for coherent growth.

The value $q^* = 2000$ cal per g atom

is in excellent agreement with the experimental activation energy $q^* = 1600$ cal per g atom observed by Kurdjumov and Maksimova for isothermal transformation of austenite to martensite in the temperature range $79 \leq T \leq 173^\circ\text{K}$ where the rate of transformation is measurably slow,⁷ although these authors assumed that q^* was associated with nucleation, rather than growth, of martensite plates. The very important work of Kurdjumov and Maksimova proves that the austenite \rightarrow martensite transformation proceeds isothermally with a rate that approaches zero at the absolute zero of temperature, and is evidence strongly in favor of the nucleation and growth hypothesis of martensite formation.

Conclusions

Martensite start temperatures and martensite transformation curves have been calculated from the basic assumption that the austenite \rightarrow martensite transformation proceeds by nucleation and growth. Martensite is identified as coherent supersaturated ferrite, and martensite nuclei are identified as small carbon-free austenite regions retained from the austenitizing temperature.

Agreement between experiment and theory is satisfactory, and there is reason to believe that adequate thermodynamic data will allow accurate calculation of M_s temperatures and martensite transformation curves for steels of arbitrary composition and heat treatment.

Acknowledgment

The authors' viewpoint concerning the austenite \rightarrow martensite transformation has been influenced through study of Professor C. Zener's thought provoking article on the kinetics of austenite decomposition.²⁶ The authors are indebted to Professor M. Cohen, to Professor R. F. Mehl, and to members of the Metallurgy Division of the General Electric Research Laboratory for stimulating conversations and helpful criticism.

Some Observations in the Structure of Alpha Brass Single Crystals after Cutting and Polishing

ROBERT MADDIN,* Junior Member, and WALTER R. HIBBARD, JR.,† Member AIME

A series of X ray experiments conducted by G. I. Taylor¹ in 1927 and later substantiated in 1939 by J. A. Collins² both on axially strained aluminum single crystals, revealed evidence that during single slip crystallite rotation occurs in such a manner that "all parts of the material rotated about the transverse direction in the plane of slip."¹

The actual method of preparing the specimens for X ray examination is not discussed in detail by Taylor except to say that "this specimen was cut parallel to the plane of slip, as calculated from measurements of marks in the surface of the specimen. It was ground and etched till the effect of the new cuts had disappeared. This was verified by applying the same treatment to an undistorted specimen. The X ray reflections‡ in this case were perfect ones."¹

Collins, on the other hand, cut his crystals in a mechanical shaper. These

surfaces were polished on No. 1, No. 1/0, No. 2/0 and No. 3/0 papers and on a broadcloth lap using No. 600 alundum as a polishing medium. "Finally, the surface was deeply etched in Tucker's reagent. An undeformed crystal was prepared in the manner described and X rayed to determine whether or not the machining and polishing operations had produced any strain or distortion in the crystal. The Laue spots all seem to be sharp,

free from tails and streaks indicating no detectable strains had been introduced in the crystals."²

Taylor's X ray technique involved the use of "homogeneous X rays from an iron anti-cathode"; whereas Collins used K_{α} radiation of copper at 31kv and 20 milliamperes.

Glancing angle X ray photograms were taken (1) with the axis of rotation of the spectrometer table in the plane of slip and at right angles to the slip direction, and (2) with the axis of the spectrometer table lying along the slip direction.

However, eight minute exposures were used in each case and the angle setting of the spectrometer table was increased by one degree for each exposure.

With the discovery of the action of three slip systems³ in the plastic deformation of single crystalline alpha brass where, formerly, only one had

† Assistant Professor of Metallurgy, Yale University.

‡ Presumably Laue back-reflection photograms.

¹ References are at the end of the paper.

FIG 1—Laue photograph of {111} section from crystal showing absence of streaks or tails.

been considered to have operated, C. H. Mathewson suggested that the experiments of Taylor and Collins be repeated in order to examine critically the possible effects of the deformation process in terms of pole rotations introduced by the action of more than one slip system.

Consequently, the orientation of an undeformed single crystal of alpha brass was determined by the Laue back-reflection method. A disk, with its flat surfaces parallel to a convenient (111) plane, was carefully cut from the crystal with a No. 14B jeweler's saw in a goniometric miter box. The disk was polished carefully by hand on a series of fine files followed by No. 1/0, No. 2/0 and No. 3/0 metallographic papers. The disk was next etched in 1:1 HNO₃ so as to remove at least 0.125 in. from the cut surface. The (111) plane was within one degree of being parallel to the surface as determined by a Laue back-reflection photograph. The effects of cutting and polishing were seemingly removed as adjudged by the condition of the Laue spots shown in Fig 1. Although these spots are multiple indicating lineage imperfections somewhat less than 2° in magnitude, they are sharp and free from tails or streaks as they appeared in first photograph orienting the specimen.

The disk was mounted on a goniometer head set at the proper θ angle (21°30') for primary octahedral reflections. Intense monochromatic copper K radiation was obtained by reflection from the C-cleavage surface of a suitably oriented pentaerythritol crystal. The tube was operated at 31kv and 11 milliamperes. The crystal reflected beam passed through a collimator 2 in. long containing a 1 mm bore. A 1.75 in. specimen to film distance was used. Satisfactory photograms were obtained using 8-hr exposures, Fig 2.

A spread of at least 35° may be seen in Fig 2. This spread in orientation may be interpreted as indicating that mechanically cutting a single crystal affects its structure throughout a considerable thickness. Changing the θ angle to 30° (an increase of 8°30') resulted in a very weak 8° spread after 10 hr exposure.

The depth to which surface preparation disturbances can be detected in single crystals has been considered by Lacombe and Chaudron.⁴ However, their disturbed structures were measured as less than 100 microns dependent upon the material. In the present investigations a minimum of 0.125 in. was removed after mechanical cutting and polishing and yet a disturbed structure was apparent, when

FIG 2—Glancing angle photogram of the crystal showing spread in orientation of the {111} plane.

$\theta = 21^\circ 30'$; monochromatic radiation; eight hour exposure.

investigated with directed characteristic radiation.

Since the present investigation made use of monochromatic X rays rather than white radiation to detect these disturbances and the exposures were considerably longer than those of Taylor and Collins, it would appear that they may not have removed with all certainty the mechanically disturbed surface by their treatments and the method of detection used. This suggests a reinvestigation of their findings, which is under way.

The authors would like to acknowledge the assistance of Mr. Marritt L. Kronberg of this Laboratory for setting up the monochromator.

Simultaneous Aging and Deformation in Metals

J. D. LUBAHN*

The influence of precipitation from solid solution on the subsequent deformation resistance of alloys is well known. However, the influence of precipitation or aging that occurs simultaneously with deformation may be entirely different and of considerable importance. It is thought¹ that the presence or absence of a yield point jog in impure iron at room temperature and the presence or absence of discontinuous flow at higher temperatures may be directly related to aging phenomena, particularly since the yield point jog is absent when the carbon and nitrogen are sufficiently removed.²

As a preliminary attack on the problem of simultaneous aging and deformation, three kinds of tests—constant strain rate tensile tests, constant load creep tests, and variable strain rate tensile tests—were carried out on an age hardenable aluminum alloy.

Constant Strain Rate Tensile Tests

Stress-strain curves at a strain rate of about 0.001 min^{-1} were obtained for specimens of 61S that had been quenched into liquid nitrogen after a one-hour solution treatment at 521°C , then aged at room temperature 10 min., 20 min., 4 hr, and 26.5 hr before testing. Strain-time curves were obtained on the same chart with the stress-strain curve by means of an auxiliary pen, driven parallel to the axis of the chart drum at constant speed by a synchronous motor and gear chain. The angle of rotation of the chart drum was proportional to strain. The strain rates reported are the measured slopes of the strain time curves. Constant

FIG 1—Effect of amount of prior room-temperature aging on the room-temperature stress-strain curve of solution treated 61S. Strain rate = 0.0013 min^{-1}

FIG 2—Effect of strain rate and prior room temperature aging on the flow stress at 0.003 plastic strain.

strain rate was approximated (within a factor of 2) by manual adjustment of the oil inlet valve of the hydraulic testing machine in such a way that the course of the recorder pen was parallel to pre-drawn strain-time lines of the desired slope.

The specimens were machined from $\frac{3}{16}$ in. rod. The cylindrical portion was 0.357 in. in diam by $1\frac{3}{4}$ in. long and

FIG 3—Discontinuous flow in 61S aged 10 min. at room temperature before room temperature testing at 0.00075 min^{-1} (or equivalent rate of head separation during discontinuous flow).

smoothed into the $\frac{1}{2}$ in. — 13 threaded ends by $\frac{1}{4}$ in. fillets. Strain was measured by an averaging Baldwin-Southwark microformer-type strain gauge with a 1.4 in. ga. length between conical points, used in conjunction with a Baldwin-Southwark stress-strain recorder and tensile testing machine.

As expected, the resulting stress-strain curves, two of which are plotted in Fig 1, show that for a given strain rate the flow stress is higher the longer the period of aging preceding the test. The entire stress-strain curve is smooth only for specimens aged for sufficiently long periods of time before testing. Although the early portions of the other curves also are smooth, the later portions exhibit discontinuous flow.*

* The term "discontinuous flow" will be used to designate any failure of the metal to follow a smooth stress-strain curve or strain-time curve.

FIG 4—Discontinuous flow in 61S aged 10 min. at room temperature before room-temperature testing at 0.00075 min^{-1} (or equivalent rate of head separation during discontinuous flow).

FIG 5—Discontinuous flow in 61S aged 10 min. at room temperature before room-temperature testing at 0.00075 min^{-1} (or equivalent rate of head separation during discontinuous flow).

FIG 6—Discontinuous flow in 61S aged 10 min. at room temperature before testing at 0.0003 min^{-1} (or equivalent rate of head separation during discontinuous flow).

For aging times that are not too short, flow stress values can be obtained from the early, smooth portion of each stress-strain curve. Flow stress values at a plastic strain of 0.003 increase with aging time for tests at a given strain rate (Fig 2), and a few tests indicate that a slower strain rate produces a higher flow stress (for a given initial condition of aging). This reverse rate effect will be discussed in connection with another type of test to be described below.

After discontinuous flow began, a constant rate of head separation* was maintained, for it was no longer possible to keep the strain rate constant. The discontinuous flow exhibited different characteristics under different conditions of strain rate, amount of strain, and prior aging treatment. Usually there was a characteristic periodicity of rising and falling load, with slow extension prevailing during each period of falling and rising load and with sudden extension at the maximum load (Fig 3). This periodic flow sometimes was superimposed on a second kind of periodic disturbance (with a longer period) where groups of load variations occurred at regular intervals of strain (Fig 4), or where alternate lengthening and shortening combined with rising and falling load

* The Baldwin-Southwark testing machine had a pump control that provided a constant rate of oil flow for a given position of the inlet valve, regardless of the load. Thus a constant rate of head separation was obtained by keeping a constant opening of the inlet valve. Such a procedure will not produce a constant elongation rate of the gauge length if the load is changing, however, for some of the head motion is used up in fixture deflection. Variations in elongation rate as great as 20 to 1 may be expected for a constant inlet valve setting.

FIG 7—Discontinuous flow in 61S aged 2 min. at room temperature before room-temperature testing at 0.0008 min^{-1} (or equivalent rate of head separation during discontinuous flow).

FIG 8—Creep curve for 61ST at room temperature and 41,900 psi initial stress (tested several months after aging).

actually produced loops in the stress-strain curve (Fig 5).

At a smaller rate of head separation, smooth sections of normal stress-strain curve were separated by comparatively short, uniformly-spaced, strain intervals where a very pronounced rising and falling of load accompanied unusually slow extension (Fig 6). When a specimen was tested almost immediately upon warming to room temperature from the liquid nitrogen quenching bath, discontinuous flow began immediately; and under these conditions almost square steps were observed in the stress-strain curve (Fig 7). Similar periodic flow has been observed by McReynolds³ during extension of specimens of several alumi-

num alloys. He employed a very soft tensile machine designed to produce a constant rate of increase of stress, rather than a constant strain rate.

Creep Tests

61ST was subjected to constant-load creep tests at room temperature. The load was applied through an 18:1 lever with three hardened steel knife edges. The knife edges were all in the same plane. The strain time curve was obtained with the same device employed for determining strain rates in tensile tests. The gear train for the time-drive was arranged so that quick changes in speed of 30:1 could be made as required

to avoid a strain-time curve that was too nearly axial or circumferential for accurate slope measurements. 61ST tested in creep at room temperature several months after commercial aging (8 hr at 350°F) exhibited smooth strain-time curves as shown in Fig 8. On the other hand, 61ST tested within a few hours after the commercial aging treatment exhibited sudden periodic extensions superimposed on a smooth

strain-time curve, as shown in Fig 9. Similar behavior has been observed with copper.⁴ The difference in behavior between 61ST freshly aged at 350°F and that tested long after aging suggests that the freshly aged material had the greater capacity for change at room temperature.

A material that is aging rapidly during deformation ought to exhibit a very pronounced departure from the

behavior of pure metals and other non-aging materials. To check this point, a creep test was made on 61S aged 20 min. at room temperature after quenching into liquid nitrogen from 521°C. Fig 10 shows that a large plastic extension* occurred upon application of the load, after which the material did not elongate further. Furthermore, suc-

* The extension was too rapid for the recorder to follow.

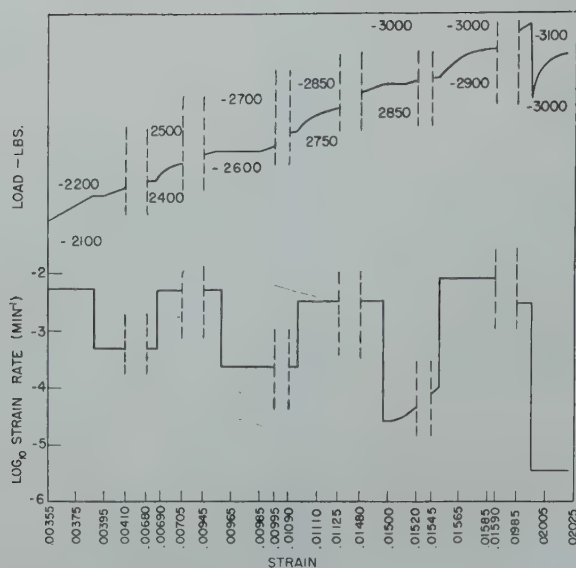

FIG 13—Tensile transients for OFHC copper at room temperature.

FIG 14—Tensile transients for pure (99.996 pct) aluminum at room temperature.

cessive additions of small load increments never caused gradual straining. After each load increment, either sudden plastic extension occurred or the specimen remained elastic.

The peculiar behavior observed upon successive application of small load increments to a currently aging metal was attributed to the fact that aging was proceeding during the test. If, as suggested above, the deformation behavior of recently aged 61S (61ST) can be affected by further room-temperature aging, then it might be expected that 61ST would exhibit creep behavior similar to that shown in Fig 10 for solution treated 61S. This expectation was realized (Fig 11).

Variable Strain Rate Tensile Tests

In these tensile tests the strain rate was changed suddenly from one constant value to another. When such a change is made, an immediate shift from a stress-strain curve characteristic of one rate to a second curve characteristic of the other rate might be expected. Actually, however, there is usually a period immediately following a rate change where the behavior conforms to neither curve, with rigorous conformity to the new curve being approached later. The temporary disturbance following a rate change has been called a "transient."^{5*}

A peculiar transient is observed for 61ST tested at room temperature. Fig 12 shows that after changing the

* The experimental equipment and procedure for measuring tensile transients are described in ref 5.

strain rate a new stress-strain curve appears to be approached; but then the stress changes in the opposite direction and approaches that corresponding to the curve preceding the rate change. This lack of rate effect for steady deformation (that is, after the dying-out of the transient) of 61ST at room temperature is surprising, for OFHC copper (Fig 13) and pure aluminum (Fig 14) both show a definite (though small) rate effect at room temperature.

The creep tests described above suggested that aging at room temperature could significantly affect the deformation of 61ST; it is possible that aging is responsible also for the peculiar transients and the lack of rate effect in 61ST tested at room temperature. To investigate this possibility, tensile transient tests were made at a series of temperatures. At liquid nitrogen temperature (-194°C) a definite rate effect was observed (Fig 15) and the transient consisted only of a gradual shift from one curve to another, as is observed for non-aging metals (see Fig 14). This behavior would be expected if no aging occurred at -194°C . At the temperature of dry ice (-78°C) there was still a definite rate effect, although overshooting* was observed during the transient (Fig 16). In ice water (0°C) the overshooting during the transient was more pronounced and the rate effect (though small) was in the opposite direction to that observed at lower temperatures; upon increasing the rate, a lower stress-strain curve was approached than that preceding the rate change, and conversely (Fig 17). At 93°C the rate effect was large and in the expected direction, as shown in Fig 18.

The quantity $n = (\log S_2/S_1)/(\log \dot{\epsilon}_2/\dot{\epsilon}_1)^{\dagger}$ was used as a measure of the rate effect. It was found to be roughly constant regardless of the change in rate, as illustrated in Fig 19. The influence of testing temperature on the rate effect is summarized in Fig 20, which shows n to have a pronounced minimum in the neighborhood of room temperature. It might be inferred that the rate effect in 61ST is a combination of an inherent rate effect (that observed in non-aging metals, where higher rates produce higher stresses) and a superimposed, inverse rate effect, due to aging, for which lower rates produce higher stresses. Fig 20

FIG 17—Transient effects in a tensile test on 61ST at 0°C .

FIG 18—Transient effects in a tensile test on 61ST at 93°C .

FIG 19—Determination of n values (rate effect) illustrated for two temperatures. Derived from data of Fig 16 and 17.

shows that the contribution of the aging to the overall rate effect is at a maximum near room temperature and disappears in the vicinity of -150°C .

According to the above viewpoint, transients are caused by a disturbance in the balance between two rate ef-

fects. Any disturbance of the balance between the inherent rate effect and the rate effect due to aging, such as a temporary pause in the plastic straining, might cause an unusual transient. An experiment on 61ST at room temperature in which a tensile test was

* Overshooting means that the stress changes to a value beyond that characteristic of the new strain rate, then slowly returns.
† The symbol ϵ denotes strain rate.

FIG 20—Effect of testing temperature on the rate effect for 61ST.

temporarily interrupted by a sojourn at a slightly lower load yielded such a transient following the interruption, even though the strain rate was the same before and after the interruption (Fig 21).

Conclusions

If a metal is aging while it is being plastically deformed, it may show unusual deformation characteristics as follows:

1. Discontinuous yielding in a tensile test.
2. Periodic sudden extensions in a constant load creep test.
3. Failure ever to undergo gradual extension at constant load.
4. Unexpected transients following a sudden rate change.
5. An inverse rate effect, where an

increase in flow stress (beyond the transient) is required to maintain a smaller strain rate.

On the Problem of Grain Boundary Movement

C. G. DUNN,* Member AIME, F. W. DANIELS,* and M. J. BOLTON*

Recent observations on grain boundary movements in silicon iron have indicated the possibility of studying grain growth phenomena in two-grain specimens in which several variables affecting growth are readily controlled. These variables are (1) the energy per unit area (γ) in the grain boundary, (2) the orientation relationship of the two grains, and (3) the radius of curvature (τ) of the moving boundary.

Ideally, one grain A should be a narrow rectangular parallelepiped adjacent to a second grain B as shown two dimensionally in Fig 1. Such a two-grain group becomes unstable when one end of grain A is shaped according to the dotted line. Since the width w of grain A remains constant during growth of grain B, τ should also remain constant. The other vari-

FIG 1—Schematic diagram of two grain-group for studying growth.

ables mentioned above can be controlled in the preparation of each two-grain specimen.^{1,2,3} For a particular orientation of each grain, γ is

not necessarily fixed; γ may also depend on the orientation of the grain boundary, but this may be controlled to some degree.

The energy relationships for the growth of grain B may be derived from the more simple arrangement of two grains A' and B' shown schematically in Fig 2. Here B' largely surrounds A'. Assume these grains are oriented with a common plane parallel with the flat

FIG 2—Schematic diagram of two grains A' and B'.

portion of the specimen. Consider equal lengths l of grains A' and A. The total grain boundary energy for A' is twice that for A. Therefore, the width of A' will be taken equal to $2w$ so that both grains have the same grain boundary energy for transferring a unit volume of metal from A to B or A' to B'. When a volume V —that is, $2wlt$, where t is the thickness of the flat specimen*—transfers to B or B', the energy E released is obviously given by the following equation:

$$\frac{E}{V} = \frac{\gamma}{w} \quad [1]$$

Thickness of the specimen does not enter this equation. Consequently, growth in such two-grain specimens should be independent of thickness. If γ is independent of grain boundary orientation, the shape of the active part of the grain boundary should reasonably approach a semicircle. When this occurs, w becomes identical with the radius of curvature τ of the advancing part of the boundary and Eq 1 then expresses the usual driving force for grain growth.⁴ If γ varies with grain boundary orientation, γ in Eq 1 applies to the straight part of the boundary.

In the application of Eq 1 to grains A and B, it is assumed that the edge of grain A does not introduce an energy term. If a surface energy is involved, Eq 1 should be modified. It is also believed that w and τ may be different merely because a groove tends to form at the open end of the curved grain boundary. The term to use in Eq 1, therefore, is w rather than τ .

The present technique permits a time-temperature investigation at constant curvature to be made. Also, the rate of grain boundary movement can be measured as a function of temperature alone and the results used to calculate activation energies.

That the above method is experi-

mentally feasible is indicated by the following example from our preliminary work. Silicon iron specimens capable of supporting exaggerated grain growth were prepared in the form of long strips 0.025 in. thick. Using a controlled grain growth technique,¹ one strip was converted into a suitable two-grain specimen with the common grain boundary lying parallel to the long dimension. The (110) planes of both grains were in the plane of the strip, and the [001] directions were 25° apart.

A 1 in. length cut from this specimen was annealed 4 hr at 1400°C in pure dry argon to eliminate boundary irregularities and to reveal the position of the boundary by thermal etching.⁵ A final small two-grain specimen was prepared from the annealed piece and given an anneal of 10 hr at 1400°C in pure dry argon.

A photograph of the specimen in the as annealed condition is shown in Fig 3. The old boundary position extends across the length of the specimen. The new boundary (one end indicated by arrow) is curved along the advancing portion and coincides with the old boundary for a short distance. Observing these thermally etched boundaries at about 300 diam magnification, the old boundary appears as a "ghost line" whereas the new boundary is well defined. Reality of the new boundary was also confirmed by an X ray Laue photograph.

The specimen was then annealed an additional 48 hr at 140°C. No movement of the grain boundary occurred. It appears that the advancement was stopped by inclusions during the first anneal.

An estimate of the available energy for growth is of interest. With γ equal to 500 ergs per cm² approximately^{6,7} and w equal to 1.3 mm, Eq 1 gives, on changing units, a driving energy of 0.00009 cal per cm³. This energy may be contrasted with the value 9 cal per cm³ reported for cold worked iron.⁸ Larger values of γ/w could be obtained using smaller values of w .

FIG 3—Photograph of a two-grain specimen showing growth of one grain. Thermal etch. $\times 10$.

More information using the present technique is anticipated from investigations now under way at this laboratory. It is hoped that results may be reported in the near future.

The Transverse Bending of Single Crystals of Aluminum*

M. K. YEN† and W. R. HIBBARD, JR.,‡ Junior Members AIME

Previous studies of plastic deformation of metals have emphasized the important role of bending and constraints during strain under relatively pure stresses.¹⁻⁵ Some new phenomena such as early conjugate slip⁶ and polygonization⁷ are intimately concerned with the relief of bending stresses, the former by slip and the latter by a process analogous to recrystallization. However, few analyses of the bending deformation of single crystals were found in the literature, and those^{8,9} are sufficiently previous to the modern interpretations of slip to invite further investigation in this area.

The transverse bending mode of testing, using the two-point loading method, was selected because the center portion of the specimen may be considered as under a theoretically pure bending stress with a uniform bending moment. Considerable attention was given to both the lattice distortion and flow characteristics of the crystals during deformation.

Experimental Procedure

A specimen under the action of equal and opposite couples at both ends is said to undergo pure bending. The shear and moment diagrams of a specimen under the two-point loading method of transverse bending are shown in Fig 1. The moment over the middle-third of the span is equal to $PL/6$, and the vertical shear is zero. Fig 2(A) illustrates the stress distribution in the elastic range on a plane across the middle of the specimen. It can be seen that the normal stress has a maximum value at the extreme surfaces on the tension and compression sides, and decreases proportionately to zero as it approaches the neutral plane.

FIG 1—Shear and moment diagrams of a beam under transverse bending by the two-point loading method.

However, when the plastic range is reached, the stress distribution is no longer a straight line relation, but changes in a manner which can be best illustrated as shown in Fig 2(B). The following calculation and stress analysis are mainly in accordance with the works reported by Timoshenko¹⁰ and Kochendörfer.⁹

From the simple beam formula, the maximum normal stress will occur at the surface of the specimen. For a round specimen with a radius r and for a rectangular specimen with a height

FIG 2—Stress-distribution in a beam for (A) elastic range and (B) plastic range.

$2h$ and width $2b$, the maximum normal stress, S_n , will be given by the following formulas:

For round specimen:

$$S_n = \frac{2PL}{3\pi r^3} \quad [1]$$

For rectangular specimen:

$$S_n = \frac{PL}{8bh^2} \quad [2]$$

Since it is reasonable to consider that slip takes place under the same conditions as in uniaxial loading, the resolved shear stress S_s , along the operative slip direction will be as follows:

For round specimen:

$$S_s = \frac{2PL}{3\pi r^3} \sin \chi \cos \lambda \quad [3]$$

For rectangular specimen:

$$S_s = \frac{PL}{8bh^2} \sin \chi \cos \lambda \quad [4]$$

where λ is the angle between the specimen axis and the slip direction and χ , the angle between the specimen axis and the major axis of the glide ellipse.

It was also reported by Kochendörfer⁹ that the critical bending moment, that is, the bending moment exerted on the specimen to initiate slip, should be higher than the value given by the equations stated above. Based

FIG 3—Bending apparatus assembly at X ray tube.

upon his analysis, the critical shear stress observed in bending may be 1.5 to 1.7 times greater than that in uni-axial loading for rectangular and round specimens respectively.

A special bending device to apply a transverse load by the two-point loading method used in this investigation consisted of three major parts: 1. Back-reflection camera with demountable pin-hole system. 2. Bending fixture with load-measuring device. 3. Deflectometer with a dial indicator.

The assembled equipment is shown in Fig 3. The back-reflection X ray camera had two interchangeable collimating pin-hole systems, 1.0 and 0.5 mm in diam.

In the bending device, the specimen was supported by two steel knife-edges with a span of exactly 3 in. The load was transmitted to the specimen through two knife-edges one inch apart which were mounted on a sliding steel plate bearing against a calibrated spring. The load was measured by reading the deflection of the compressed spring on the scale attached. The deflectometer consisted of a pivoted lever which was mounted so that the lower end contacted the center of the back side of the specimen. The upper end of the lever was attached to the stem of a dial indicator whose scale could be estimated to one ten-thousandth of an inch.

Two different types of specimens were made from high-purity aluminum rod having the following chemical compositions:

| | |
|-----------------|--|
| Pct | |
| 99.975 Aluminum | |
| 0.006 Silicon | |
| 0.015 Copper | |
| 0.006 Iron | |

Round specimens, $\frac{1}{4}$ in. in diameter and 4 in. in length were prepared by Found¹¹ using a modified Bridgman method. Flat specimens were produced by a strain-annealing method comparable to that reported by Carpenter and Elam.¹²

The round specimens, used for preliminary work, were carefully metallographically polished by hand and etched with 2 pct hydrofluoric acid. Back-reflection Laue photograms were used to insure complete removal of any distortion.

The flat specimens were cut from strain-annealed pieces mounted in a special fixture which was used as a guide for a No. 8 jeweler's saw to cut along the longitudinal axis. After the sawing was accomplished, the specimen was then alternately polished and etched using 2 pct hydrofluoric acid and emery paper down to No. 000. Subsequent wet-polishing with alumina on a slow-speed wheel provided a smooth surface ready for the final electrolytic polishing.

The electrolytic polishing process used a dilute solution of fluoboric acid with low current density. Any smudge on the surface could be removed by immersing for about one minute in a hot solution containing 35 cc of 85 pct phosphoric acid and 20 g of chromic acid per liter. A subsequent rinsing with distilled water and alcohol and a final drying operation were then necessary.

After the specimen had been prepared according to this method, a one-inch gauge length was scribed on its center portion. A scratch was also made on the end of the specimen to serve as a reference mark for aligning purposes. The specimen was then placed carefully on the bending device

and adjusted in such a manner that the two gauge marks coincided with the two knife edges for load application, and the reference mark was in a vertical position.

The back-reflection Laue method described by Greninger¹³ was used for the determination of crystal orientation.

By suitably arranging a mirror with a binocular microscope, the front and top surfaces of the specimen could be observed concurrently during loading.

The load on the specimen was applied by gradually turning the knob on the back of the compressive spring which pushed the two knife edges forward against the specimen. The compression of the spring as well as the corresponding deflection of the specimen were recorded simultaneously so that the load-deflection curve could be made. X ray photograms and micrographs were taken at successive deflections of about 50 thousandths of an inch, in addition, to analyze the various surface markings.

Discussion of Results

Ten crystals, four round specimens and six flat ones, were investigated. The round specimens, approximately $\frac{1}{4}$ in. in diam, were used for preliminary work. Flat specimens A-10, A-11, and A-12 were bent after electrolytic polishing. Flat specimens A-13, A-14, A-15 were tested after mechanical polishing and etching with a dilute solution of hydrofluoric acid. The designations, dimensions and initial orientations for all specimens are shown in Table 1. In order to simplify

Table 1 . . . Dimensions and Initial Orientations of Round and Rectangular Specimens

| Specimen | Dimension, In. | Area of Cross-section Sq In | Initial Orientation | | |
|-------------|----------------|-----------------------------|---------------------|-----------|--------------------------|
| | | | χ | λ | $\cos \chi \sin \lambda$ |
| Round | A-2 | 0.218 diam | 0.0374 | 43° | 0.431 |
| | A-3 | 0.243 diam | 0.0464 | 38° | 0.406 |
| | A-4 | 0.242 diam | 0.0461 | 52° | 0.412 |

the description of different positions on the specimen, the following designations are used: The "front" and "back" are the convex and concave sides on the bent specimen. The symbols "Top-T" and "Top-C" indicate

FIG 4—Axis rotations of bending specimens.
(▲) tension side and (+) compression side.

the regions on the top surface near the tension and compression edges respectively. For round specimens, only the symbols "front" and "back" are applicable. Unless otherwise noted, photograms and micrographs are taken with the stress axis horizontal and in the plane of the page.

Lattice Rotation in Bending

Axis orientations for the unstrained crystals and after various amounts of bending are shown in Fig 4. The axis of the unstrained crystal is designated by the small circle (o) at the center of the projection. The axes determined at the front and back side of the specimen after bending are represented by the triangle (▲) and cross (+) respectively. Thus the movement of the specimen axis relative to the axis of the unstrained crystal was observed.

For a single crystal subjected to tensile loading, the lattice rotation takes place in such a way that the slip direction gradually approaches the stress axis. For compression, the slip plane rotates toward a position parallel to the plane of compression. In the case of f.c.c. metals, the specimen axis dur-

ing simple slip moves toward [110] and [111] for tensile and compressive stresses, respectively, whereas in duplex slip the end positions are [112] and [110] for tension and compression respectively.^{14,15} Referring to Fig 4, it can be seen that when aluminum crystals were subjected to bending stress, the stress axis on the tension side of all specimens appeared to follow generally the Taylor and Elam rotation¹⁴ toward the active slip direction. However, in the compression side, the change of orientation deviated from the path toward the (111) pole to a certain extent. In specimens A-10 and A-11, the axis on the compression side appeared to rotate toward a (110) pole instead of the (111) pole. This deviation could be ascribed to the restriction of flow in bending and possibly the presence of a secondary slip system.

Micrographic Observations

Round specimens A-2, A-3, A-4, and A-5 were prepared by polishing and deep-etching. It was noted that both the interlineage boundaries and a slight cored structure, similar to that in copper crystals observed by Hibbard,¹⁶ were developed. However, the

interdendritic spacing of the cored structure was considerably smaller than that of copper. A considerable number of slip lines were observed on the front and back surfaces even at very low deflection. The slip lines were localized in character but were gradually propagated toward the neutral plane as the load increased. The density of the lines also increased with an increase of load, but approached a constant value of approximately 1200 per inch at higher deformation. The lines generally appeared fairly equally spaced but slightly wavy in appearance.

Flat specimens A-10, A-11, and A-12 were prepared by mechanical polishing followed by the electrolytic polishing. Fig 5 and 6 show two photographs of specimen A-10 after a total deflection of 0.554 in. It was found that the surface markings on the top surface started at the edges of the specimen and moved toward the neutral plane with an increase in deformation. The density of lines increased with the degree of deformation but decreased as they approached the neutral plane. Considerable shift of the neutral axis toward the compression side was observed at higher deformation. This can be ascribed to the difference in specimen thickness between the tension and

compression sides caused by plastic flow and the resulting change in the stress distribution.

At first glance, no marked difference in the microscopic appearance of the markings on the tension and compression sides was observable at a magnification of 100 \times . However the microstructures at high magnification exhibit a rather distinctive aspect shown in Fig 7 and 8. Parallel narrow dark lines could be resolved on the tension side, but poorly defined light-colored bands with considerable width were observed on the compression side.

The development of markings on the front surface of these specimens started with equally spaced parallel lines (see Fig 9). The density of lines increased two fold as the deflection increased from 80.5 to 250.0 thousandths of an inch. Another set of markings inclined 45° to the specimen axis then appeared during further bending. The 45° lines appeared discontinuous in nature and were displaced where they met the vertical ones (see Fig 10). It was found that the lines inclined at 45° were the expected octahedral traces, whereas the vertical ones were thought to be cubic traces at an early stage of the investigation. In Fig 11 the crystal orientation of specimen A-10 is plotted on a stereographic projection with the pole of the front surface located at the center of the primitive circle. The traces of the markings on both the front and the top surfaces are sketched in the upper-left corner of the drawing. The loci of the poles of traces Top-I and Front-I intersect at a pole of an octahedral plane which was found to be the primary operative slip-plane having the maximum value of resolved shear stress. Trace Front-III was found only with slight oblique illumination at low magnification. (See Fig 6.) It appears as a band-like structure which makes an angle of about 90° with the octahedral traces. This band-like structure could not be resolved at higher magnification and may be regarded as evidence of a type of rotation of crystallites about an axis normal to the slip plane described by previous investigators.^{17,18}

The trace Front II, which made an angle of about 90° with the specimen axis, was a somewhat confusing one. Referring back to Fig 11, the most probable plane in the zone of the axis is a cubic or a (100) plane. Since cubic slip does occur in aluminum at high temperatures, it led to the possibility that the cubic plane might slip under a

FIG 5—Specimen A-10. Top surface after 0.554 in. deflection. 4 \times .

FIG 6—Specimen A-10. Front surface after 0.554 in. deflection. 4 \times .

FIG 7—Specimen A-10. Surface Top-T after 0.250 in. deflection. 1000 \times .

FIG 8—Specimen A-10. Surface Top-C after 0.250 in. deflection. 1000 \times .

rather complicated stress introduced by bending. Similar results were also found in specimens A-11 and A-12. The orientation of specimen A-11 is shown

in Fig 12. By further study of specimen A-11 vertical traces Front II and Top I were established as continuous traces from the same plane. Referring to Fig

12, the pole of these two vertical traces Front II and Top I must be in the neighborhood of the specimen axis, but no significant plane could be found in that region of the projection. It appears therefore, that a possible explanation is that these lines are strain markings or cracks in the anodic coating left from electrolytic polishing. Further experiments on the specimens prepared by mechanical polishing and etching substantiate this finding.

When the specimens A-10 and A-12 were subjected to bending with a deflection of a tenth of an inch, a second set of slip markings (Top Trace II) was revealed at the Top-C surface of the specimens. From the analysis of the surface markings shown by Fig 11, it can be seen that these were the traces of a secondary octahedral plane. This was found to be in the (111) plane which had the second highest resolved shear stress among the twelve (111) [110] systems. The early occurrence of the secondary slip system may be ascribed to the restriction of flow at the compression side which varies from the condition for a crystal under pure compression and thus forces the secondary system into operation. Referring back to the projections showing lattice rotation, Fig 4, it can be seen that the rotation on the compression side is different from that in uniaxial loading in that the specimen axis was rotated toward the (110) direction and not toward the pole of the slip plane as in pure compression. This appeared to collaborate the microscopic observation of double slip since it is known that the [110] direction is usually the end position of the duplex slip for face-centered

FIG 11—Stereographic profection of specimen A-10 after 0.554 in. deflection with front surface parallel to the plane of the projection.

cubic crystals under compression.

In order to eliminate the uncertainty in the surface condition introduced by electrolytic polishing, specimens A-13, A-14, and A-15 were subjected only to mechanical polishing with fine alumina followed by etching with diulte HF solution. No appreciable difference was noticed in microscopic appearance of surface markings at low magnification between specimens with or without electrolytic polishing. The band-like structure found in specimen A-15 was comparable to that in Fig 6 of specimen A-10. In addition, a similar type of band structure both parallel and per-

pendicular to the traces of the operative slip plane of specimen A-13 was found.

However, at high magnification only traces of the theoretically predicted octahedral plane were observed. Except at Top-C surface of specimen A-13, a secondary set of slip markings was found to be the traces of the octahedral plane having the second highest resolved shear stress among all twelve possible slip systems. The slip markings generally appeared to be fairly straight and equally spaced. It was found, however, in the neighborhood of the region where the slip direction intersected the specimen surface that the markings ap-

FIG 9—Specimen A-10. Front surface after 0.081 in. deflection. 500 X.

FIG 10—Specimen A-10. Front surface after 0.554 in. deflection. 1000 X.

FIG 12—Stereographic projection of specimen A-11 after 0.300 in. deflection with front surface parallel to the plane of the projection.

peared to be either step-like or discontinuous in nature. Fig 13 shows slip markings on the Top-T surface and front surface of specimen A-15. The markings appeared to be straight and had an average distance between them of from 5 to 10 microns. The closest approach distance was in the order of one micron. Fig 14 shows slip markings on the front surface of specimen A-13 at $\times 1000$ magnification. The pictures were taken on the surface where it is intersected by the direction of slip. The short step-like markings appeared not to follow any definite crys-

tallographic angle as reported in alpha brass.¹⁹ This may be due to the more complicated stress condition in bending where these steps were probably too small to be identified with any particular planes. Similar results were also found in specimen A-15 on the Top-T surface where it was intersected by the direction of slip (Fig 13). Regions showing the discontinuity of markings were also observed in both specimens A-13 and A-15. These markings were similar to those reported by Crussard²⁰ in aluminum crystals as well as by Andrade²¹ in deformed lead crystals.

They generally lost their width accompanied by a great decrease in their intensities as they passed each other. It is also interesting to note that the phenomenon of bending of the glide-lamellae did take place in specimen A-15 as shown in the upper edge of Fig 13.

Slip markings of specimen A-15 under oblique illumination are shown in Fig 15, and appear to be dark and light bands on the tension and compression sides respectively. The regions free from any resolvable slip markings are close to the neutral plane, at which the stress should be theoretically zero. The density of the markings on both sides increased from the inside outward and gradually approached a constant value at the edges of the specimen.

Asterism

When a crystal is deformed by uniaxial loading, distortion generally occurs by rotation of the crystallites about an axis lying in the slip plane normal to the slip direction. This type of rotation was more or less confirmed by analysis of the Laue spots obtained from deformed crystals.²⁻⁵ Recently it was found that in addition there is also a relocation of glide-lamellae by a twisting distortion around the polar axis of the slip plane.^{17,18} However, in the present investigation, the asterism of Laue spots in the X ray photographs did not appear to follow either of these types of distortion. The change of the Laue spots always exhibited the same

FIG 13—Specimen A-15. Top-T surface after 0.389 in. deflection. 1000 X.

FIG 14—Specimen A-13. Front surface after 0.300 in. deflection. 1000 X.

pattern regardless of the initial orientation or the orientation of the operative slip plane with respect to the stress axis. In general, the Laue spots on the photograms taken from the Front surface were elongated in the direction parallel to the specimen axis, whereas those from the Back surface were distorted so as to become elongated in the direction 90° to the former ones. However, no appreciable change in the shape of Laue spots on either the Top-T or Top-C surface was noticeable.

Fig 16 shows the change in shape of Laue spots on the Front surface of specimen A-10 with an increase in deflection. It can be seen that the elongation of spots did not occur until the specimen was subjected to bending far beyond the elastic range. This may be regarded as evidence in favor of the idea that asterism does not indicate the existence of elastic strain, but rather plastic deformation resulting from bending.

Fig 17 shows the types of Laue spots obtained from the Front, Top-T and Back surfaces of two other crystals, A-11 and A-15, with different initial orientations. It is apparent that all the specimens exhibited the same type of distortion as far as the nature of the asterism is concerned. It appears that the axis of rotation causing the asterism on the tension side is in vertical direction while that on the compression side

FIG 15—Slip markings on the top surface of specimen A-15 near the neutral plane. The dark markings are near the tension side and the white ones are near the compression side. 50 X.
Reduced one-half in reproduction.

is horizontal. The fact of no appreciable change of Laue spots from the top surface of the specimen further confirms these rotation axes.

Furthermore, it was also found that in specimens A-12 and A-13 the Laue spots were not only elongated but also divided into small individual areas as shown in Fig 18 and 19. The traces of the active slip plane are indicated in

the left corner of the photogram. It can be seen that the fragments of the spots appear to be aligned in a specific pattern, divided into two groups, one roughly parallel to the traces and the other normal to it. This break-up of the Laue spots in deformed crystals after annealing was observed by Collins and Mathewson¹⁷ in aluminum and by Andrade and Tsien²² in potassium and sodium. Very recently, Cahn⁷ in a study of bent zinc crystals suggested "the deformation leads to elastic bending of glide-lamellae: when the crystal is annealed, the lamellae undergo 'polygonization.' The orientation of each new grain is the same as that of the part of the original crystal from which it grew but the elastic strain has vanished." In addition, the break-up of the Laue spots was also reported even in deformed aluminum crystals by Crussard.²⁰ It appears that the discrete asterisms in specimens A-12 and A-13 may be rationalized as a process of fragmentation occurring during deformation at room temperature. In Fig 18 and 21, the fragments of the Laue spots parallel to the traces of the operative slip plane as shown at left-upper corner may be regarded as a rotation of crystallites about an axis parallel to the slip plane. The fragments oriented normal to the traces may be rationalized as a break-up of crystallites due to the torsional rota-

tion around the pole of the slip plane.^{17,23} The latter was reported recently by Heidenreich and Shockley¹⁸ from a study of Laue spots and Kikuchi lines produced on electron diffraction patterns of extended aluminum crystals.

Load-deflection Diagrams

The load-deflection curves for aluminum crystals under bending were found to resemble the load-elongation curves reported for the crystals under tension. A definite yield point at a total load of several pounds was usually observed. The curve then gradually flattened with an increase in deflection. The load-deflection curves for flat specimens were quite consistent with each other. The yield point was in the neighborhood of 3 lb which resulted in a normal stress on the extreme surface of the specimen of about 1150 psi with a corresponding resolved shear stress in the neighborhood of 500 psi. Fig 20 shows the data recorded for specimens A-10, A-12, and A-14 having different initial orientations. The yield point and the rate of strain-hardening indicated by the load-deflection curves did not appear to vary significantly for different orientations. This agrees with the results of shear tests in aluminum crystals reported by Burgers and Leebink.²⁴ They stated that slip in aluminum crystals deformed in shear may be found along lattice planes and directions differing from the usual slip system, (111) [110], and no appreciable variation on the shear stress required for different combinations of planes and directions was observed.

Flow-pattern in Bending

In order to understand the unique characteristics of flow in bending, two auxiliary experiments were performed. The first one was made on a study of the stress distribution pattern over the surface of a specimen by means of the commercial Stresscoat manufactured by Magnaflux Corporation, Chicago, Ill. It was found that the pattern produced by Stresscoat was practically the same as that found on specimens A-10 and A-11 prepared electrolytically and thus having an oxide coating. This may be regarded as confirmation that the anomalies in the surface markings of the electrolytically polished specimens resulted from surface cracks or strain markings in the anodic coating. It is believed that the major axis of

FIG 18—Laue photograph of specimen A-12, Top-T surface, after 0.510 in. deflection. 2 X.
Reduced approximately one-third in reproduction.

the strain ellipsoid on the tension side lay parallel to the specimen axis whereas that on the compression side was normal to it. A similar analysis was also reported by Yamaguchi and Tagino²⁵ who found that fissures produced in a thin oxide layer during creep

tests were oriented in the direction perpendicular to the major axis of the strain ellipsoid on the tensile specimen.

The second auxiliary experiment was the study of the flow pattern of bent specimens made of paraffin. The specimens were cast in a metallic mold hav-

FIG 19—Laue photograph of specimen A-13, front surface, after 0.300 in. deflection. 2 X.
Reduced one-third in reproduction.

FIG 21—Schematic diagrams of flow patterns on bent wax specimens W-1 and W-2.

ing a rectangular cross-section of approximately $\frac{1}{4}$ by $\frac{1}{2}$ in. Two sets of cross-lines, one at an angle of 0° and 90° and the other at 45° with the axis of the specimen, were carefully drawn on the various surfaces of specimens W-1 and W-2. The specimens were then bent, after being warmed slightly on a gas flame, to a deflection of about $\frac{3}{4}$ in. The originally square grid was distorted to a greater or less extent at the various positions of the specimen as shown schematically in Fig 21. The arrows indicate the direction of flow derived from the flow

pattern on the paraffin specimens W-1 and W-2.

Mechanism of Deformation by Bending

A most significant characteristic of the process of plastic deformation by bending is that slip does not occur across the entire crystal but is restricted to a limited area. Slip markings appear to progress from the higher stressed to the lower stressed region, gradually losing both intensity

and width as the stress diminishes. The development of slip markings was found to consist of two different stages. At first a band-like structure was readily seen by unaided visual examination, then distinct slip markings appeared in the bands. These well-defined markings progressed toward a lower stress region with an increasing deformation. The line density was increased by the formation of new markings which appeared between the old ones under further loading. It is believed that the slip process in bending consists of an elastic bending followed by a plastic distortion, probably similar to the fragmentation processes described by Mark, Polanyi and Schmid,¹ Burgers⁴ and others.^{2,3,5} A schematic diagram of the distortion in two adjacent glide-lamellae under different stress conditions is shown in Fig 22. If the two undistorted glide-lamellae, shown in Fig 22A, were subjected to a pure shear, the lamellae would be deformed as illustrated in Fig 22B. Based upon this mechanism, the shear stress is about a thousand times larger than the observed critical shearing stress. However, it was found in this investigation that macroscopic bending of glide-lamellae did occur so that the stress distribution on the entire slip plane would be different from that produced by pure shear. This is shown schematically in Fig 22 C, D and E, that is, elastic bending, bending and plastic shear, and bending and fragmentation. It can be seen that under such conditions the slip process is composed of the successive glidings of a group of atoms at a time. The external force required to produce such a slip should be much less than the value required for an entire plane as a unit. The shear strain at the left end of the bending lamellae (Fig 22 C, D, and E) is practically equal to zero and increases gradually to a maximum value at the right end.

Furthermore, it is noteworthy that this mechanism of bending of glide-lamellae can be employed to interpret satisfactorily the asterism on Laue photograms of deformed aluminum crystals reported by Yamaguchi.² These results were criticized by Komar and Machalov⁵ who suggested that the bending of the glide-lamellae is macroscopic rather than microscopic. They found that the length of the asterism on the Laue photograms of extended magnesium crystals decreased as the surface of the crystal was etched off successively. However, referring to the

FIG 20—Load-deflection diagram of flat specimens A-10, A-13, and A-14.

mechanism of bending described in this paper, the phenomena of a decrease in the length of asterism as the outer layers of the crystal are removed by etching would be adequately explained, since the bending in the material between slip markings approaches a maximum at the outermost layer of the specimen and a greater distortion in Laue spots on X ray photograms would be expected there.

Flow Characteristics in Bending

Two different types of flow were observed on the tension and compression sides of the bent specimens. It appeared that the crystal acted as if it were divided into two parts separated by the neutral plane. The tension and compression sides experienced unusual types of axial loading where the flow of metal was restricted in a direction perpendicular to the neutral plane. There a stress-gradient existed such that the maximum stress occurred at the outermost layer of both the tension and compression sides and diminished gradually in the direction of the neutral plane. Thus the flow direction on the tension side was along the specimen axis whereas that on the compression side was in the direction roughly perpendicular to the top surface. It was found that the rectangular cross-section of all flat specimens became approximately trapezoidal during deformation, in good agreement with the characteristics of flow in a bent crystal as discussed above. The ideal flow characteristics in bending may be represented by the schematic diagram shown in Fig 23. The arrows illustrate the variation of strain introduced by the stress-gradient in a bent crystal. Sections of the undeformed crystal, shown by the dotted line, will gradually deform to those contours indicated by the solid lines during bending. Based upon this picture, the asterism on Laue photograms of a bent crystal may be interpreted as on overall bending of crystallites resulting from the process of fragmentation. Since the flow in bending is restricted in certain directions, the crystallites could not follow the type of rotation found in uniaxial loading. Instead of the usual type of rotation about an axis lying in the slip plane normal to the slip direction, the different shapes of Laue spots seem to indicate that the crystallites were bent about an axis in the slip plane and perpendicular to the direction of flow.

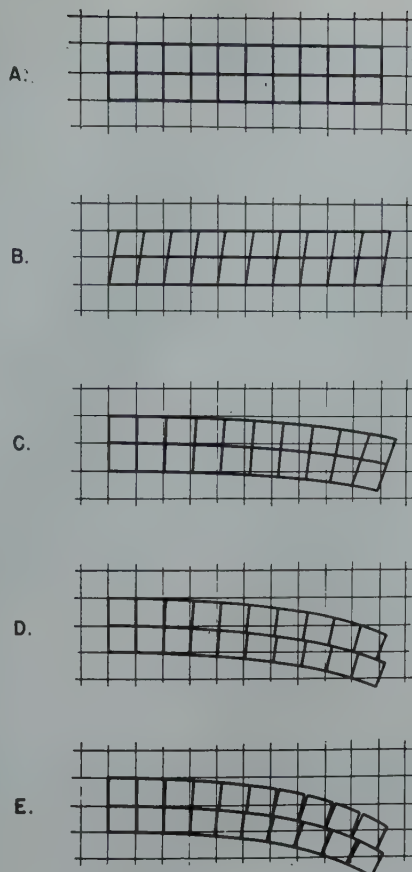

FIG 22—Schematic diagrams of slip mechanism.

(A) Undeformed, (B) Pure shear, (C) Elastic bending, (D) Bending and plastic shear and (E) Bending and fragmentation.

Summary

1. When an aluminum crystal is subjected to a bending stress, the major operative slip system is the same as for uniaxial loading. That is to say, the slip occurs on the octahedral plane which has the maximum resolved shear stress given by the equation $S_s = S_n \cos \lambda \sin \chi$, where S_n is the normal stress calculated by the simple beam formula.

2. The change of orientation on the tension and compression sides of a crystal during bending resembles closely that of two separate crystals deforming under tension and compression loading respectively. In general they appear to follow the Taylor and Elam rotation,

FIG 23—Schematic diagram of characteristics of flow in bending.

that is, the stress axis rotates toward a [110] slip direction on the tension side and toward (111), the pole of active slip plane, on the compression side. However, a certain amount of deviation was observed. This may be due to the complication introduced by the restriction of flow during bending and consequently requiring the early operation of a secondary slip system.

3. The anomalous surface markings on the electrolytically polished specimens may be attributed to the strain-markings or cracks on the anodic coating of the surface layer. It was found that these markings were analogous to the cracks produced on a deformed specimen treated with Stresscoat. The absence of these markings on mechanically polished and etched specimens further substantiated this interpretation.

4. "Cross-slip" or the step-like appearance of slip lines was observed on specimen surfaces intersected by the slip direction. However, no definite cross-slip plane could be identified. This may be due to the complicated stress distribution in the bending where these steps might be too small to permit the resolution of a particular plane.

5. The phenomena of slip over local regions of the specimen was noticeable in all the bending specimens. The growth of slip markings appears to undergo a process such that the slip markings occur initially at a higher stress region and move toward a lower stressed matrix, gradually losing both their intensity and width as the stress diminishes. The macroscopic bending of glide lamellae was also found.

6. From the study of the flow characteristics and the Laue spots on the X ray photograms of various bent specimens, it was found that the cause of subdividing of spots may be regarded as a result of crystallite fragmentation. The fragmentation appeared to take place by rotating the crystallites in the glide lamellae about an axis normal to the slip plane in addition to the usual type of bending about an axis lying in the slip plane perpendicular to the direction of slip. Following the rotation of crystallites, the elongation or asterism of Laue spots may be rationalized as an overall bending taking place about an axis in the slip plane and normal to the direction of flow.

Acknowledgments

High Temperature Sealing of Cobalt*

CHARLEY R. JOHNS† and WILLIAM MARSH BALDWIN, JR.,‡ Junior Member AIME

Introduction

Cobalt is reported^{1,2} to scale in accordance with the Pilling and Bedworth³ parabolic law:

$$w^2 = Kt \quad [1]$$

where w = weight increase per unit surface area

K = constant

t = time

The reported values of the parabolic oxidation constant, K , in the temperature range 600 to 1100°C follow an Arrhenius type of equation as inspection of Fig 1 shows. According to Valensi's theory⁵ on the scaling of metals where multiple-layered scales (for example, MeX , MeX_2 , and others) are possible, this fact could be construed as indicating that a single oxide only is formed on cobalt in this temperature range. Since the single straight line extends above 920°C where only CoO is stable in air (see Fig 2) it might be inferred that this is the only oxide formed on scaling.

Arkharov and Voroshilova¹⁰ have studied the scales formed when cobalt is heated in air in the temperature range 385 to 800°C and report that

CoO is indeed found in the scale but that Co_3O_4 is also found as an overlay and in increasing amounts in the lower temperature ranges. No quantitative data regarding the relative proportions of the two oxides were reported. Again in the light of Valensi's theory this would indicate that the straight line in Fig 1 would be expected to undergo an inflection at some point in the temperature range 385 to 800°C.

Chauvenet² has studied the oxidation rates of CoO to Co_3O_4 and has found this reaction to proceed parabolically with time but reports parabolic scaling rates which are

These authors also state that a thin exterior veneer of Co_3O_4 may have formed also but was too thin to identify with X rays. In view of the instability of Co_3O_4 in air above 400°C (see Fig 2) this is unlikely.

considerably (about ten times) larger than the scaling rates of cobalt metal itself.

This is difficult to explain in terms of Valensi's theory although a full discussion of the possible discrepancy cannot be made in view of the lack of sufficient data.

These points made an investigation of the scaling behavior of cobalt in air an attractive study.

Discussion of Results

Relatively large (approximately⁹⁵ 95 sq cm of surface area) samples of 0.020 in. thick electrolytic cobalt strip,* sanded with 2/0 paper, were heated in air in a cyclone type furnace. The samples were weighed before and after the scaling treatment. The weight increases so observed obeyed the Pilling and Bedworth parabolic law at all temperatures studied. The parabolic scaling constants when plotted on a logarithmic scale as a function of absolute temperature are reproduced

in Fig 1. Here it may be seen that in the higher temperature ranges the present data coincide quite well with the previously reported data. There is, however, a definite inflection in the data at around 625°C, the data for the temperature range below this point showing a slope that is roughly $\frac{1}{2}$ that of the straight line drawn through the data above this point. This inflection would be expected on the basis of the reasoning presented above. If the straight line in the lower temperature range is due to the exclusive formation of Co_3O_4 , the oxidation rate of CoO to Co_3O_4 in this temperature range should follow a straight line parallel to the lower branch of the cobalt curve and lying at a value $\frac{1}{4}$ that of the aforementioned lower branch. This is, of course, at complete variance with the experimental results of Chauvenet on the oxidation of CoO and illustrates in quantitative terms how her data cannot be reconciled with the requirements of Valensi's theory. In an attempt to resolve this discrepancy, samples of cobalt were oxidized to CoO at temperatures above which none of the other oxides is stable thermodynamically (around 920°C) and then subsequently oxidized in the temperature range in which Co_3O_4 was stable. These results are entered in Fig 1. In the present case the data parallel those of Chauvenet's (and incidentally, the scaling data for straight cobalt in the temperature range above 625°C) but do not behave in accordance with Valensi's theory. It must be admitted that the present data are of the proper order of magnitude to fit Valensi's requirements, and it may be that experimental errors prevent the data from exactly duplicating the values required by his theory, but for the present we must regard the case of the scaling of cobalt in air as being still unsettled.

An internal check on the data and on Valensi's theory could have been obtained if the proportions of CoO and Co_3O_4 in the scale could have been determined quantitatively in the temperature ranges between 500 and 800°C, but the absolute thickness of the scales formed in this temperature range are extremely small compared with other metals in which such quantitative determinations have been made (for instance, copper,⁵ iron¹¹) indicating the necessity of developing special techniques for such determinations.

Stages in the Deformation of Monel Metal as Shown by Polarized Light

D. H. WOODARD,* Associate Member AIME

Introduction

One of the principal uses of polarized light in metallurgy is to show the granular structure of metals by contrasting reflections. This use is confined largely to anisotropic metals, such as beryllium, tin, magnesium, and the like.¹ Recently, Hone and Pearson² have extended the use of polarized light to include the isotropic metal aluminum. This was made possible by the formation of an anodic film that was optically anisotropic and that had a fixed and reproducible structural relationship to the grains in the substrata. With their method, it was possible to indicate localized textures in annealed aluminum sheet. In the course of an investigation of plastic deformation at the National Bureau of Standards, it was found that the isotropic single phase alloy Monel could be made optically anisotropic by treatment with the usual Monel contrast etchant. Experiments soon showed that differences in orientation could be detected easily.

Previous investigations involving the use of polarized light have been restricted to annealed metals. In this paper it will be shown that inhomogeneous plastic deformation which results in lattice bending and development of deformation bands experienced by individual grains in polycrystalline Monel, is revealed in the microstructure. This interpretation of the microstructure was confirmed by a study of slip lines formed after prior plastic strain.

Materials and Procedure

The material used was Monel, the

chemical composition of which was C—0.17 pct, Mn—1.28 pct, Fe—1.61 pct, S—0.009 pct, Si—0.17 pct, Cu—30.70 pct, Ni—66.04 pct. The material was divided into 2 lots which were treated as follows: Lot A was heated at 1700°F for 3 hr to produce a fully annealed, coarse grained structure. Lot B was heated at 1400°F for 1 hr to produce a close approximation of a fully annealed structure without appreciable increase in the grain size of the original material. After each of these heat treatments the material was cooled in air.

Samples for metallographic examination were cut from tensile and compression test specimens and were prepared by grinding on lead-tin laps, followed by electrolytic polishing.[†] Etching and the development of ridges were avoided by keeping the voltage above 3.8 and by preventing contamination of the polishing solution with water.

Monel, when polished and treated with most etchants, is optically isotropic. However, when given a light etch for about 4 sec with the Monel contrast solution[‡] the surface of the metal becomes optically active. The microstructure when observed under

crossed nicols* appears different from that viewed by ordinary light. This is shown by a comparison of micrographs made of the same area of a plastically deformed specimen using polarized light (Fig 1a) and white light (Fig 1b).

If Monel, which has been lightly treated with the contrast etchant, is slightly deformed by compression, rectangular figures are apparent over the specimen. However, within too short a period to be photographed, these rectangles become circular, probably because of surface tension effects within the etched film. The two observations,

* The expression "crossed nicols" employed in this paper conforms to the usages of optical crystallography. It does not mean that *Nicol prisms* are employed but merely that polarizing elements in the incident and reflected beams are crossed with respect to each other. The less explicit term "polarized light" is used in places where no ambiguity would result.

the rectangular figures becoming circular and the failure of the unetched surfaces to reflect polarized light, suggest that the Monel contrast etchant forms a film which is anisotropic.

Unless otherwise specified, all micrographs were made on a Bausch and Lomb Metallographic Research Microscope, equipped with a Foster vertical illuminator prism³ which acts also as polarizer and analyzer fixed in the crossed position. Measurements of the intensity of the reflected resolved polarized light were made at the bellows eyepiece with a specially constructed photometer, which consisted essentially of a photo-multiplier tube, RCA-931, a bank of dry cells arranged to have 90 volts across each dynode, and a microammeter. As the current coming from this photo-multiplier is proportional to the intensity of the incident light, all light intensity values are expressed in microamperes.

Differences in Orientation Shown by Polarized Light

ANNEALED MONEL

It has been shown by many investigators that the orientation of fully annealed single phase alloys is uniform

from point to point in individual grains and that the orientation varies from grain to grain in a more or less random manner. For fully annealed Monel, the intensity of the reflected polarized light is uniform over the entire area of each individual grain as illustrated by the micrographs of Fig 2. It should be noted, however, that in the case of Monel, the annealing must be complete and grain growth started before uniform reflection, that is, uniform orientation over individual grains, is obtained

The micrographs in Fig 2 show that each grain undergoes a half cycle of intensity from maximum to minimum for a 45° rotation of the plane of polarization, although the angle for maximum reflection varies from one grain to the next. It was noted that the difference in intensity between the maximum and the minimum of the reflected light may vary from one grain to another. It is, therefore, possible for two grains to be at different stages in their 90° cycle and yet reflect light with the same intensity. While the same intensity for different grains may mean different orientations, it is obvious that for any fixed direction of the planes of polarization, a difference in intensity must mean a difference in orientation. It is on this basis that

polarized light is used in this study of plastic deformation.

INDIVIDUAL GRAINS IN PLASTICALLY DEFORMED MONEL

Fig 3 shows the microstructure of Monel after extensions of 2, 14, 30, and 38 pct, when deformed at a rate of 2½ pct every 5 min. These micrographs, like others photographed under crossed nicols, are referred to as intensity patterns because the areas of extinction can be changed to areas of brightness or vice versa, although the outlines in the pattern remain the same. Obviously, plastic deformation has caused nonuniform reflections from individual grains. If differences in intensity denote differences in orientation, then it follows that plastic deformation has caused inhomogeneous distortions in the lattice structure. This is in agreement with results obtained by Barrett and Levenson⁴ who showed, by means of X rays and etch pits, that plastic deformation caused areas of nonuniform orientation over the individual grains. After a study of the intensity patterns shown in Fig 3 and other similar patterns, it was possible to classify the nonuniformities of reflection into four types shown by grains A, B, C, and D. These will be discussed under Results.

FIG 4—Effect of plastic deformation and angular rotation of crossed nicols on the overall intensity of light reflected from Monel metal B. Curves A, B, C, D, and E represent specimens extended 0, 14, 33, and 38 pct respectively.

CORRELATION OF INTEGRATED INTENSITIES WITH DEGREE OF DEFORMATION

It was observed, in examining plastically deformed specimens, that the overall intensity of the reflected polarized light with crossed nicols changed as the plane of polarization or the specimen was rotated. These changes were measured by the photometer at regular angular intervals and the results are shown in Fig 4. The data for curve A, obtained from a transverse section of a fully annealed specimen, represents a condition of random or nearly random orientation. It is evident that plastic deformation results in the formation of four peaks in each curve and that increasing plastic deformation, from 0 to 38 pct, causes the amplitude to increase.

Since any orientation of an individual grain goes through four intensity cycles, it is apparent that the integrated intensity of many grains will show four peaks as more and more grains approach a common alignment. Any such directional deviation from the original state must be considered as a development of preferred orientation. X ray studies have shown that a progressive increase in preferred orientation results when polycrystalline metals are deformed plastically in tension. There is apparently a relationship between the degree of preferred orientation and the variation in integrated intensity, where preferred orientation appears under crossed nicols before its development can be detected by X rays.

In this connection, it is interesting to note that Mebs and McAdam⁵ have interpreted variations of Poisson's ratio as showing the anisotropy of this same heat of Monel after 4 pct reduction of area. Hill⁶ has shown that the development of preferred orientation accompanies anisotropy.

If plastic deformation, accompanied by a bending of the lattice, occurred in such a manner as to permit extension in the direction of flow, a plane cutting the specimen in this direction should show more areas of certain specific planes than would be observed in the case of a purely random orientation. The development of the peaks of Fig 5 is attributed to such a phenomenon. At present, there is very little information available on the intensity of the reflection from specific planes or on the number or orientations of the planes which combine to show this preferred orientation.

EVIDENCE OF BENT LATTICE STRUCTURE

Thin straight parallel lines usually seen on polished and etched surfaces of annealed metals after slight compression are considered to be traces of crystallographic planes, that is, the intersection of these planes with the surface of the metal. Sometimes however, these lines are curved and the question has been raised as to whether a set of such curved lines represents traces of a set of crystallographic planes which are bent, or the traces of several sets of parallel crystallographic

planes which remain straight but which combine to give the effect of curved lines. The ability of polarized light to show changes in orientation along the length of a line furnishes an answer to this question and thereby yields information as to a mode of deformation.

Deformed Monel specimens were sectioned, polished, etched, and then deformed further to form traces, some of which are curved. It can be readily seen in Fig 5a and d that the slip lines bend as they go from one orientation to the other as evidenced by changes in the intensity pattern. The bends are not abrupt, as is the case at the grain boundaries, but have measurable radii of curvatures. In such cases, the intensity patterns show a gradual change in orientation which indicates a gradual change in position of the crystallographic axes. This bending of the slip lines, therefore, is interpreted as being due to a bending of the crystallographic planes of which these lines are traces. In a metal, such as Monel, which has a face-centered cubic structure, these slip lines are assumed to be traces of octahedral planes. There are four sets of these planes, each set inclined to each of the other sets at an angle of 70°.

Fig 5b, c and d show the microstructure of two specimens that had less prior strain than did the specimen whose microstructure is shown in Fig 5a. In Fig 5b, there are two sets of traces in the central grain, one set about horizontal, the other inclined about 30° to it. As the orientation changes, there is no change in direction of the horizontal set, but there is a change in the ends of the traces of the other set. The case of having two sets of traces, one straight and the other bent while going through a region of changing orientation, can be explained as follows: During the process of plastic deformation the lattice may be bent around an axis parallel to the surface in such a manner that the metal surface cuts off a longitudinal section of the cylinder. Then an octahedral plane at right angles to the axis of bending would intersect the surface of the metal in a straight line regardless of the amount of lattice bending. If the octahedral plane is at any other angle, the intersection of that plane with the specimen surface should show a change of direction with a change of orientation. The further the octahedral plane inclines toward the axis of bending, the greater is the curvature of the slip line with change in orientation. This is shown in the main grain of Fig 5c, where the traces go through the main grain with

practically no change in direction with change in orientation. However, when they go through the twin, where an octahedral plane is inclined at the twin angle, the straight lines become curved with changes in orientation. This is clearly seen in Fig 5d which is an enlargement of the twinned region.

From a study of many orientation patterns, and the slip lines formed on the surface by further plastic deformation, it appears that initial bending occurs around axes nearly perpendicular to the octahedral planes and that the slip lines run approximately perpendicular to these axes of bending. The similarity of the microstructures of Fig 3 (deformed before polishing) and of Fig 5 (deformed both before and after polishing) indicates that the curvature of the traces and the accompanying changes in intensity were not due to a rumpling of the surface.

It was found that the number of slip lines formed on a specimen initially annealed, polished, and etched increased and their spacing became more irregular as the amount of plastic deformation increased. As can be seen in Fig 5a and b, the intensity pattern of the individual grains indicates that the strain was inhomogeneous and this resulted in the irregular spacing of the slip lines. A series of annealed specimens, compressed 4, 14, 32, and 36 pct before being sectioned and polished, were etched and then given 2 pct further compression. Examination showed that the 32 pct and 36 pct specimens had fewer slip lines present than the 4 pct and 14 pct. This showed that it is more difficult to develop slip lines on specimens that had a large amount of prior compression than on those that had a lesser amount. However, the greater the deformation before sectioning, polishing, etching, and deforming further, the deeper, wider, and more irregular become the slip lines.

Discussion of Results

TYPES OF LATTICE BENDING

The concept of deformation by lattice bending has been presented by many investigators. Polanyi⁷ related the elongation of Laue spots from zinc crystals with bending of the slip plane (*Biegegleitung*). Sun and Chu⁸ interpreted Laue photographs of rock-salt crystals as showing that the first deformation occurs by a simple bending of the lattice around a fixed axis; as the crystal deforms further, bending begins around one or more new axes. Single

crystals of cadmium, when oriented so that the glide plane is nearly parallel to the axis of compression, deform by a mechanism which Orowan⁹ terms "kinking." Hess and Barrett¹⁰ have shown that the kink bands described by Orowan are a special form of deformation bands and result from a bending of the lattice.

When the intensity patterns of Fig 4 are interpreted in terms of lattice bending, four types of deformation can be seen:

1. Broad diffuse bands of brightness and extinction, as typified by grain A: These represent lattice bending around an axis which is nearly parallel to the surface. These appear on specimens that have been sectioned longitudinally after slight plastic deformation.

2. Areas of brightness surrounded by areas of extinction, as typified by grain B: These are typical of a dome type of lattice bending wherein the crystallographic planes have been bent so that they are no longer flat planes, but are wrinkled into the shape of a dome.

3. Bands of brightness and extinction with the bands ending in areas of extinction and brightness respectively, as shown in grain C: Here the change in orientation at the end of the band shows that the deformation is of the twisted or screw type.

4. Bands of brightness or extinction

FIG 5—Effect of prior plastic deformation on the development of slip lines in Monel metal A.

(a) compressed 28 pct, (b), (c), and (d) compressed 2 pct. (a), (b), and (c) $\times 250$. (d) $\times 750$. Reduced one half in reproduction.

sharply outlined in more or less irregular shapes and mainly extending in the direction of flow as shown by grain D: Bands of this type represent fully formed deformation bends and usually appear after severe necking of the specimen.

Examination of many intensity patterns shows that initial plastic deformation occurs through the bending of the lattice around a single axis and that, as the amount of deformation increases, lattice bending takes place around several axes.

From the extreme irregularity of the intensity patterns, it is evident that directions of flow can vary within small areas and that the deformation is by no means uniform or regular as would be the case for twinning.

DEVELOPMENT OF DEFORMATION BANDS

In the early stages of plastic deformation, the changes in orientation are gradual, as seen in Fig 3a and b. As deformation increases, the changes in orientation become gradually sharper and more distinct in more or less irregular areas. After severe plastic deformation, these areas of changed orientation become elongated and sharply outlined. They are clearly seen in Fig 3d and 6a and b. As their development is a gradual process, it is quite evident that

FIG 6—Inhomogeneous deformation within individual grains in severely deformed specimens of Monel metal A.

After prior compression of 36 pct for 6(a), 28 pct for 6(b), (a) (above) $\times 500$, (b) (below) $\times 250$. Reduced one half in reproduction.

these areas are deformation bands and not deformation twins.

As these deformation bands are formed, the area bounding them becomes thinner and more distinct until, with severe plastic deformation, they become grain boundaries. Frequently, a well-defined grain boundary was seen to end in a deformation band boundary which became gradually wide and diffuse. Such a condition could exist if, due to inhomogeneous plastic flow, there is, as postulated by Mott,¹¹ a shearing action along the orientation boundary (band boundary). With severe distortion, and its accompanying shear along the newly formed orientation boundary, this oriented boundary becomes a grain boundary. Further deformation is then a unique and distinct process within each orientation. In this way, a grain can be fragmented into smaller grains by plastic deformation.

CONTINUANCE OF DEFORMATION BANDS ACROSS GRAIN BOUNDARIES

Boas and Hargreaves¹² concluded from hardness measurements that the distortion in a grain is confined largely to the areas adjacent to the grain boundaries and is transmitted to a neighboring grain along its boundaries. However, Hibbard,¹³ by means of X ray determinations of orientation, showed that deformation was not restricted to any particular area of the

grain. Examination of many intensity patterns, such as those in Fig 3, show that differences in orientation do not occur more frequently near the grain boundaries than in the center of the grain. While many areas were observed, similar to Fig 6a, in which deformation bands in one grain are adjacent to deformation bands in the next, the proportion of such areas is small. From a consideration of the intensity patterns, it is evident that the transmission of deformation across a grain boundary is dependent upon the relationship of the two adjacent orientations. The response of a grain to the deforming stress is affected not only by the orientation of the grain itself but by the restricting action of adjacent grains of different orientation.

EFFECT OF LATTICE BENDING ON THE MECHANISM OF PLASTIC DEFORMATION

If deformation of Monel is to occur through lattice bending, then the concept of deformation by slip must permit gradual changes in lattice orientation, such as are seen in Fig 3a and b, and must account for the relative proportions of deformation by lattice bending and by slip. It is quite evident that slip did not occur through the distortion of layered regions which would leave the rest of the lattice undisturbed.

It is evident that when the lattice is bent, the lattice constants on the concave side would differ from those on the convex side. In such a case, there are limitations as to the amount that the lattice can be bent elastically without deforming plastically. The plastic deformation, or atomic readjustment, could occur through the motion of dislocations, where the nonuniform stresses set up by the bending of the lattice serve as the trigger mechanism to start the dislocations into motion. It is hoped that more quantitative information will be obtained from a program now underway which will coordinate the results obtained from polarized light with those obtained from other methods.

The current widespread interest in orientation changes during plastic deformation and the inability of other methods to present these changes visually has resulted in the publication of this paper at this time.

Summary

The microstructure of Monel can be revealed, when viewed under crossed

nicols, as an intensity contrast pattern when a polished specimen has been etched with the ordinary contrast etching reagent. Differences in the intensity of the reflections were interpreted as differences in crystalline orientation. On the basis of this hypothesis, variations in crystalline orientation were shown to be present in individual grains in plastically deformed specimens. A study of these variations led to the conclusion that the individual grains were deformed in an extremely irregular flow pattern, some of the irregularity resulting from the restrictive action of neighboring grains.

A study of the microstructure of specimens that had been deformed plastically, sectioned, polished, etched, and then deformed further indicated that curved slip lines are the traces of crystallographic planes which had become bent as a result of the prior plastic deformation. Changes in lattice orientation are attributed to a bending of the lattice and are shown to become sharper and more distinct as the amount of plastic deformation is increased. These changes lead to the formation of deformation bands and to fragmentation of the grains.

It was shown that the integrated intensities of reflections from many grains varied as the specimen was rotated with respect to the plane of polarization of the incident light. The integrated intensity increased with an increase in the degree of deformation, thereby indicating that polarized light can be used to detect preferred orientation.

Influence of Temperature on the Stress-strain-energy Relationship for Copper and Nickel-copper Alloy

D. J. McADAM, JR.,* Member AIME

Introduction

In a series of papers the author and associates have discussed the influence of temperature on the tensile properties of metals.¹¹⁻¹⁸ These papers present much information about the influence of temperature and the stress system on the conventional indices of mechanical properties, with special attention to the fracture stress. A recent study of the data, however, has revealed much additional information about the influence of temperature on the fundamental factors involved in the flow of metals. The present paper presents results of this study. Attention will be confined almost entirely to results derived from tension tests of unnotched cylindrical specimens at strain rates a little slower than those used in ordinary tension tests.

According to a concept first presented by Ludwik and elaborated in recent papers by others,^{8,9,22,23} the mechanical state of a metal depends on the total plastic strain, but not on the temperature during straining, provided that the only structural changes are those essential to plastic deformation. In the summer of 1948, however, the author made the previously mentioned study of results of a general investigation by the author and associates and reached the conclusion that the mechanical state depends not only on the total strain, but also on the temperature during the straining. A number of diagrams were then prepared. These conclusions were presented without diagrams in a discussion last October of a paper by Dorn, Goldberg and Tietz.²

The metals used in the investigation on which this paper is based were Monel and oxygen-free copper. The

Monel was supplied by the International Nickel Co. through the courtesy of Dr. W. A. Mudge. The copper was supplied by the Scomet Engineering Co. through the courtesy of Dr. Sidney Rolle. The data to be presented are based on results of tests at temperatures ranging between 165 and -188°C . Description of the apparatus and methods of test are given in previous papers.^{10,11,12}

The present paper is the first part of the general discussion of the influence to temperature on the stress-strain-energy relationship for metals. The next paper will deal with metals that are subject to structural changes other than those induced solely by plastic deformation.

Influence of Temperature and Plastic Strain on the Flow Stress of Monel and Copper

For a study of the influence of temperature on the stress-strain relationship, flow-stress curves obtained with annealed metals at various temperatures will be compared with curves obtained with the same metals after cold drawing or cold rolling at room temperature. Diagrams thus obtained with Monel and copper are shown in Fig 1 to 8. Fig 1 to 7 show the variation of the flow stress with temperature and plastic strain; Fig 8 is a diagram of a different type, derived from Fig 4 to 7. In Fig 1 to 7 strain is expressed in

terms of A_0/A , in which A_0 and A represent the initial and current areas of cross-section. Since values of A_0/A are represented on a logarithmic scale, abscissas are proportional to true strains; moreover, the true strains representing prior plastic deformation and those representing subsequent strain during a tension test are directly additive.

Fig 1 shows flow-stress curves obtained with annealed Monel. Five of the curves are based on results of tension tests. Between yield and the maximum load, the flow was under longitudinal tensile stress; between the maximum load and fracture, the local contraction induced transverse radial tensile stress. The portions of curves designated F , therefore, represent flow with increasing radial stress ratio, the ratio of the transverse stress S_3 to the longitudinal stress S_1 . Curve F_0 is based on the ultimate stresses of specimens taken from bars that had been cold drawn various amounts.¹⁷ Since the tensile stress at the maximum load is unidirectional, curve F_0 represents the course that a flow-stress curve would take if the stress during an entire tension test could be kept unidirectional.

The flow-stress curve F obtained at room temperature (Fig 1) has been established accurately by numerous measurements of the diameter of the specimen during the extension from yield to fracture.¹⁷ At the time of the experiments, however, no apparatus was available for measuring the diameter during tension tests at low temperatures. Nevertheless, curves have been established to represent with sufficient accuracy the flow at low temperatures. Each flow-stress curve must be tangent to a curve U , which starts at a point representing the ultimate stress of annealed metal. Since the ultimate stress is based on the area of

FIG 1—Flow of annealed Monel and ultimate stress of cold-worked Monel at various temperatures.

cross-section at the beginning of a tension test, this strength index varies with the amount of prior plastic deformation of the bar from which the specimen was taken. The variation is linear with L/L_0 or with A_0/A , until the load reaches a maximum and local contraction begins.* However, when A_0/A is represented on a logarithmic scale, the theoretical variation of the ultimate stress with prior plastic strain is represented by a curve U . To each curve U , the corresponding flow-stress

* L_0 and L represent the initial and current lengths.

curve must be tangent at a point representing the true stress at the maximum load. Except in some of the earliest of the tension tests by the author and associates, the extension at the maximum load was determined by means of an automatic diagram, and the point of tangency of the flow-stress curve with curve U can thus be established accurately. However, since the flow-stress curve and the tangent curve generally are close together for a considerable distance on each side of the point of tangency, the course of the flow-stress curve in this region can be

established with sufficient accuracy, even when the extension at the maximum load has not been measured. Moreover, an additional check for the point of tangency is available when the extension at the maximum load has been determined at room temperature; for Monel, the extension at the maximum load increases slightly with decrease of temperature, as illustrated in Fig 1. Between the points representing yield and maximum load, the flow-stress curves for Monel at low temperature have been constructed so as to be in proper correlation with each other and with the accurately established curve representing flow at room temperature.

In order to extend the curves beyond the points of tangency with curves U , it is necessary to establish at least approximately the points representing the beginning of fracture. Points R in Fig 1 represent breaking stresses obtained by dividing the load at beginning fracture by the cross-sectional area determined after fracture. However, because plastic deformation of a ductile metal generally continues at the rim of the cross-section while the fracture is extending from the axis to the periphery, the area of cross-section generally decreases during fracture. The breaking-stress values indicated by points R , therefore, are too high. At room temperature, the transverse measurements during flow have made it possible to determine accurately the true fracture stress, the stress when the flow-stress curve reaches a maximum and fracture begins. This stress is represented by point T . Although transverse measurements were not made during flow at low temperatures, approximate values of the true fracture stresses have been estimated on certain assumptions and are indicated by points T . These points must be on the nearly straight lines extending downward from points R at such a slope that percent decreases in stress are equal to percent decreases in A_0/A^* . Points T on these lines have been located on the assumption that the percent decrease in coordinates from R to T should be the same for low temperatures as for room temperature. The flow-stress curves between the points representing maximum load and beginning fracture have been constructed so as to be in proper correlation with each other and with the curve obtained at room temperature.

* The lines are not quite straight because the scale is semilogarithmic.

The curves thus constructed are sufficiently accurate for use in a study of the influence of temperature and plastic strain on the flow stress. The first part of this study will be a comparison of these curves with the three points representing ultimate stresses of cold-drawn Monel. Since this metal had been reduced 40 pct in cross-section by cold drawing, and since ultimate stresses of severely cold drawn metal are practically the same as flow stresses at the maximum load, the three points representing ultimate stresses in Fig 1 have been placed at an abscissa representing a value of 1.67 for A_0/A . The point representing the ultimate stress at room temperature thus coincides with curve F_0 .

If the flow stress (for a constant strain rate) were merely a function of temperature and total strain, the points representing ultimate stresses of cold-drawn Monel at -128 and -188°C would be much higher than they are in relation to the corresponding flow-stress curves. They would be below these curves, because the curves to the right of the points representing the beginning of local contraction are affected by the increasing radial stress ratio (S_3/S_1), but they would be higher than the corresponding points representing flow of annealed Monel at the maximum load. As shown in Fig 1, however, the points representing ultimate stresses of cold-drawn Monel at low temperatures are much lower in the diagram than the corresponding points representing the flow stresses of annealed Monel at the maximum load. The evidence, therefore, indicates that the flow stress at any instant depends not only on the temperature and total strain at that instant, but also on any prior changes in temperature during the flow.

For a thorough study of the influence of temperature and strain on the flow stress it is necessary to compare curves representing flow at various temperatures, but with the same stress system. Such a comparison is not made in Fig 1. The ideal stress system for this purpose is unidirectional tensile stress ($S_3/S_1 = 0$). As shown in Fig 1, a complete curve (F_0) has been derived to represent flow under this stress system at room temperature.¹⁷ In Fig 2, this curve and other curves of Fig 1 have been reproduced for comparison with curves representing flow under unidirectional tensile stress at low temperatures. Fig 2 also contains flow-stress curves for cold-drawn Monel.

FIG 2—Influence of temperature on the flow of Monel under unidirectional tensile stress.

Curve F for cold-drawn Monel at room temperature is based on frequent transverse measurements during flow, and thus the point representing the beginning of fracture has been accurately established.¹⁷ The F curves for cold-drawn Monel at low temperatures have been established approximately by the method used in establishing the F curves of Fig 1. The F_0 curves representing flow at low temperatures are not based directly on results of experiment; experiments to extend such a curve beyond the point representing the maximum load in a tension test would involve cold drawing or cold

rolling at the low temperature. However, each of these curves in Fig 2 has been constructed with proper divergence from the corresponding F curve. Since the same amount of local contraction would cause about the same increase in the radial stress ratio (S_3/S_1) at low temperatures as at room temperature, the ratio of ordinates of corresponding F_0 and F curves at the same abscissa has been made about the same for low temperatures as for room temperature.

The junctions of the F and F_0 curves for cold-drawn Monel at low temperatures represent incipient flow at these

FIG 3—Influence of temperature on the flow of copper under unidirectional tensile stress.

temperatures after the indicated strain at room temperature. The dotted curve *S* passing through each of these junctions represents approximately the locus of incipient-flow stresses at the indicated temperature after various strains at room temperature. Such curves, although they do not represent continuous flow, will be termed "secondary flow-stress curves" to distinguish them from the primary curves from which they are derived. For accurate determination, such a curve should be based on results of tests of specimens that had been extended various amounts at room temperature. However, when a single point has been

established far out on a secondary flow-stress curve, the curve can be constructed in proper correlation with the primary curves, so as to be accurate enough for a study of the influence of temperature and strain on the flow stress. Each secondary curve begins at the origin of the corresponding primary curve; it diverges continuously downward from that curve and upward from the *F₀* curve for annealed Monel at room temperature. Beyond the points representing ultimate stresses of cold-drawn Monel, the ratios of corresponding ordinates of the three *F₀* curves increase very little. Comparison of the primary and secondary *F₀* curves in

Fig 2 shows that the mechanical state depends not only on the total strain, but also on the temperature during the strain.

Fig 3 shows results of tests of annealed copper rod and of rod that had been plastically deformed three different amounts before the tension tests. Two lots of the copper rod had been cold drawn to 40 and 54 pct reduction in cross-section, and one lot had been cold rolled to 75 pct reduction. The points representing ultimate stresses and the corresponding strains of the cold-worked copper coincide exactly with *F₀* curve for annealed copper at room temperature; this curve is based on numerous ultimate stress values for cold-drawn wire and cold-rolled strip.¹⁷ However, Fig 3 is based almost entirely on results obtained with the annealed rod and severely cold-rolled rod, which were tested at room temperature and at low temperatures.

Curves *F* for annealed copper and severely cold-rolled copper have been established accurately by numerous transverse measurements of the diameter of the specimen during flow.¹⁷ The true fracture stresses thus have been determined accurately. Although transverse measurements were not made during flow at low temperatures, the curves representing flow at these temperatures have been established by proper correlation with curves *U*, with the *F₀* and *F* curves for room temperature, and with the points representing fracture at room temperature. Since the points representing ultimate stresses of the severely cold-rolled copper are far out along the secondary flow-stress curves *S*, the divergence of these curves from their origins must be approximately as indicated in the figure.

Comparison of the *S* curves with the *F₀* curves from which they diverge gives additional evidence that the mechanical state of a metal depends not only on the total strain, but also on the temperature during the strain. Since "mechanical state" involves both strength and ductility, and since attention is being confined to resistance to flow, the term "strength state" will be used instead of "mechanical state," with the understanding that "strength" here means resistance to flow, not resistance to fracture. In general use, the word "strength" designates a property that varies with the temperature, as indicated by the variation of the hardness and flow stress. In the term "strength state," however, the word "strength" implies a condition

of the metal, a property independent of temperature. In future discussion, the term "intrinsic strength" will be used with the same significance as "strength state."

The lower the temperature, the more rapid is the increase of the intrinsic strength with strain. The intrinsic strength or strength state is unchanged when the temperature is changed without change in the total strain. In Fig 2 and 3 for example, points at the same abscissa on the F_0 curve for room temperature and the two secondary flow-stress curves represent the same strength state, although they represent very different flow stresses. The effect of temperature on the flow stress evidently involves two factors: (1) a direct effect; (2) an effect of temperature on the rate of increase of the intrinsic strength with strain. The direct effect is illustrated by the vertical distance between the F_0 curve for room temperature and the corresponding S curve; the effect of temperature on the rate of increase of the intrinsic strength with strain is illustrated by the divergence of the primary and secondary curves for the same temperature. For a comparison of strength states by means of flow stresses, the flow-stresses must be determined at the same temperature.

From a set of F_0 curves and secondary flow-stress curves, such as those in Fig 2 and 3, the relationship between the direct temperature factor and the intrinsic strength factor can be determined. By the use of these factors, other locus curves may be developed, each representing incipient-flow stresses at one temperature after various strains at any other temperature, higher or lower, within the range represented in the diagram. These derived curves can be established in exact correlation with the primary and secondary curves, and extended throughout the strain range of curves from which they are derived. For a systematic study of the stress-strain-temperature relationship, three groups of these derived curves should be available. In Fig 4 and 5, three groups of these curves for Monel have been assembled together with the F_0 curves and S curves, which have been reproduced from Fig 2. In Fig 6 and 7 three similar groups of curves for copper have been assembled together with the F_0 curves and S curves, which have been reproduced from Fig 3. These derived curves will be termed "tertiary flow-stress curves." Like the secondary curves,

FIG 4—The flow stress of Monel as affected by temperature and total strain.

they do not represent continuous flow.

Before further consideration of the tertiary curves, attention will be given to curves of another type, the curves designated A to C in Fig 4 to 7. Each of these curves shows the influence of temperature on the strain that will produce the same strength state. These constant-state curves have been derived from the primary and secondary flow-stress curves by applying the following principles: (1) Varying the temperature without varying the plastic strain causes no change in the strength state. (2) Two specimens of the same metal, whatever their strain history, are in the same strength state if their flow

stresses are the same at the same temperature. The first principle implies that points at the same abscissa on the F_0 curve for room temperature and the S curves represent the same strength state. The second principle implies that a horizontal line drawn between a primary and a secondary curve representing flow at the same temperature will intersect these curves at points representing the same strength state.

For an example of the use of these principles in deriving a constant-state curve, reference may be made to curve C in Fig 4. A point on the F_0 curve for room temperature has been selected

MONE L

FIG 5—The flow stress of Monel as affected by temperature and total strain.

to represent state C. According to principle (1), the vertical line drawn through this point intersects the secondary flow-stress curves S at points representing the same strength state. According to principle (2), horizontal lines drawn from these intersections will intersect the corresponding F_0 curves at points representing the same strength state. The positions represented by the black circles have thus been established, and curve C drawn through these points represents a constant strength state. This method has been used in constructing all the constant-state curves in Fig 4 to 7.

Although a constant-state curve

represents constant intrinsic strength, it does not represent constant ductility. With decrease in temperature, the strain to produce constant intrinsic strength decreases, while the total ductility of Monel and copper increases. The residual ductility thus increases as the temperature is lowered. Consequently, since "constant mechanical state" implies constant strength and ductility, it is not possible to produce such a state by varying the plastic strain with the temperature. Moreover, although a constant strength state may be produced by varying the strain with the temperature, the structural state is not constant. With decrease in tempera-

ture, the strengthening effect of plastic strain of Monel and copper increases, but the damaging effect¹⁷ does not.

Attention will now be given to the three previously mentioned groups of tertiary flow-stress curves. One of the groups obtained with Monel is in Fig 4 and the other two are in Fig 5; one of the groups obtained with copper is in Fig 6 and the other two are in Fig 7. In deriving these curves, the points represented by inverted triangles have been established by a graphical method similar to the method of establishing the constant-state curves. Beyond these triangles, the tertiary curves have been extended by an arithmetical method involving the use of a direct temperature factor and an intrinsic strength factor. This method will be discussed later.

For an illustration of the graphical method, reference may be made to the inverted triangles on the G curves of Fig 4. Each of these curves represents the locus of incipient-flow stresses at the indicated temperature, after various strains at -188°C . In establishing a point on such a curve, this point should be placed at the proper distance directly below a selected point on the F_0 curve representing strain at -188°C . For convenience in establishing the two triangles on each of the G curves, the two specific strains selected are those represented by the black circles on the uppermost F_0 curve; these are the strains that will produce strength states A and C. If two specimens be strained these amounts at -188°C and then heated to room temperature, the points representing the incipient-flow stresses will be directly below the black circles on the F_0 curve. Moreover, since the two specimens will still be in states A and C, the incipient-flow stresses at room temperature should be the same as if the specimens had been strained to these states at room temperature. The two triangles on the lowest G curve, therefore, have been placed on the horizontal lines extending from the black circles on the F_0 curve for room temperature. From points directly above these two circles and on the secondary flow-stress curve S for -128°C , horizontal lines have been drawn to establish the two triangles on the G curve representing incipient-flow at -128°C . The same graphical method has been used to locate the triangles on all the tertiary flow-stress curves of Fig 5, 6 and 7.

The method of establishing these tertiary curves involves the assumption that, within the temperature range

represented, there are no structural changes other than those essential to plastic deformation. It also involves the assumption that, if the flow stresses of two specimens of the same metal with different temperature-strain histories are equal at one temperature, they will be equal at any other temperature within the range represented. This assumption implies that the direct effect of temperature on the flow stress is the same for two specimens with the same intrinsic strength, whatever may be the difference in the temperature-strain history. If this assumption were incorrect, the concept of intrinsic strength would be as untenable as the concept of absolute velocity. However, the concept of intrinsic strength is supported by scattered evidence in the literature. Moreover, it receives additional support from the results of a study of the influence of temperature on strain energy.

In Fig 4, the group of G curves is similar in one respect to the group of secondary flow-stress curves S . In each group, the curves represent incipient-flow stresses at several indicated temperatures after strains at *one temperature*. By comparison of ordinates of the curves of either group with the associated F_0 curve, information may be obtained about the direct effect of temperature on the flow stress. Similar groups of curves are shown in Fig 6. Fig 5 and 7, however, each contain two groups of a different type from those in Fig 4 and 6. The curves in each group in Fig 5 and 7 represent incipient-flow stresses at *one temperature* after strains at several indicated temperatures. Attention will be confined almost entirely to Fig 5, although the discussion would apply as well to Fig 7. The upper group, comprising the K curves, shows results of straining at several temperatures followed by determination of the incipient-flow stresses at -188°C . Since the uppermost F_0 curve represents flow at -188°C , it belongs in the same group with the K curves. The lowest curve in this group is the secondary flow-stress curve S for -188°C . All the curves of the upper group have the same origin, the point representing yield at -188°C . The lower group in Fig 5, comprising the L curves and the F_0 curve for room temperature, shows results of straining at several temperatures followed by determination of the incipient-flow stresses at room temperature. All the curves of this group have their origin at the point representing yield at room temperature.

Since the ordinates in each of these

FIG 6—The flow stress of copper as affected by temperature and total strain.

groups represent incipient flow stresses at the same temperature, the ordinates at constant strain are proportional to the intrinsic strengths, and a horizontal line drawn through either of the two groups would intersect the curves at points representing the same intrinsic strength. In the lower group of curves in Fig 5, horizontal lines have been drawn to intersect the lowest F_0 curve at points representing strength states A, B and C. These horizontal lines intersect the tertiary flow-stress curves at points representing strength states A, B and C. The strength states

represented by horizontal lines A, B and C, therefore, are the same as those represented by curves A, B and C. The flow stresses represented by curves A, B and C, however, are primary flow stresses; the flow stresses represented by the horizontal lines are incipient-flow stresses after change to room temperature.

If ordinates in the curves of either the upper or lower group of Fig 5 be compared at the same abscissa, the ordinates will be proportional to the intrinsic strengths produced by the same strain at the indicated temperatures. Since the temperatures of pri-

OXYGEN-FREE COPPER

FIG 7—The flow stress of copper as affected by temperature and total strain.

mary flow were the same for both the upper and lower groups, the intrinsic strengths produced by the same strain should be in the same proportion for each group. Consequently, although the incipient-flow stresses represented by the curves of the upper and lower groups differ greatly, the ordinates at the same abscissa should be in the same proportion in each group. As will be shown in the discussion of Fig 8, the ordinates in each of the groups in Fig 5 and 7 are in correct proportion.

The effects of the difference between room temperature and -188°C are represented in Fig 5 by five ordinate

ranges. The extreme ordinate range, the range between the highest and lowest F_0 curves, represents the effect of this temperature difference on the primary flow stress. Within this ordinate range are four other significant ranges. The ordinate ranges of the upper and lower groups of curves represent the effect of the above-mentioned temperature difference on the intrinsic strength. The range below the upper group of curves and the range above the lower group of curves, each represent the *direct* effect of the same temperature difference on the flow stress. Thus there are two ordinate

ranges representing the effect of the same temperature difference on the intrinsic strength, and two ordinate ranges representing the direct effect of this temperature difference on the flow stress. However, when the effects of this temperature difference are expressed in terms of ordinate ratios instead of ordinate differences, a single ordinate ratio will represent the effect on the intrinsic strength and a single ordinate ratio will represent the *direct* effect on the flow stress. The product of these two ratios is the ordinate ratio for the highest and lowest F_0 curves in Fig 5. The effect of a temperature difference on the primary flow stress, therefore, should be expressed as the product of two flow-stress ratios, one of which will be called the intrinsic strength ratio and the other the direct temperature factor.

Plastic strain has very different effects on these two factors. Since the curves in each group from which intrinsic strength ratios are derived diverge from the corresponding point representing yield (Fig 5 and 7), the intrinsic strength ratio at yield is 1.0 and the ratio increases continuously with plastic strain. The direct temperature factor, for a change between room temperature and -188°C, is represented by the ordinate ratio for the uppermost secondary flow stress curve S and the F_0 curve for room temperature. For copper, this ratio is about 1.3 at yield, and changes little with plastic strain (Fig 7). For Monel, the ratio is about 1.9 at yield, but the ratio decreases rapidly with strain until it is about the same as for copper; thereafter the ratio changes very little.

Diagrams of a different type have been derived from Fig 4 to 7 and are shown in Fig 8. In this figure temperatures are plotted as abscissas. The temperature scale is the same that has been used in previous papers by the author and associates.^{11-16,19} Temperatures in degrees K are plotted on a logarithmic scale. Since abscissas are proportional to the logarithm of the degrees Kelvin, the scale is the same in principle as Kelvin's original thermodynamic scale. This scale has been used because, within the range from room temperature -188°C, it gives a nearly linear relationship between temperature and conventional strength indices for various metals. Ordinates in the upper division of Fig 8 represent flow stresses; in the lower division ordinates represent flow-stress ratios.

Attention will be given first to the curves in the upper division. In this

division, there are three groups of five curves, and two curves representing the influence of temperature on the yield stress. Each group of five curves represents variations of the flow stress when the plastic strain is constant at the amount indicated by the value of A_0/A . Each of these groups has been derived from corresponding groups of flow-stress curves in Fig 4 to 7 by using flow-stress values represented by the ordinates at the indicated value of A_0/A . To simplify the correlation between the curves in Fig 8 and the curves from which they are derived, the same letters have been used to designate the curves in Fig 8 and the corresponding curves in Fig 4 to 7. Moreover, the same symbols that designate established points on the curves in Fig 8 have been inserted at corresponding points on the vertical dot-and dash lines of Fig 5, 6, and 7.

In each group of five curves in Fig 8, the F_0 curve and the S curve are derived from corresponding primary and secondary flow-stress curves; the other three curves in the group are derived from tertiary flow-stress curves. The S curve and the G curve have similar meaning. The S curve represents the variation of the incipient-flow stress with temperature, after the indicated strain at room temperature; the G curve represents the variation of the incipient-flow stress with temperature after strain at -188°C . Each of these curves, therefore, represents constant intrinsic strength, and hence it represents the direct effect of temperature on the flow stress. The K curve and the L curve also have similar meaning. The K curve represents the effect of constant strain at various temperatures on the incipient-flow stress at -188°C ; the L curve represents the effect of constant strain at various temperatures on the incipient flow stress at room temperature. The flow-stress variation represented by each of these curves, therefore, is proportional to the variation of the intrinsic strength with temperature.

As indicated by the S curves in Fig 8, the direct effect of temperature on the flow stress is nearly linear between room temperature and -188°C , on this temperature scale. The linear relationship is found not only at severe strains corresponding to A_0/A values of 4.6 for Monel and 10 for copper, but also at values of 1.3 for Monel and 4 for copper, abscissas at which the secondary flow-stress curves (Fig 2 and 3) are most accurately

FIG 8—Influence of temperature on the flow stress of Monel and copper at constant strain.

established. The linear relationship, however, probably ends a little above room temperature. The downward bending of the S curves for copper in Fig 8 possibly is due to the softening effect of "relaxation." If the S curves for Monel were extended above room temperature, they probably would turn upward because of strain aging.¹¹ Between room temperature and -188°C neither Monel nor copper shows evidence of either strain aging or relaxation. There is some doubt that

the linear relationship persists below -188°C . Continuation of the linear relationship on this temperature scale, between -188°C and the temperature of liquid hydrogen (-252.8°C) would require about 35 pct increase in the flow stress. Results of tension tests by DeHaas and Hadfield¹ and by Kostenetz⁷ indicate that the increase in the flow stress between -188°C and -252.8°C for most of the metals tested would be not more than about 20 pct. However, results obtained by Kos-

FIG 9—Influence of temperature on the strain energy of Monel for constant intrinsic strength

tenetz with some steels indicate an increase of about 35 pct, and his results for aluminum indicate an increase of 67 pct. The evidence based on these tests, therefore, is inconclusive. It appears probable, however, that the S lines for Monel and copper should be slightly curved if extended below -188°C ; the curvature would be qualitatively similar to that of the F_0 curves in Fig 8.

The F_0 curve, even in the absence of strain aging, probably would reverse its curvature if extended far enough

above room temperature. If extended over a sufficient temperature range, the curve would thus be similar in form to a curve representing the influence of temperature on the ultimate stress. Below the point of reversal the curvature is due largely to the influence of temperature on the intrinsic strength factor, as illustrated by curves K and L in Fig 8.

In each group of five curves in Fig 8, two curves represent the direct effect of the same range of temperature on the flow stress, and two curves repre-

sent the effect of the same range of temperature on the variation of the flow stress with the intrinsic strength. However, when the effect of this range of temperature on each of these four curves is expressed in terms of flow-stress ratios instead of flow-stress differences, only one curve is obtained to represent the *direct* effect of temperature, and only one curve is obtained to represent the effect of temperature on the intrinsic strength ratio. Curves so obtained are shown in the lower division of Fig 8. Lines DTF represent the variation of the direct temperature factor with temperature, and curves ISR represent the variation of the intrinsic strength ratio. Ratios are expressed in terms of the flow stress at the indicated strain at room temperature. Lines DTF are based on averages of closely agreeing ratios derived from lines S and G ; curves ISR are based on closely agreeing ratios derived from curves K and L . However, there is another way in which the ISR curves can be derived. From a pair of F_0 and S curves in Fig 8 intrinsic strength ratios can be derived by calculating ratios of corresponding ordinates. Since the S curve represents the effect of lowering the temperature without change of intrinsic strength, any point on this curve represents the intrinsic strength produced by the indicated strain at room temperature. The ratio of ordinates of the F_0 and S curves at the same abscissa, therefore, is the ratio between the intrinsic strength produced by straining at the indicated temperature and the intrinsic strength produced by the same strain at room temperature. Ratios thus obtained from the F_0 and S curves are identical with those obtained at the same abscissas from curves K and L .

The fundamental factors involved in the effect of temperature on the flow stress, therefore, can be derived directly from corresponding F_0 and S curves. These factors could then be used to establish curves G , K , L , DTF and ISR in Fig 8 without the use of the tertiary flow-stress curves in Fig 4 to 7. Moreover, the same arithmetical method can be used, in conjunction with the graphical method, to derive the tertiary flow-stress curves in Fig 4 to 7 from the F_0 and S curves.

As indicated by the ISR curves in Fig 8, the influence of temperature on the intrinsic strength factor gradually becomes less prominent as the temperature is lowered between room temperature and -188°C . However, if

the *ISR* curves were extended to some point above room temperature the steepness probably would begin to decrease, even in the absence of strain aging. The influence of prior plastic strain on the steepness of the *ISR* curve is illustrated by the relation between the two *ISR* curves for Monel. With decrease in the prior plastic strain, the steepness of the *ISR* curve decreases. At yield, the curve would become a horizontal line, and the influence of temperature on the flow stress would depend entirely on the direct temperature factor.

Influence of Temperature on the Strain Energy of Monel and Copper

The energy applied in the plastic deformation of metals is converted partly into heat and partly into latent energy. The conversion into latent energy is associated with the work-hardening, that is, the increase of intrinsic strength with strain. Since the strain energy is a function of the area beneath a flow-stress curve, the evidence in Fig 4 to 7 indicates that both the total strain energy and the latent energy vary with the temperature at which the metal is strained. The flow-stress curves in Fig 4 to 7, therefore, have been used to develop diagrams representing the influence of temperature on the strain energy of Monel and copper. The diagrams thus obtained are shown in Fig 9, 10 and 11. The energy values represented in these figures have been derived from the areas beneath flow-stress curves in Fig 4 to 7. The areas were determined by the use of original unreduced diagrams (20 in. wide) which were on coordinate paper with fine subdivisions. Since abscissas in these diagrams are proportional to true strains, the area beneath a flow-stress curve is proportional to the strain energy per unit volume of the *flowing* metal, even when this volume is decreasing because of local contraction. In calculating energy values per unit volume from the areas, a factor was used to convert abscissas to natural strains, and other factors were used so as to determine the energy equivalent of unit area in calories per gram atom.

Fig 9 and 10 show the energy relations for constant strength state; Fig 11 shows the energy relations for constant strain. Attention will be given first to the relations for constant state. States B and C represented by curves

FIG 10—Influence of temperature on the strain energy of copper for constant intrinsic strength.

W in Fig 9 are the same as those represented by curves *B* and *C* in Fig 5; states *A* and *B* represented by curves *W* in Fig 10 are the same as those represented by curves *A* and *B* in Fig 7. The circles on the *W* curves in Fig 9 and 10 correspond to circles on the constant-state curves in Fig 5 and 7. Just as curve *C* in Fig 5 represents the effect of temperature on the *strain* that will produce state *C*, so curve *W* on the right side of Fig 9 represents the effect of temperature on the *strain energy* that

will produce the same strength state. The similarity in form between the *W* curves in Fig 9 and 10 and the constant state curves in Fig 5 and 7 indicates that, for constant state, the variation of the strain energy with temperature is similar to the variation of the plastic strain.

Curves *W* in Fig 9 and 10 represent the influence of temperature on the *total* strain energy. However, just as the influence of temperature on the flow stress involves a direct tempera-

FIG 11—Influence of the temperature of Monel and copper on the strain energy for constant strain.

ture factor and an intrinsic strength factor, so the influence of temperature on the strain energy involves the same two factors. The relative influence of the two factors varies greatly with the metal. When the yield stress varies greatly with temperature, the influence of the direct temperature factor is most prominent. Curves W' have been developed to represent the influence of temperature on the work-hardening energy, the energy that remains after allowance for the influence of the direct temperature factor. Although partial

allowance for this factor may be made by utilizing only part of the area beneath a flow-stress curve, the part above the point representing the yield stress, the allowance thus made is incomplete. Complete allowance can be made by the method now to be described. Whereas curves W in Fig 9 are derived from the areas beneath F_0 curves in Fig 5, curves W' in Fig 9 are derived from areas beneath the L curves in Fig 5. The strain energy values represented by the symbols on curves W' in Fig 9 correspond to the

strain values indicated by symbols of the same kind on the horizontal lines representing strength states B and C in Fig 5. Curves W' , therefore, represent strain energy values derived from curves representing incipient flow at one temperature after strain at various temperatures. It should be emphasized that curves L in Fig 5 and 7 do not represent continuous flow. The ordinates of curves W' in Fig 9 and 10, therefore, do not represent strain energies for continuous flow at room temperature. They represent merely the energy values obtained by making allowance for the influence of the direct-temperature factor on the strain energy, and thus obtaining values for what may be called work-hardening energy. Since the values for work-hardening energy represented by a W' curve are relative to the total strain energy at room temperature, curve W'' crosses curve W at the abscissa representing room temperature (300°K). The values represented by a W' curve thus are merely relative values. They have been desired for use in the following study of the relation between applied energy and latent energy.

The relation between the total strain energy and the latent energy induced by plastic strain has been investigated by Taylor and Farren²⁰ and by Taylor and Quinney.²¹ The metals used in their experiments were copper, annealed mild steel, and annealed decarburized mild steel. For various stages during plastic deformation of these metals the increments of applied energy and latent energy were determined. With copper, the ratio of these increments (latent energy ratio) was about 9 pct throughout a wide range of plastic strain, but eventually decreased rapidly to about 4 pct. With the mild steel, the ratio decreased continuously from about 13 to about 7 pct. With the decarburized steel, the ratio decreased from about 10 to about 3 pct. With all three metals, however, the ratio of the total latent energy to the total applied energy changed very little throughout a wide range of plastic strain, a range which was much greater for copper than for the steels. For a qualitative study of the influence of temperature of the latent energy ratio, it has seemed best to assume a ratio of 10 pct for Monel and copper at room temperature. This ratio, therefore, has been used in Fig 9 and 10.

Since each of the four W curves of Fig 9 and 10 represents the strain energy relation for constant intrinsic

strength, a reasonable assumption is that each curve also represents the strain energy relation for constant latent energy. Beneath each of the W curves, therefore, a horizontal line E has been drawn to represent the influence of temperature on the latent energy E . The constant ordinate of line E is one-tenth the ordinate of curve W at room temperature. Comparison of corresponding ordinates of line E and curves W and W' shows that the latent energy ratios E/W and E/W' increase greatly with decrease in temperature. The variation of these ratios with temperature is represented directly by the curves in the lower division of Fig 9 and 10. The influence of temperature on these ratios evidently is nearly the same for both Monel and copper in each strength state. Moreover, comparison of these curves with the curves in the lower division of Fig 8 shows that the variation of the latent energy ratio with temperature is similar to the variation of the intrinsic strength ratio. The evidence indicates that the E/W ratio at -188°C is nearly three times the ratio at room temperature. If the ratio curves were extended to a point above room temperature, the steepness probably would begin to decrease. Moreover, above a certain temperature, the latent energy ratio would be affected by relaxation, and the influence of the strain rate on the ratio would become prominent.

Curves H in Fig 9 and 10 represent the total heat per gram atom, that is, the integral of the variation of the atomic heat with temperature. This will be termed "internal heat" to distinguish it from the part of the strain energy that is evolved as heat. Comparison of curves W and W' with curve H shows that the effect of temperature on the strain energy, for constant intrinsic strength, is qualitatively similar to the effect of temperature on the internal heat. The greater the internal heat, the greater is the total strain energy required to produce constant intrinsic strength, and the greater is the outflow of energy as heat. In the middle division of Fig 9 and 10, the total strain energy, work hardening energy, and latent energy are represented as superimposed on the internal heat.

Fig 11 shows the influence of temperature on the energy relations for constant strain. Curves W and W' in this figure have been derived from areas extending to the indicated abscissas beneath curves F_0 and L in Fig 5 and 7. Curves W and W' in Fig 11 are

similar in form to curves F_0 and L of Fig 8. This similarity would be expected since each curve represents results obtained with constant strain, and since the curves in both figures are derived from the F_0 and L curves of Fig 5 and 7. For constant plastic strain, therefore, the variation of the strain energy with temperature would be similar to the variation of the flow stress. Curves E in Fig 11 have been derived from the corresponding W curves by making the ordinate ratios for the two curves the same as the corresponding values of the latent energy ratio E/W , as represented by ordinates of the curves in the lower division of Fig 9 and 10. Curves E in Fig 11, therefore, are similar in form to curves E/W in Fig 9 and 10. They also are similar to the curves ISR of variation of the intrinsic strength ratio (Fig 8).

In the lower division of Fig 11, the total strain energy, work hardening energy, and latent energy for constant strain are represented as superimposed on the internal heat. The curves thus obtained should be compared with the curves representing the superimposed energies for constant intrinsic strength (Fig 8).

The diagrams in Fig 1 to 11 present various pictures of the influence of temperature on the stress-strain-energy relationship for metals that are practically free from structural changes or relaxation within the range from room temperature to -188°C .

Conclusions

1. The mechanical state of a metal depends not only on the total strain, but also on the temperature during the straining.

2. With decrease in temperature the total strain required to produce a constant strength state decreases, while the ductility of many metals increases. By "strength state" or "intrinsic strength" is meant a condition of the metal, a property independent of temperature.

3. The mechanical state which involves both strength and ductility cannot be held constant by varying the total strain with the temperature.

4. The influence of temperature on the flow stress involves two factors: (1) A direct temperature effect; (2) the influence of temperature on the rate of increase of intrinsic strength with strain. The lower the temperature, the more rapid is the increase of intrinsic strength with strain.

5. The effects of the direct temperature factor and the intrinsic strength factor on the flow stress should be expressed in terms of flow-stress ratios rather than flow-stress differences. The ratio of the flow stresses for the same total strain at two different temperatures is the product of two flow-stress ratios, one representing the direct temperature factor and the other representing the intrinsic strength ratio.

6. Both these factors can be determined from a set of primary flow-stress curves and a corresponding set of secondary curves, each representing the locus of incipient-flow stresses at a given temperature after various plastic strains at room temperature.

7. By the use of the two factors so obtained other (tertiary) locus curves can be obtained, each representing incipient-flow stresses at one temperature after various plastic strains at another temperature, either higher or lower.

8. With plastic strain the intrinsic strength ratio increases continuously, but there is not much change in the direct temperature factor.

9. The variation of the total strain energy with temperature involves the same two factors that affect the flow-stress. By making allowance for the influence of the direct temperature factor it is possible to determine the influence of temperature on the work-hardening energy.

10. The ratio of the latent energy induced by plastic strain to either the total strain energy or the work-hardening energy increases with decrease in temperature. The variation of the latent energy ratio with temperature is similar to the variation of the intrinsic strength ratio.

11. For constant intrinsic strength (constant latent energy) the variation of either the total strain energy or the work-hardening energy with temperature is qualitatively similar to the variation of the internal heat per gram atom, the integral of the variation of the atomic heat with temperature. The greater the internal heat, the greater is the total strain energy necessary to produce constant intrinsic strength, and the greater is the outflow of energy as heat.

The Thermodynamical Treatment of Very Small Solid Solubilities

LESTER GUTTMAN*

The question of whether classical thermodynamics alone imposes any lower limit to solid solubilities was raised during a discussion among various members† of the Institute for the Study of Metals. Although our conclusions are not new,¹ they may be worth reiterating, since confusion on this subject seems to persist.

In a binary system (A,B), the conditions for equilibrium, at constant pressure and temperature, between a solid solution and a liquid solution are

$$\mu_A^S = \mu_A^L \quad [1a]$$

$$\mu_B^S = \mu_B^L \quad [1b]$$

Here μ denotes the chemical potential either of component A or B, as shown by the subscripts, and the superscripts *s* and *l* refer to the solid and liquid solutions, respectively. These two conditions are just sufficient to determine the compositions of both phases. Suppose, however, that the solid phase is found experimentally not to contain any of component B; then we cannot evaluate μ_B^S , which is defined by

$$\mu_B^S = \left(\frac{\partial F^S}{\partial n_B^S} \right)_{n_A^S, P, T}$$

Here n_A^S and n_B^S are the number of mols of A and B, respectively, in the solid, whose free energy is F^S . Eq 1b cannot be used, but it is no longer needed: we stated at the outset that the solid has the composition "pure A," and only the liquid composition need now be determined, from Eq 1a. All the equilibrium properties of the system can be derived from Eq 1a rigorously and simply. Hence there is no purely thermodynamic reason to exclude phase diagrams which show precisely zero solid solubility. Marsh² has objected to such diagrams as implying that even the transformation of pure A begins at the eutectic temperature. In any case, the user of the diagram must have a certain minimum knowledge of how to interpret it, and

it would seem simpler to remember the general rule that eutectic temperatures have no significance for pure components, rather than to show, say, by broken lines, on a scale which will often be exaggerated, a hypothetical solid-solubility about which we know only that it is less than a certain amount.

The case of an intermetallic compound in equilibrium with a binary liquid solution does not require a separate treatment since nothing in the foregoing was dependent on the nature of the components. Therefore, thermodynamics alone does not exclude the possibility that (intermetallic) compounds may exist with compositions always precisely those given by their chemical formulas.

With the aid of *extra*-thermodynamic methods, one may conclude that the solubility of one solid in another is never exactly zero. On the other hand, one would generally expect that the solubility will be small unless the components resemble one another (as do the metals), or form weakly-bound crystals. Therefore, it is useful to know that when there is no direct evidence for solid-solubility, one may neglect it without violating thermodynamic principles.

Kinetics of the Reactions of Titanium with O_2 , N_2 and H_2

EARL A. GULBRANSEN* and KENNETH F. ANDREW*

Introduction

In a recent communication¹⁴ we have reported on the kinetics of the reactions of zirconium with O_2 , N_2 and H_2 as a function of the time, temperature and pressure variables. A systematic study was made and the results correlated with fundamental theories of gas-metal reactions. This paper will present a similar study for titanium.

Titanium and zirconium are members of the IV group of the periodic table and possess many similar physical and chemical properties as a result of their similar electronic configuration for the outer electrons. The two metals are relatively inert to both gas and liquid phase corrosion at room temperature. However, at moderate temperatures the metals become active and react readily with the common gases including O_2 , N_2 and H_2 which are of interest in this study.

A study of the kinetics of these gas-metal reactions is of interest for three reasons: (1) to understand the rate of reaction of titanium and its role in the behavior of high temperature alloys; (2) to understand the practical difficulties of the reduction, refining and working of titanium; and (3) to correlate the data with fundamental theories of gas-metal reactions and crystal structure predictions.

Literature Survey

Several review papers⁸ and books^{42,43} exist on the preparation and properties of titanium and its alloys.

THE METAL

Titanium has, at room temperature,

a hexagonal lattice of the zinc type. Hägg¹⁹ gives a value of 2.953Å for the (*a*) axis, a value of 4.729 for the (*c*) axis and a density of 4.427 at 20°C. Burgers and Jacobs⁵ have observed the transformation of the hexagonal to the body-centered cubic structure at 880°C and have established a value of 3.31 for the cube edge and a density of 4.31.

TITANIUM-OXYGEN

Carpenter and Reavell⁶ using a pressure change method have studied the reaction at temperatures of 742° and 1000°C and for a pressure of one-fifth of an atmosphere. The probabilities for reaction are calculated from kinetic theory and they report a value of 10^{-5} for O_2 at 1000°C and 10^{-6} at 740°C.

The titanium-oxygen system has been investigated by Ehrlich.^{10,11} Five phases are observed. Between (TiO_2 and $TiO_{1.90}$) an alpha-phase, consisting of a rutile lattice, is found. A beta-phase is observed between ($TiO_{1.80}$ and $TiO_{1.70}$). A gamma-phase is homogeneous between ($TiO_{1.56}$ and $TiO_{1.46}$) and has a structure of the corundum type. The delta-phase exists between $TiO_{1.25}$ and $TiO_{0.6}$ and has a sodium chloride structure. From $TiO_{0.42}$ to Ti the metal structure is observed.

The surface oxide films have been studied by Hickman and Gulbransen.²⁰

The rutile structure is observed in the temperature range studied, 300 to 700°C.

Three crystalline modifications of TiO_2 exist: rutile and anatase which are tetragonal and brookite which has an orthorhombic structure. Anatase is reported³⁶ to exist in two forms: I and II. Anatase II changes to anatase I at 642°C. Anatase I is stable up to 915°C where rutile becomes the stable modification. At 1300°C rutile transforms to brookite which melts at 1900°C. The monoxide, TiO , may be prepared from the dioxide by high temperature reduction with carbon or magnesium. Its melting point is 1750°C.

TITANIUM-NITROGEN

Carpenter and Reavell⁶ report that at 1000°C a linear rate law is observed. The probability of reaction is given as 10^{-8} at 1000°C. Fast¹² has studied the solubility of nitrogen and its effect on the mechanical properties of the metal.

The crystal structure of TiN has been shown by several workers^{2,21,44} to follow the sodium chloride structure. However, the calculated density is found to differ from the pycnometric value. This is studied by Brager^{3,4} in detail. He has suggested that the titanium sites in the lattice are only partially filled at low temperatures. As the temperature of preparation is raised the vacant sites become occupied which expands the lattice and increases the hardness and density. An (*a*) value of 4.22Å is given for room temperature.

TITANIUM-HYDROGEN

The solubility and the crystal structures observed in this system have been reviewed in a recent book by Smith.⁴⁰

Cleveland Meeting, October 1949.

TP 2684 E. Discussion of this paper (2 copies) may be sent to *Transactions AIME* before Dec. 1, 1949. Discussion is tentatively scheduled for publication in May 1950.

Manuscript received April 22, 1949; revision received July 22, 1949.

Systematic studies of the adsorption have been made by Huber, Kirschfeld and Sieverts²² and by Kirschfeld and Sieverts²⁹ up to temperatures of 1000°C and at various pressures. The results show the formation of two phases of variable composition, an alpha and a beta phase. Hägg¹⁹ has made an X ray crystal structure investigation of this system. The alpha phase is found to have the same structure as titanium and is homogeneous up to 33 at. pct of hydrogen. The beta phase is homogeneous from 50 at. pct to 66.7 and has a face-centered cubic structure.

Equilibria Calculations on the Reactions of Titanium with Gases

Titanium reacts with many of the common gases, with the exception of the inert gases, to form stable compounds. The chemical equilibria of these reactions may be calculated when the reaction products are TiO₂, TiN or TiC. Data on the free energy of formation of the hydride are not available.

Table I shows the reactions which are considered in this work together with the results and the literature references for each reaction.

The logarithms of the gas pressure or pressure ratios are tabulated as a function of the temperature in °C for the several reactions. For the reaction to form TiC the equilibrium constant *K* is tabulated.

The results show the following: (1) TiO₂, TiN and TiC are stable at all temperatures calculated in this study and from a thermodynamic point of view titanium will remove O₂, N₂, CO and CO₂ at the lowest pressures used in modern vacuum technology; (2) the reaction of water and carbon dioxide to form the oxide and hydrogen and carbon monoxide respectively are possible up to 800°C and perhaps higher in vacuums of the order of 10⁻⁷ mm of Hg.

Apparatus and Method

BALANCE

The vacuum microbalance and auxiliary equipment used for all of the kinetic measurements have been described.^{15,16} The sensitivity of the balance is 0.86 divisions per microgram and the weight change can be estimated to 0.3×10^{-6} g. The balance zero point is constant and the instrument is insensitive to pressure and small changes in the temperature of the surroundings.

VACUUM SYSTEM AND FURNACE TUBE

The vacuum system and furnace tube have been described.^{15,17} The system is constructed of all glass and ceramic materials. The furnace tube is double walled and is made from synthetic zircon. Vacua of McLeod gauge pressures of 10⁻⁶ mm or lower can be achieved with these tubes at temperatures of 1175°C and perhaps higher. The difficulties associated with and methods for the measurement of pressure in furnace tubes at high temperatures have been considered in another work.¹⁷

GAS PURIFICATION

The purification of the oxygen, nitrogen and hydrogen is the same as previously described.¹⁵ The source of nitrogen is specially purified nitrogen and is obtained from our Bloomfield Lamp Works. A mass spectrometer analyses of the gases used for the nitriding experiments showed oxygen to be present to about 0.01 pct (the limit of the sensitivity of the mass spectrometer for the gas sample and pressure used).

Method

The methods used have been previ-

ously described.^{14,15,16,17}

SAMPLES

Two types of titanium samples are used for the measurements: commercial titanium of approximately 99 pct purity with 0.77 pct of carbon, and iodide titanium. Both samples were obtained from the Remington Arms Co. Although no detailed analysis of the iodide titanium is available it is probably of a high degree of purity. A spectrographic analysis of the commercial titanium showed impurities of silicon and of iron. No quantitative spectrographic information is possible for these impurities since standards of known analysis are not available.

The specimens are cut from 15 mil sheets of the metal and weigh 0.6840 g. They have surface areas of 9 to 10 cm². The specimens, unless otherwise noted, were abraded starting with number one grit and finishing with 4/0 paper. The last two stages of the abrading are carried out under purified kerosene to minimize formation of oxide films.

Discussion of Results

HIGH VACUUM REACTION

The reaction of titanium in high vacua must be carefully considered if the metal is to be maintained in an essentially film free condition. This problem has been discussed in a previous paper for the case of the zirconium reaction.¹⁴ Titanium like zirconium acts as a getter for many gases at low pressures and elevated temperatures. This behavior makes the problem a difficult one.

Due to the thermodynamic stability of TiO₂ it is impossible to reduce the oxide by hydrogen. Thus, the practical solution to maintaining the titanium in a film free condition is the use of the best high vacua possible.

A number of studies show that titanium can be heated to the reaction temperature without formation of further oxide or other films. If iodide titanium is heated, for example, in a vacuum of 10⁻⁶ mm of Hg or lower no weight change of any kind is observed until a temperature of 550°C is reached. Above this temperature the specimen loses weight and at a temperature near 1000°C the rate of weight loss increases rapidly. This behavior is quite different from that observed for zirconium.¹⁴ We conclude that titanium is not as efficient a getter as zirconium and that the metal

can be heated without further film formation.

REACTION WITH OXYGEN

The reaction is studied as a function of the time, temperature and pressure and the results are presented in Fig 1, 2, 3 and 4. The weight gain in micrograms per cm² is plotted against the time in minutes. Assuming the ratio of real to measured area to be unity and the oxide to be TiO₂,²⁰ the thickness of the film in Angstroms is 58.5 times the weight gain in micrograms per cm². A scale of 1000 Å is marked on the curves.

Time

Fig 1 shows the time course of two oxidation experiments on commercial and iodide titanium at 550 and 600° respectively. A comparison is made with the oxidation reaction of iodide zirconium at 425°C. The oxygen pressure is 7.6 cm for all experiments. The iodide titanium reacts at a lower rate than commercial titanium. The comparison with zirconium shows that titanium is less reactive at these temperatures.

The shapes of the oxidation curves are similar to those observed for other metals. A rapid reaction rate is observed in the early stages of the reaction which gradually decreases as the film thickens. In this sense the oxide film has protective properties.

Time and Temperature

Fig 2 shows the effect of temperature on the reaction over the temperature range of 250 to 600°C. A comparison of the 250°C curve with the 600°C curve shows a film thickness of 210 Å after 2 hr of reaction at 250°C and a film of 7300 Å at 600°C.

The effect of temperature on the reaction rate is very marked and appears to follow an exponential law.

Time and Temperature Equations

Three equations have been used extensively to explain the time variation of the oxidation rate. These are:

- (1) the parabolic law^{33,34,39,46}
$$W^2 = Kt + C$$
- (2) the logarithmic law⁴¹
$$t = \beta(e^{W/\alpha} - 1) \text{ and}$$
- (3) the linear law
$$W = K't + C$$

In the above equation W refers to the weight gain, t the time and K' , K , C , α and β are constants.

In order to explain the temperature

FIG 1—Reaction of Ti and Zr with O₂ 7.6 cm O₂.

FIG 2—Reaction of Ti with O₂. Effect of temp. 250–600°C.

coefficient of the reaction rate Dunn⁹ has applied the Arrhenius equation to the parabolic rate law constant K . Mott³³ has interpreted the physical significance of the activation energy for the various types of diffusion process of ions and electrons through an oxide film. To further understand the significance of the temperature dependence one of the authors¹⁸ has applied the transition state theory¹³ of chemical reactions and diffusion processes to the oxidation reaction. The parabolic rate law constant is given by the equation:

$$K = \frac{2kT}{h} \lambda^2 e^{\Delta S^*/R} e^{-E/RT}$$

ΔS^* and E are the entropy and energy of activation, λ , the interatomic distance between diffusional states, k is Boltzman's constant and h is Planck's constant. The equation is useful since both ΔS^* and E can be calculated. ΔS^* is the probability or steric factor for a given reaction.

Time and Temperature Correlation

Plots of the weight gain vs. the

logarithm of the time show smooth curves of increasing slopes and indicate that the logarithmic law does not hold. A study of Fig 2 shows that the linear rate law is not applicable for the conditions studied.

Parabolic rate law plots are made for all of the data. In general the data deviate from the straight line during the initial stages of the reaction. However, good agreement is observed after 20 min. reaction time. This type of deviation has been predicted by Mott.³⁴

Temperature Dependence and Activation Energy

The temperature coefficient of the reaction rate is one of the most important quantities to evaluate. If the reaction can be related to a mechanism it is possible to correlate the temperature coefficient of the reaction with an energy of activation. For the oxidation of titanium it is possible to calculate diffusion constants and an energy and entropy of activation since the data can be fitted to the parabolic rate law during a large part of the reaction.

Fig 3 shows the parabolic rate law

constants K in units of cm^2 per sec plotted against $\frac{1}{T}$. These parabolic rate law constants vary from 2.8×10^{-16} cm^2 per sec at 250°C to 6.27×10^{-13} at 600°C . In terms of Angstroms of film thickness, the above rates correspond to 1.7\AA per sec at 250°C to about 80\AA per sec at 600°C . The slopes are evaluated for the time range of 60 to 120 min.

Both commercial and iodide titanium experiments are included in Fig 3. Each group appears to fit a straight line re-

lationship. The iodide titanium reacts at a slower rate. Below 350°C the data are scattered and the straight line relationship is no longer obeyed. An energy of activation of 26,000 cal per mol is calculated from the plot and the temperature independent factor $e^{\Delta S^*/R}$ evaluated from the expression derived for the parabolic rate law constant by the transition state theory.

Table 2 shows the values for the parabolic rate law constants and diffusion constants and the entropies, energies and free energies of activation of

the rate determining process. The K values are related to thickness by the use of the density of the oxide and the stoichiometric ratio of oxygen in the oxide. A surface roughness ratio of 1 is assumed.

The energy of activation of 26,000 cal per mol is higher than the value observed for the oxidation of zirconium,¹⁴ namely 18,200. The entropies of activation are less negative than those observed for the oxidation of zirconium. ΔS^* varies from -18.0 to -19.1 cal per mol per $^\circ\text{C}$ for titanium oxidation while values of -23.1 to -25.2 are obtained for the zirconium reaction.

A comparison of the reaction rate at 400°C shows a parabolic rate constant K of 0.667×10^{-14} cm^2 per sec for the titanium oxidation and a K of 13.20×10^{-14} cm^2 per sec for the zirconium reaction. Iron at the same temperature has a K value of 0.409×10^{-14} cm^2 per sec or roughly equivalent to the titanium rate.

Calculation of Diffusion Constants

Let us assume with Wagner⁴⁷ and Mott³³ that the metal ions are diffusing through the oxide lattice together with electrons by one mechanism or another. If this is done we can calculate the diffusion constant K from the parabolic rate law constants of the expression, $D = K/2$. Thus, at 400°C , the value of D is calculated to be 0.334×10^{-14} cm^2 per sec and at 600°C a value of 3.14×10^{-13} cm^2 per sec. These values represent the coefficient of self diffusion of titanium in its oxide.

The mechanisms for self diffusion of titanium are as follows: (1) formation and diffusion of interstitial titanium ions and (2) formation and diffusion of titanium defects (absence of titanium ion in lattice). Calculations by Huntington and Seitz²³ have shown that for copper the diffusion of lattice defects is the more probable process. It is at present difficult to choose between the above mechanisms for titanium oxide since calculations have not been made for systems closely analogous to this one. However, the activation energy must be associated with the formation and diffusion of either interstitial ions or lattice defects.

Pressure Effect

The effect of pressure on the reaction at 550°C is shown in Fig 4. The pressure is varied by a factor of 100 from 7.6 cm to 0.76 cm of oxygen. The effect is

FIG 3—Reaction of Ti with O₂ log K vs 1/T 250-600°C.

FIG 4—Reaction of Ti with O₂. Effect of pressure at 550°C.

| 600 | 62.7 × 10 ⁻¹⁴ | 1.048 × 10 ⁻⁶ | -19.1 | 26,000 | -16,700 | 42,700 |

largest for the thin film range. No simple relationship with the pressure has been determined. We conclude that the effect of pressure on the reaction rate is minor for the temperature and pressure range studied. This small effect is in agreement with the mechanism of metal ion diffusion. If oxygen atoms or ions diffuse through the film one might expect the rate to follow a square root function of the pressure for some pressure and temperature conditions.

REACTION WITH NITROGEN

The difficulties associated with the study of the kinetics of the nitrogen reaction on zirconium have been discussed in a previous paper.¹⁴ These difficulties are the prevention of the high vacuum reaction with oxygen, water vapor, and others, and the prevention of secondary reactions by elimination of the impurities such as oxygen, hydrogen, and others in the nitrogen.

In this section the reactions of commercial titanium with purified lamp grade of nitrogen are studied in detail as a function of time, temperature and pressure.

The results are shown in Fig 5-8 and discussed in the following subsections. In all of the figures the weight gain in micrograms per cm² is plotted against the time and, where necessary, the temperature is given at the top of the graph.

Comparison of Nitrogen Reaction on Titanium and Zirconium

Fig 5 shows a comparison of the nitrogen reactions of the two preparations of titanium with the corresponding reaction for zirconium. The time course of the reactions for the iodide preparations of the two metals are practically identical at 600°C. The commercial preparation of titanium reacts at a greater rate. A purified lamp grade of nitrogen is used.

Time and Temperature

Fig 6 shows the time course of the reaction of commercial titanium with pure nitrogen for several temperatures. The reaction rate decreases as the reaction proceeds. The effect of temperature on the reaction rate is uniform and the rate of reaction appears to be an exponential function of the temperature. At 850°C a total reaction of 158 micrograms per cm² is found after 2 hr of reaction while at 550°C a total reaction of 6 micrograms per cm² is observed.

The shapes of the time curves are very similar to what one observes for the oxidation reaction. This leads one to apply the parabolic rate law expression to the nitride data. A plot of the square of the weight gain shows a straight line over the complete thickness range and indicates that the rate law $W^2 = Kt$ explains empirically the time course of the reaction. It is of interest to see if this rate law can be placed on a reasonable physical basis.

Van Liempt⁴⁵ in a study of the degassing of metals has solved the diffusion equation using an approximation

method. The same method may be used for the reverse adsorption process. Van Liempt's equation is $Q/Q_0 = \frac{8}{d} \sqrt{\frac{Dt}{\pi}}$ where Q is the quantity of gas evolved or taken up at any time t , Q_0 , the original quantity of gas in the metal, and D , the diffusion coefficient. This expression gives the parabolic rate law, $\frac{W}{W_0} = K \sqrt{t}$. The temperature is involved in the solubility W_0 and in K which involves the diffusion constant D . Since both W_0 and K are temperature dependent it is impossible until

FIG 5—Reaction of Ti and Zr with pure N₂ 600°C.

FIG 6—Reaction of Ti with pure N₂ 550-850°C.

FIG 7—Reaction of Ti with pure N₂ log K vs. $\frac{1}{T}$.

data on W_0 are available to calculate D and the energy of activation E although an empirical energy of activation may be calculated.

Table 3 shows the values of the parabolic rate law constants for the temperature range of 550 to 850°C and Fig 7 shows a logarithmic plot of the parabolic rate law constant against $\frac{1}{T}$. A straight line is found for the temperature range of 550 to 850°C. An empirical energy of activation of 36,300 cal per mol is calculated. This can be compared to a value of 39,200 cal per mol obtained for the corresponding reaction with zirconium. This value is considerably higher than the energies of activation found for the oxidation process on most metals.

| 850 | 1123 | 0.8904 | 3.2×10^{-12} |

$E = 36,300$ cal per mol

Pressure

Fig 8 shows the effect of pressure on the time course of the nitride reaction at a temperature of 800°C. The pressure is varied from 7.6 cm to 0.076 cm, or by a factor of 100. Although the rate of reaction does vary with pressure the overall effect is small when compared to the predictions of the linear or square root law.

The influence of pressure on the permeability of metals to gases has been discussed by Barrer¹ and by the authors in a previous paper.¹⁴ Two possible permeation rate-pressure equations have been used to explain the data. These are: (1) the linear rate law which is based on a mechanism of activated diffusion without dissociation and (2) the square root law which is based on a mechanism of activated diffusion with dissociation. The second type usually accounts for the permeation of gases through metals.

The pressure dependence of the reaction rate is not explained by either of the rate expressions. This indicates that the solubility term W_0 is not pressure dependent. A similar result is found for the nitrogen reaction on zirconium.¹⁴ One explanation is that a nitride film is

formed on the metal and that this film dissolves into the metal, the thickness of this film depending upon the relative rates of reaction and solution. This nitride film is not observed by visual and electron diffraction studies after removing the nitrogen and cooling at room temperature. The presence of the nitride film prevents the gas pressure from exerting its normal effect on the solubility.

REACTION WITH HYDROGEN

The reaction is studied as a function of time, temperature and pressure and a comparison is made with the hydrogen reaction on zirconium. The stability of the reaction product is studied as a function of the temperature under high vacuum conditions. Fig 9 to 14 show the results. The hydrogen is prepared by diffusion through a palladium tube after a preliminary purification.

Fig 9 shows a preliminary study of the reaction of commercial titanium with hydrogen at 2.0 cm pressure as a function of the temperature. The reaction appears to start at a temperature of about 290°C and the rate of reaction increases rapidly with temperature. Visual and electron diffraction analyses of the specimen showed no evidence of a surface film after cooling and it is assumed that the hydrogen is dissolving in the metal to form a compound or stable complex. The specimen loses weight on evacuating the hydrogen atmosphere. This indicates that the reaction product is unstable to a vacuum of 10^{-6} mm of Hg at a temperature of 400°C. This will be discussed in more detail later.

Time and Temperature

It is of interest to examine the time behavior of the reaction rate. Typical

FIG 8—Reaction of Ti with pure N₂. Effect of pressure 800°C.

FIG 9—Reaction of Ti with H₂ and stability of hydride.

FIG 10—Reaction of Ti with H₂. Effect of temperature.

curves are shown for commercial titanium in Fig 10 for temperatures of 250 to 300°C. At temperatures of 250°C the reaction rate $\frac{dW}{dt}$ is constant with time. At a temperature of 300°C the reaction rate $\frac{dW}{dt}$ increases with the time. Some difficulty is observed in obtaining reproducible results. This may be due to the high sensitivity of the hydrogen type of reaction to impurities in the metal, to the presence of surface film, and to the lack of uniform metal specimens.

The shape of the time curves indicate that the reaction does not obey the parabolic rate law which is predicted by the equation of van Liempt⁴⁵ and discussed on p. 745. If it is considered

that cracks and blisters are forming in the metal during reaction, the time course of the reaction cannot be expected to follow the parabolic law.

The 300°C curve after 2 hr of reaction shows a hydrogen uptake corresponding to the formula $TiH_{0.13}$. Hägg¹⁹ has shown that titanium will take up hydrogen to 66.7 at. pct or to a formula TiH_2 . We have not attempted to check this value.

A comparison of the reactions of titanium and zirconium with hydrogen is shown in Fig 11. Both the iodide and commercial forms of titanium react more rapidly than the iodide form of zirconium. The shapes of the curves are different in the sense that $\frac{dW}{dt}$ decreases with time in the zirconium reaction

and increases in the titanium reaction. In regard to the hydrogen reaction titanium appears to react more rapidly on a simple weight gain basis than zirconium.

Temperature

A study of the reaction with hydrogen as a function of the temperature is necessary if the details of the reaction mechanism are to be worked out. However, the data are not of sufficient reproducibility to give a good value for the temperature coefficient. Qualitatively, very little reaction occurs at 250°C while at 300°C a very rapid reaction is observed.

Pressure

The permeation of gases through metals has been summarized by Barrer¹ and discussed briefly here, under "Reaction with Nitrogen." If the reaction is limited by a process involving activated diffusion with dissociation of the hydrogen molecules the reaction rate may be expressed by the following:

$$\frac{dW}{dt} = kp^{1/2} e^{-b/T}.$$

This formula predicts that at constant temperature the reaction rate should follow the expression:

$$\frac{dW}{dt} = Ap^{1/2}.$$

Fig 12 shows the effect of pressure on the reaction rate at 275°C for a pressure range of 6.0 cm to 0.1 cm of H_2 . The reaction is very sensitive to pressure although the 2.2 cm experiments are in disagreement with each other. The pressure effect for the hydrogen reaction is very different from the pressure effect in the nitrogen reaction.

Fig 13 shows a plot of the initial reaction rates $\frac{dW}{dt}$ as a function of the square root of the pressure. The two values of $\frac{dW}{dt}$ for the 2.2 cm pressure are averaged and included in the plot. Fair agreement with the square root law is found. This correlation shows that the diffusion of hydrogen into the metal is mainly by atoms of hydrogen rather than molecules and confirms the square root law.

Stability

Fig 14 shows the stability of the hydrogen complex with titanium as a function of temperature in a vacuum

FIG 11—Reaction of Ti and Zr with H_2 300°C 2.1 cm H_2 .

FIG 12—Reaction of Ti with H_2 . Effect of pressure.

FIG 13—Reaction of Ti with H_2 . Plot of $\frac{dW}{dt}$ vs $P^{1/2}$ 275°C.

FIG 14—Reaction of Ti with H_2 275°C 2.2 cm H_2 stability curve.

of 10^{-6} mm of Hg. Hydrogen is added to titanium at a temperature of 275°C and a pressure of 2.2 cm of H_2 . The reaction product is stable at 275°C in a vacuum of 10^{-6} mm of Hg. The temperature is gradually raised. At a temperature of about 350°C the hydrogen starts to be evolved. All of the hydrogen is removed from the metal if the heating is continued. This experiment confirms the results shown in Fig 9. At 400°C in this experiment the hydrogen is evolved at an appreciable rate. A comparison may be made with the stability of the zirconium-hydrogen reaction product.¹⁴ In that case hydrogen started to be evolved at a temperature of about 435°C. This indicates that the titanium-hydrogen complex is less stable than the corresponding zirconium-hydrogen complex.

Conclusions

A study of the thermodynamic equilibria of the several gas phase reactions of titanium with oxygen, nitrogen, water vapor, carbon monoxide and carbon dioxide show the following results: (1) TiO_2 , TiN and TiC are stable at all temperatures up to the transition temperature calculated in this study; (2) from a thermodynamic point of view titanium will remove O_2 , N_2 , CO and CO_2 at the lowest pressures used in high vacuum technique; and (3) the reactions of water and carbon dioxide to form the oxide and hydrogen and carbon monoxide respectively are possible up to 800°C and perhaps higher in vacuums of the order of 10^{-7} mm of Hg.

The oxidation reaction follows a modified parabolic rate law. An energy of activation of 26,000 cal per mol is calculated from the temperature dependence of the parabolic rate law

constants. Diffusion coefficients and entropies of activation for the reaction process are calculated. The oxygen reaction is found to be insensitive to pressure.

The nitrogen reaction is of special interest. The time course of the reaction can be fitted empirically to a parabolic rate law. The temperature dependence of the parabolic rate law constants is used to calculate an empirical energy of activation of 36,300 cal per mol. The effect of pressure is small. The nature of the reaction is believed to be one involving the solution of nitride into the metal under the conditions of a nitride film present on the surface. The nitride is found to be stable to temperatures of at least 900°C.

The reaction with hydrogen obeys the square root of pressure law. In contrast to the nitrogen reaction a film is not formed during the reaction and it is shown that hydrogen is probably diffusing into the titanium lattice as atoms. The hydrogen reaction product is stable in a vacuum of 10^{-6} mm of Hg to a temperature of about 350°C.

Structure of Diborides of Titanium, Zirconium, Columbium, Tantalum and Vanadium*

JOHN T. NORTON,[†] Member AIME, H. BLUMENTHAL,[‡] and S. J. SINDEBAND,[‡] Member AIME

The interstitial phases formed by the transition elements with carbon, nitrogen and boron constitute a unique class of substances which are of considerable technical interest because of their well developed metallic properties and their high hardness and melting points. They are also of interest from the point of view of structure.

It was pointed out by Hägg¹ some years ago that the principal factor determining these structures was the relative sizes of metal and metalloid atoms. He predicted that if the ratio of the radii of metalloid to metal atoms was less than 0.59, the metal atoms would be arranged in a close-packed fashion of relatively simple type. This prediction has been amply confirmed. It appears, however, that this specification applies most generally to those structures in which the metalloid atoms occupy isolated positions in the lattice and there is no tendency for strong binding between the metalloid atoms themselves. The series of borides of the type MeB_2 formed from the transition elements of the fourth (Ti, Zr) and fifth (V, Cb, Ta) groups of the periodic table provide an opportunity to investigate this situation further. If one takes as a basis the radius of 0.87 Å for the boron radius and the Goldschmidt values for the metal atoms in 12 coordination, then the radius ratio varies from 0.54 for zirconium to 0.64 for vanadium, which latter is considerably greater than Hägg's limit of 0.59. It was of interest, therefore, to see if these five elements would form borides of the MeB_2 type and have simple isomorphous structures.

When this investigation was initiated, relatively little information had been published on the structure of this group of borides. McKenna² reported the preparation of ZrB_2 by a carbon reduction process. Its structure was hexagonal and the approximate lattice constants were given as $a = 3.15$ Å, $c = 3.53$ Å. Ehrlich³ reported the structure of TiB_2 as being of the C 32 type with $a = 3.02$, $c = 3.21$ and $c/a = 1.06$ Å. Recently, Kiessling⁴ published the results on ZrB_2 , showing it to be one in which the metal atoms are arranged in a simple hexagonal lattice with the boron atoms in flat sheets, midway between the layers of metal atoms. The structure is C 32 type with $a = 3.169$, $c = 3.530$ and an axial ratio = 1.11 Å. He also states that CbB_2 and TaB_2 are isomorphous with ZrB_2 .

Preparation of Borides

The borides of titanium, zirconium, columbium and tantalum were made by the electrolysis of fused salt baths after the method described by Andrieux.⁵

The bath, totalling about 6500 g in each case had the following general composition: Metal Oxide + B_2O_3 + CaO + CaF_2 . The actual proportions of the ingredients were determined for each individual case.

Although Andrieux reports the preparation of vanadium boride by the same electrolytic method, several attempts proved unsuccessful. However, it was possible to prepare VB_2 by the carbon reduction method used by McKenna to produce ZrB_2 . The mixture consisted of $V_2O_5 + 6 B_2O_3 + 11 C$ and the reduction was carried out in an induction heated graphite crucible. This method proved satisfactory for ZrB_2 and TiB_2 and undoubtedly the others could be made in the same way.

The borides, which were all in the form of fine gray metallic crystals from the electrolytic bath or gray powders from the reduction process, were carefully separated from other constituents and analyzed chemically for metal and boron content. The densities of the boride powders were measured using a standard 10 cc pycnometer at 18°C and ethyl benzene proved to be the most satisfactory liquid for this purpose.

X Ray Technique

The boride crystals, as prepared, were too small for single crystal examination so that powder techniques were employed. Patterns of the finely ground borides were prepared, using the Norelco recording X ray spectrometer. The lines on these patterns were indexed with the aid of Hull-Davy charts and the approximate dimensions

FIG 1—The unit cell of MeB_2 (C 32 type).
The open circles are metal atoms and the shaded circles are boron.

FIG 2—Sheets of metal atoms (A) and boron atoms (B) in the MeB_2 crystal.
In each case the unit cell is outlined.

of the unit cell obtained. Patterns were also made on the Phragmen focussing camera covering the angular range from 50 to 85°. It was found possible to index these lines readily and the cell constants were calculated more accurately. In order to prove the assumed structure, the density was calculated from the X ray data and compared with the measured density. Also, the diffraction line intensities were calculated and compared with those measured from the spectrometer records.

All lattice dimensions are reported in true Angstrom units and are considered correct within $\pm 0.002 \text{ \AA}$. Copper K alpha radiation was used throughout and the wavelengths used in the calculations were:

$$\alpha_1 = 1.54050 \text{ \AA}$$

$$\alpha_2 = 1.54434 \text{ \AA}$$

In calculating densities, the expression

$$\rho = 1.66020 \frac{\Sigma A}{V}$$

was used, where

ρ = density

ΣA = sum of at. wt of atoms in unit cell

V = volume of unit cell in \AA^3

Results

The borides of titanium and zirconium proved to be quite pure, possibly because there was a considerable background of experience in their preparation and they were made in considerable quantities. The other three borides were somewhat less pure as indicated by a few faint extra lines in the diffraction patterns and by the chemical analysis. These impurities consisted of graphite and constituents of the electrolytic bath and it was difficult to make a complete separation. The diffraction lines of ZrB_2 , TiB_2 and

Table 1 . . . Chemical Composition of Borides, Wt Pct

Table 2 . . . Lattice Constants and Density of Borides

| Substance | Lattice Constants, \AA | | | Density, G per Cm^3 | |
|----------------|---------------------------------|-------|-------|------------------------------|-------|
| | a | c | c/a | Calc. | Obs. |
| ZrB_2 | 3.170 | 3.533 | 1.114 | 6.09 | 6.17 |
| CbB_2 | 3.086 | 3.306 | 1.071 | 7.21 | 6.60 |
| TaB_2 | 3.088 | 3.241 | 1.074 | 12.60 | 11.70 |
| TiB_2 | 3.028 | 3.228 | 1.064 | 4.52 | 4.52 |
| VB_2 | 2.998 | 3.057 | 1.020 | 5.10 | 4.61 |

VB_2 were sharp but those of CbB_2 and TaB_2 were somewhat diffuse. Further work is necessary in order to decide whether or not this is an indication of a range of homogeneity.

The chemical analyses given in Table 1 show clearly, however, that the borides correspond to the formula MeB_2 . The X ray diffraction data for all five borides is in complete agreement with a structure in which the metal atoms are arranged in a simple hexagonal lattice having an axial ratio slightly greater than unity. The lattice constants decrease with decreasing atom size and the axial ratio also decreases slightly. The lattice constants and densities are given in Table 2. The structure, therefore, corresponds to space group $D_{6h}^{16} - C6/\text{mmm}$ with metal atoms at $0, 0, 0$; and boron

atoms at $\frac{1}{3}, \frac{2}{3}, \frac{1}{2}$; and $\frac{2}{3}, \frac{1}{3}, \frac{1}{2}$. This is in agreement with Kiessling's results and shows that the five borides are indeed isomorphous.

Discussion of Results

From the structure as shown in Fig 1 it will be seen that the fundamental unit is a triangular prism of metal atoms with a boron atom at the center and that the prisms are packed together so as to share faces. From another point of view, the metal atoms are arranged in layers, parallel to the basal plane with the atoms in each layer having a close-packed arrangement, each metal atom with six equidistant neighbors in the plane and two neighbors, above and below, at slightly greater distance. The boron atoms are also arranged in flat sheets midway between the metal atom layers and each boron atom has three close neighbors. This is indicated in Fig 2. It thus appears that there would be strong boron-boron binding in such a structure.

From the point of view of close-packed interstitial structures, it is of interest to observe how the lattice dimensions change with metal atom

Table 3 . . . Calculated Lattice Dimensions in \AA

| CbB_2 | 3.09 | 1.79 | 2.43 | 3.31 | 2.85 |
| TaB_2 | 3.09 | 1.79 | 2.41 | 3.24 | 2.85 |
| TiB_2 | 3.03 | 1.75 | 2.38 | 3.23 | 2.92 |
| VB_2 | 3.00 | 1.73 | 2.31 | 3.06 | 2.63 |

size and these values, given in Table 3, afford some basis for speculation. All of these dimensions decrease with decreasing metal atom size. Perhaps it is simplest to consider the two extreme cases. In ZrB_2 , the distance of closest approach (D.C.A.) of the metal atoms in the metal atom sheet is the same as is the case in metallic zirconium. The hole in which the boron atom is placed is limited in size both by the neighboring boron atoms and by the metal atoms. This hole is larger than the normal boron radius of 0.87 Å but it appears that the boron atom must fill it, first because this is generally true in interstitial phases and secondly because the separation of the metal atom sheets is considerably greater than would be expected from the metal atoms alone. A boron radius of about 0.92 Å is consistent with this structure. The metal atoms are in contact with one another in the sheet and the boron atoms are in contact with one another and with their metal neighbors giving a close packed arrangement.

On the other hand, in VB_2 the D.C.A. of the vanadium atoms in the metal sheet is considerably greater than in vanadium metal. If the metal sheet is close packed, the boron hole is limited by the metal atoms to a radius of about 0.81 Å which probably is too small. If the vanadium atoms are not closely packed and have the same size as in the metal, then the boron hole is limited to a radius of 0.87 Å by the boron neighbors and by the metal neighbors to about 0.91 Å. Thus it seems again as if the boron atoms are essentially in contact with both metal and boron neighbors but that the packing in the metal sheets has been loosened and as a result, the separation of the metal sheets has decreased. Kiessling⁴ has reported that CrB_2 is isomorphous with the borides discussed here and it would be very interesting to know the lattice constants, for chromium is considerably smaller than vanadium and the radius ratio is 0.68.

The results show that there is no discontinuity in the series as the critical value of 0.59 for the radius ratio is

Table 4 . . . Electrical and Thermal Properties of Borides

| Substance | Electrical Resistivity Microhm-cm | Thermal Conductivity Cal per Cm per Sec °C at 200°C Avg | Wiedemann-Franz Ratio $\times 10^5$ |
|----------------|-----------------------------------|---|-------------------------------------|
| ZrB_2 | 38.8 | 0.0550 | 213 |
| TiB_2 | 28.4 | 0.0624 | 179 |

exceeded and emphasizes the fact that this limiting value should be considered specific only for phases in which the metalloid atoms are in isolated positions. That the radius ratio is not the only factor controlling structure is shown by the fact that tungsten and molybdenum, as shown by Kiessling,⁶ do not form borides which are isomorphous with the series discussed here although the radius ratio has a value of 0.62. A similar situation exists in the monocarbides.

In view of the apparent boron to boron binding, it might be expected that the borides would be less metallic than, for instance, the carbides. However, this does not appear to be the case. Electrical and thermal conductivity measurements were made on ZrB_2 and TiB_2 in the form of bars sintered without binder to about 85 pct of theoretical density. The values are given in Table 4. It will be observed that the properties are excellent and in fact compare favorably with the pure metals themselves. Also, the Wiedemann-Franz ratio is quite normal. This indicates that normal metallic linkages predominate. When sufficient quantities of the other pure borides are available, these experiments will be extended.

Another interesting aspect of the borides is the possibility of metal atom replacement to form solid solutions. On the basis of limited experiments on the series ZrB_2 - TiB_2 it appears that a continuous series of solid solutions can be formed, when the borides are mixed and heated together and that the lattice constants deviate only slightly in a negative direction from Vegard's Law. These experiments are also being extended.

Summary

1. The borides of Ti, Zr, V, Nb and Ta corresponding to the formula MeB_2 have isomorphous crystal structures with the metal atoms arranged in a simple hexagonal lattice having an axial ratio slightly greater than unity.

2. The structure is of the C 32 type, space group $D_{6h}^{16} - C6$ mmm, with metal atoms at 0, 0, 0 and boron atoms at $\frac{1}{3}$, $\frac{2}{3}$, $\frac{1}{2}$ and $\frac{2}{3}$, $\frac{1}{3}$, $\frac{1}{2}$.

3. The unit cell contains one molecule of MeB_2 .

4. This structure corresponds to alternate layers of metal and boron atoms, parallel to the basal plane of the lattice.

5. As the metal atom size increases, both a and c dimensions of the lattice increase and the axial ratio also increases slightly.

6. The borides have well developed metallic properties.

Acknowledgments

The authors wish to express their appreciation to the Office of Naval Research for the support of this investigation and permission to publish the results. They also gratefully acknowledge the important assistance of Mr. A. S. Cohan of the American Electro Metal Corporation and Mr. Albert Mahfuz of the Department of Metallurgy, Massachusetts Institute of Technology.

The Diffusion and Solubility of Carbon in Alpha Iron*

JAMES K. STANLEY,[†] Member AIME

Introduction

Knowledge of the diffusivity of carbon in the low temperature form of iron (alpha iron existing below 910°C) is at the moment of considerable interest in the study of the decomposition of austenite and martensite, the elastic after-effect,^{1,2,3} the magnetic after-effect⁴ and the decarburization of steel below 910°C. Information on the solubility of carbon in iron, and to a lesser extent its diffusion, is also important in consideration of such phenomena as blue-brittleness, temper-brittleness, "magnetic" aging, quench-aging, strain-aging, and possibly the yield point. In order to obtain more information on these subjects more fundamental knowledge is necessary. It is the purpose of this work to present data on the diffusion and solubility of carbon in the alpha iron.

The high temperature form of iron (gamma; face-centered cubic) existing above 910°C is capable of dissolving relatively large amounts of carbon, up to 1.7 pct at 1130°C, while the low temperature form (alpha, body-centered cubic) existing below 910° dissolves only a limited maximum amount of less than 0.02 pct carbon at 725°C, according to data obtained here. Since the solubility of carbon in the face-centered or gamma iron is large, relatively speaking, no great analytical difficulties have been encountered in the determination of the solubility lines⁵ or of the diffusion of carbon.⁶ The limited solubility of carbon in alpha iron offers difficulties because experimental procedures and analytical methods for low carbon contents below say 0.01 pct have to be more refined than techniques used for work with gamma iron. Because of the difficulties of applying conventional methods to the determination of the diffusion

of carbon in alpha iron, virtually no work has been done on this subject. However, by proper refinement of the analytical method for small amounts of carbon, the determination of the diffusion coefficient can be made readily using modified procedures.

The solubility of carbon in alpha iron has been determined over a temperature range by various investigators, but the agreement among them is poor. The present investigation establishes the limits quite accurately. Information of this kind is useful in establishing the correctness of equilibrium diagrams but, more significantly, such information on maximum solubilities, especially when extended to alloyed ferrites, should be extremely important in the study of aging and related phenomena.

Literature

The literature existing on the diffusion, in particular, and on the solubility of carbon in alpha iron is not extensive. The data which exist are not of a high order of accuracy, much of them being in the realm of conjecture.

THE DIFFUSION OF CARBON IN ALPHA IRON

Whiteley⁷ made the qualitative ob-

servation, using metallographic techniques, that the rate of diffusion of carbon at the A₁ (725°C) point was very rapid and that its diffusion was still rapid at 550°C.

Snoek,⁴ studying the magnetic after-effect in high purity iron, arrived at the conclusion that the after-effect could be explained by the presence of small amounts of carbon diffusing under the influence of magnetostrictive strain (lattice distortion due to magnetic interaction).

In later work, Snoek⁸ made an estimate of the ratio of carbon diffusion in alpha to its diffusion in gamma iron, and concluded that for a temperature of 910°C the ratio of D_α/D_γ was 2600. Polder,⁹ basing his calculations of D on relaxation phenomena in the elastic after-effect, estimated that D_α is about $\frac{1}{3}$ of D_γ at 910°C (1183°K) and is about $\frac{1}{12}$ of D_γ at 727°C (1000°K). Polder's equation for the diffusion of carbon in alpha iron was calculated to be

$$D = 5.2 \times 10^{-4} e^{-\frac{18000}{RT}} \text{ cm}^2 \text{ per sec}$$

Ham¹⁰ obtained data for the diffusion and solid solubility of carbon in alpha iron at two temperatures by using one technique similar to that employed in this study. He found a D of $8.0 \times 10^{-7} \text{ cm}^2 \text{ per sec}$ at 702°C and of 2.7×10^{-7} at 648°C.

THE SOLUBILITY OF CARBON IN ALPHA IRON

Although pearlite is absent in steels containing 0.06 pct,¹¹ 0.05 pct,¹² or 0.045 pct C,¹³ it appears that the carbon in these steels cannot be in solution in ferrite. The solubility of carbon at the A₁ (725°C) point was first determined by Scott¹⁴ on the basis of cooling curves, and was found to be between 0.03 and 0.04 pct C.

Tamura¹⁵ by interpolating between the solubility of carbon in delta iron at 1400°C and in alpha at room temperature (assuming zero solubility) ar-

¹ References are at the end of the paper.

rived at a solubility of carbon in alpha iron of 0.034 pct at 720°C. Whiteley⁷ using the Eggertz (colorimetric) test and metallography placed the limit of solid solubility at about 0.03 pct at 720°C. Koster¹⁶ on the basis of the Eggertz (colorimetric) test placed the maximum solubility of carbon in alpha iron at 0.04 pct at the A₁ and gave the variation of carbon solubility with temperature.

Dickie,¹⁷ using electrical resistivity measurements, made estimates of the solid solubility of carbon in Armco iron and several alloy steels by measuring the change in resistivity between the quenched and tempered states. Assuming a change of one microhm-centimeter being equivalent to 0.053 pct carbon, a calculation from his data gives the following solubility in Armco iron: 500°C, 0.008 pct; 625°C, 0.0172 pct; 710°C, 0.0194 pct; 750°C, 0.0199 pct and at 850°, 0.0204 pct.

Whiteley¹⁸ on the basis of metallographic work on Armco iron, pure iron, and electrolytic iron, concluded that the solubility of carbon was relatively constant to about 550°C, and then increased to the A₁. The line connecting the A₃ and A₁, he suggested, should be convex and gave one point (0.02 pct C at 870°C) to support this idea.

Smith,¹⁹ using a carburizing technique, arrived at the solid solubility of 0.02 pct at 750°C and 0.0128 pct at 800°C. The unpublished work of Ham¹⁰ has been mentioned; he found a solubility of 0.0185 pct at 702°C and 0.011 pct at 648°C.

In a recent work, Pennington²⁰ using a decarburizing technique, arrived at values of solid solubility of 0.025 pct C at 760°C, 0.02 pct at 790°C and 0.014 pct at 815°C.

Dijkstra,²¹ making internal friction measurements on high purity iron, arrived at the following set of solubilities at the indicated temperatures:

| | | | | | | | | | |
|----------|-------|-------|-------|-------|-------|------|-------|-------|------|
| °C..... | 250 | 400 | 450 | 500 | 550 | 600 | 650 | 700 | 710 |
| Pct..... | 0.001 | 0.002 | 0.003 | 0.004 | 0.007 | 0.01 | 0.012 | 0.016 | 0.02 |

Ziegler²² indicates that the presence of oxygen decreases the solubility of carbon.

MAGNITUDE OF THE A AND Q VALUES IN THE DIFFUSION EQUATION

A knowledge of the magnitude of the frequency factor, A, in cm² per sec and the activation energy, Q, in gram-cal per gram-atom, are of importance in the study of variation of the diffusion

coefficient with temperature.

Estimates of the Q values for the diffusion of carbon, other than those mentioned by Snoek⁸ and Polder,¹⁰ have been made. On the basis of spheroidization rates of cementite in pearlite Bailey²³ assigned a value to Q of 66,000 but this is more likely the heat of activation for spheroidization than for the diffusion of carbon. Richter^{24,25} found an activation energy Q of about 20,000 in his work on the magnetic and elastic after-effects; Snoek⁴ attributed his activation energy to the diffusion of carbon.

Ham¹⁰ by actual, though limited, experiments found A and Q values of 165 cm² per sec and 37,000 gram-cal per gram-atom, respectively.

Experimental

Two methods were used in determining the diffusion of carbon in alpha iron. The first or Van Orstrand-Dewey²⁶ method consisted of diffusing carbon from a saturated "well" into an essentially carbon-free sample. The other or Grube²⁷ method consisted of diffusing carbon from a higher carbon to a lower carbon sample with both materials being in the entirely ferritic phase. Both methods are indicated schematically in Fig 1.

THE VAN ORSTRAND-DEWEY METHOD

The Van Orstrand-Dewey method can be used successfully to determine the diffusion coefficient below 725°C in the following manner (above 725°C this method no longer applies for reasons cited):

Two cylinders, one of high carbon corresponding to a composition close to the eutectoid, and the other essentially carbon-free, were welded together into what is called a diffusion couple.

This diffusion couple is then annealed to diffuse the carbon across the weld or interface. After the diffusion anneal, the distribution of carbon with respect to the interface is determined, the concentration-penetration curve is plotted, and the curve is analyzed mathematically for the diffusion coefficient.

Below a temperature of 725°C, the high carbon side of the couple corresponds metallographically to fine pear-

FIG 1—Schematic representation of penetration curves from which the diffusion coefficient is calculated.

ite in which the carbon is available in large concentration in carbides and which can be rapidly transmitted to the diffusion interface due to the high rate of diffusion of carbon in the ferrite lamellae. This diffusion of carbon, as shall be seen subsequently, is of the order of a hundred times faster in ferrite than it is in austenite. In this case the solution of the diffusion equation is assumed to apply because the carbon-rich side behaves as if the carbon concentration on that side of the couple were constant.

Above 725°C the Van Orstrand-Dewey solution cannot be applied because the carbon concentration on the high carbon side is not constant. Actually the diffusion of carbon in austenite is considerably slower than that in alpha iron and hence the carbon is depleted from the austenite at the interface giving rise to a gradient; also the position of the interface probably changes. For these reasons the boundary conditions which satisfy the differential equation applicable to the Van Orstrand-Dewey no longer apply.

THE GRUBE METHOD

This method, used so frequently in diffusion studies, depends on the diffusion of solute atoms in high concentration across an interface into a sample of lower concentration. In the present case one depends upon the diffusion of carbon from a high-carbon ferrite, ("high" being used advisedly since the maximum carbon is about 0.02 pct at 725°C decreasing above and below this temperature) into a carbon-free ferrite. If the carbon in the high-carbon

ferrite is purposely kept lower than the maximum solubility the diffusion can be checked above (this is an important advantage) and below 725°C.

SOLUBILITY OF CARBON IN ALPHA IRON

Information on solubility of carbon in alpha iron can be obtained by the Van Orstrand-Dewey method. As soon as the diffusion couple is annealed, there begins to be released at the interface from the high-carbon sample into the carbon-free sample a small amount of carbon which is assumed to be a measure of the carbon solubility at the diffusion temperature. This assumption appears to be valid. *Apriori*, it would seem that the carbon from a saturated "well" of carbon in iron should be released into a carbon-free ferrite at a concentration corresponding to its solubility limit, certainly at and below 725°C. Above that temperature the saturated "well" does not exist. A similar situation exists in the case of the diffusion of zinc in alpha-brass;²⁸ it has been shown that as zinc diffuses from α -brass into copper, it forms β -brass and at the α - β interface the zinc concentration is that corresponding to the limit of solid solubility given in the Cu-Zn diagram; for example, at 655°C the zinc released to the copper is 36.5 pct.

The solubility of carbon in alpha iron above 725°C can be studied by a decarburization method. In an early work Pennington²⁹ makes the statement that no carbon concentration gradient could be found in ferrite layers formed on the surface of 0.85 pct C steel decarburized between 725 and 910°C. This did not appear probable to the author who felt that a carbon gradient from zero at the immediate surface to the limit of solid solubility at the decarburization temperature must exist in the ferrite layer. If this were not the case one would have to look for another mechanism of decarburization.³⁰ The assumed lack of a gradient through the ferrite layer appeared to offer to Pennington a method of determining the solid solubility of carbon in ferrite. One could determine the solubility by analyzing the ferrite layer formed on decarburization assuming, of course, that the ferrite is saturated with carbon. Recently Pennington²⁰ used this method to determine the solubility at several temperatures.

Decarburization experiments were conducted to check Pennington's idea

* Oxygen determined by the vacuum fusion method.

and it was found that if a high carbon alloy were decarburized and quenched from the decarburization temperature a carbon gradient in the ferrite layer existed. Even if the sample is slowly (furnace) cooled the carbon does not redistribute itself to give a uniform carbon distribution throughout the ferrite layer. The possibility exists that Pennington's analytical methods were not sensitive enough. His assumption that the carbon content of the ferrite layer should be a measure of the solid solubility cannot be considered valid. In the experiments performed by the author the limit of solid solubility by the decarburization method is the carbon concentration existing at the intersection of the decarburization curve in the ferrite with the carbon concentration in the austenitic region. Typical decarburization curves are given under *Results*.

COMPOSITION OF MATERIALS

Several materials were used for the diffusion and solubility studies. The basic material was electrolytic iron.

Ingots 12-15 lb were melted in an induction furnace and were either undeoxidized or deoxidized with silicon or aluminum or both. The high carbon materials for diffusion and decarburization were prepared by the addition of graphite to a silicon-killed melt. The materials were deoxidized for two reasons. One was that according to Ziegler²² the carbon solubility was affected by oxygen in solution and the other was that an aluminum addition was desirable to prevent grain growth. Several series of ingots were prepared, analyzed, and the desired composition was then selected for samples. Analysis was carried out on drillings taken from the

top and bottom of the ingots. When desirable compositions were found, the ingots were homogenized by heating to 950°C, holding about 15 hr and furnace cooling. The ingots were then forged at 850-900°C to one inch rounds. Sections of the rounds were analyzed at about one foot lengths and if the carbon contents of the ends of the round were in agreement, the section was used for samples. Table 1 gives the analysis of the materials used.

The possible effect of nitrogen on the diffusion of carbon was not investigated. The nitrogen content of sample 1, which was used extensively for the diffusion study, was 0.004 pct.

PREPARATION OF SPECIMENS

Cylinders of the various materials were machined, from forgings, to one-inch lengths and 0.75 in. diam and the ends were ground on a precision grinder.

Prior to the welding of the cylinders one of the faces of each was ground on several grades of metallographic paper finishing with 3/0. The cylinders were then welded on a welding machine in a hydrogen atmosphere, using 1500 lb load and 50 pulses of current (9000 amp). The welding conditions were kept as constant as possible to give identical samples. The region of the weld interface was probably heated to about 1000°C.

After the cylinders were welded they were cooled in hydrogen till black and were removed and quenched in water. The first couple welded by this procedure was tested for sufficiency of the weld. The one end of the sample was placed in a large vise and the other end was struck with a sledge hammer. The sample did not break but merely bent

FIG 2—Diffusion weld between high-carbon and carbon-free iron.

under the strokes. This indicated that the fusion was satisfactory. Examination of the weld zone was also made microscopically. Fig 2 shows the zone and the region near it in a high and low carbon sample; Fig 3 shows the zone and the region near it in a sample entirely in the ferritic state.

A variation in the preparation of the diffusion sample was carried out in the following manner: A small cylinder of high carbon (0.75 in. diam by 0.25 in.) was placed between two low carbon cylinders (0.75 in. diam by 0.875 in. long) and the three pieces were welded together in sandwich fashion. Such specimens (called double couples) were used when comparisons on grain size and oxygen were desired. Fig 4 shows a macrograph of a double couple. It illustrates how the grain size of the material changes, depending on the composition, when the couples are welded. There is, in the case of undeoxidized samples (No. 4 and 6), a pronounced coarsening of the grain structure; very large elongated grains are formed. In the case of deoxidized samples (No. 2 and 3), there may be

little change in structure and sometimes even a definite refinement.

Specimens for decarburization were in the form of spools because it was desirable to have the decarburizing atmosphere (moist hydrogen) bathe the entire reduced section. The spools were $1\frac{1}{4}$ in. long; the ends of the spools were 1 in. in diam and $\frac{1}{8}$ in. wide and the central portion was 0.75 in. in diam and 1 in. long.

THE DIFFUSION ANNEAL

Since this study involves changes in carbon of low concentration, the diffusion anneals were carried out in a vacuum because it was felt that risks should not be taken with gases such as hydrogen, nitrogen, helium or argon which might be decarburizing in the presence of small amounts of oxygen or moisture.

A quartz tube vacuum furnace was used. The furnace was made so that it could slide over the quartz tube. In this way a vacuum could be obtained while the furnace was being brought to temperature. When the desired vacuum

(Magnification $\times 5$).
Reduced one-third in reproduction.

was obtained, the preheated furnace was pulled over the quartz tube. When the anneal was completed, the furnace was pulled away from the quartz tube.

The vacuum system consisted of a Cenco Hyper-Vac pump in series with two mercury pumps. A liquid nitrogen trap was placed between the mechanical and mercury pumps. Pressures were measured with thermocouple and ionization gauges. Even with the furnace heated to 700 or 800°C the pressures were of the order of 5×10^{-5} mm of Hg.

The furnace was wound in three sections with nichrome wire and resistors were inserted between the sections to improve the temperature distribution. An arrangement was worked out so

that a uniform (better than $\pm 0.25^\circ$) hot zone was maintained over a distance of 3-in.

Temperature control was obtained by using a Micromax controller-recorder in conjunction with a constant voltage transformer and an anticipator.³¹ Temperatures were measured accurately to 0.1 of a degree. The variation in temperature was from ± 0.6 to $\pm 1.70^\circ$. The temperature of the anneal was obtained by plotting readings on probability paper and determining the standard deviation from the average, which when multiplied by 0.6745 gives the \pm error.

Before the diffusion anneals were started, coils of chromel and alumel wire (24 gauge) were calibrated against a Bureau of Standards's platinum-platinum: rhodium secondary standard. This was done by placing the standard thermocouple and thermocouples prepared from each end of the coils into a 1 in. diam nickel-plated copper cylinder in which three holes had been drilled. The cylinder containing the three thermocouples was placed in the uniform temperature zone of the furnace and the readings of the thermocouples were obtained on a type K Leeds and Northrup potentiometer, using a Leeds and Northrup thermocouple selector switch. Slight differences between the ends of the chromel and alumel were noted. These were averaged and charts were prepared for the chromel-alumel thermocouples correlating millivolts and temperature. New thermocouples were used for each diffusion-anneal.

The thermocouples were placed into the low carbon end of the diffusion couple by drilling a hole sufficiently

large for the thermocouple bead and then peening over the edge of the hole to keep the thermocouple from coming out. Connection was made between the thermocouple and the potentiometer by chromel and alumel lead-in wires joined to the furnace by a kovar-glass seal.

The diffusion anneal was carried out as follows: The furnace, drawn away from the quartz tube, was heated to the required temperature. The diffusion couple was placed into the cold quartz tube and connections were made to the potentiometer. The quartz tube was closed and was pumped down to the desired vacuum. The hot furnace was then pulled over the quartz tube containing the specimen.

Table 2 gives the details of the diffusion anneals reported upon in this investigation.

DECARBURIZATION ANNEAL

Samples used for decarburization were annealed in a conventional Globar Type furnace with a quartz tube as a furnace chamber. No extraordinary effort was exercised to obtain a fine temperature control, and hence the temperature varied $\pm 4^\circ$ of the desired temperature. The gas used was hydrogen saturated with moisture at room temperature (3.1 pct moisture by volume at 25°C). When the anneal was completed the samples were quenched in water.

MACHINING OF SAMPLES

After the diffusion anneal, the couples were machined to approximately 0.7 in. diam to remove possible de-

carburized layers and to get a uniform diameter couple. The region of the interface was polished with emery cloth and metallographic papers of increasing fineness. The samples were etched in 10 pct nital to bring out the interface. With the specimen properly centered in the lathe, layers about 0.02 in. were machined off near the interface and the thickness was then progressively increased to 0.04 in. at a distance of a centimeter from the weld. The length of the specimen after each cut was measured to the thousandth of an inch and estimated to the ten thousandth.

On the spools used for decarburization, turnings were taken on layers about 0.005 in. thick. In general, machining was continued until martensitic areas were reached.

CARBON ANALYSIS

Before the carbon analyses were made, the chips were screened on a 100-mesh screen to remove very fine particles which experience has shown can be relatively high in carbon presumably because of tool wear. After screening, the chips were washed in acetone and were dried over a small flame.

The carbon analysis was carried out by the method described by Stanley and Yensen.³² The method is a modification of the conventional combustion method, employing the use of vacuum and liquid nitrogen.

The agreement between the present, also known as the Yensen, method and the conventional combustion one is reasonable. Various investigators^{33,34} using the Yensen method have

| | 0.0108 ± 0.0003 | |

* Naughton and Uhlig used two variations of the low pressure combustion method.

analyzed the Bureau of Standard's sample 55a and have found it somewhat lower than the certified value which was determined by conventional combustion methods. See Table 3. The differences in the two methods have been considered by Naughton and Uhlig.³⁴

ERRORS

There are certain errors in the diffusion experiment that are to be considered in obtaining the error of the diffusion coefficient. The main sources of error are those due to carbon analysis, temperature and measurement of layers. Other errors affecting D are due to: diffusion occurring during the welding of the diffusion couples, the diffusion occurring while the specimens were coming to and cooling from the diffusing temperature, and the change in dimensions due to thermal expansion.

The errors in carbon analysis and temperature can be estimated, the other errors are not readily treated. The diffusion in the welding operation is small (about 0.06 mm) as can be seen from Fig 2 but no corrections for this diffusion were made. The error due to heating up and cooling down of the diffusion couples was difficult even to approximate; however if the heating and cooling times were short compared to the time of the diffusion anneal, it was felt that no serious error was introduced. After the diffusion anneal the samples were furnace-cooled to about 500° and were then quenched. Corrections for thermal expansion can be made but were not made here because of the uncertainty of the temperature coefficient of iron in the range studied. The D values, if the expansion corrections were approximated, would be increased only by about 1 pct. It is believed that the diffusion data are good to ±10 pct.

Results

After the carbon analyses had been made they were plotted in relation to the distance from the interface on probability paper. From the best straight line obtained on the probabil-

FIG 5—Carbon penetration at 514°C.

FIG 7—Carbon penetration at 672°C.

ity plot, curves were redrawn using rectangular coordinates. The types of penetration curves obtained by the Van Orstrand-Dewey method are illustrated in Fig 5 to 12 and for the Grube method in the ferritic state in Fig 13 to 15.

The D values for the curves were derived from Fick's law* of diffusion.

The differential form of Fick's equation is:

$$\frac{dC}{dt} = D \frac{d^2C}{dx^2}$$

The solution to the differential equation for the specific boundary conditions of the Van Orstrand-Dewey method is:

$$\frac{C_x - C_b}{C_o - C_b} = 1 - \phi\left(\frac{x}{2\sqrt{Dt}}\right)$$

where, using the *cgs* system,

C_x is the carbon at distance x in centimeters

C_b is the base or initial carbon content of the low carbon samples in per cent.

C_o is the carbon on the high side of the couple or the limit of solid solubility at the temperature.

D is the diffusion coefficient in centimeters squared per second.

t is the time in seconds.

ϕ is the Gauss error function.

The solution for the Grube method

* Discussions of Fick's law and the various solutions for limiting boundary conditions can be found in Jost³⁵ and Mehl.³⁶

FIG 6—Carbon penetration at 606°C.

FIG 8—Carbon penetration at 700°C.

is:

$$\frac{2(C_x - C_b)}{C_\infty - C_b} = 1 - \phi\left(\frac{x}{2\sqrt{Dt}}\right)$$

where C_∞ is the carbon at infinity in the high carbon side of the couple and all other symbols remain as before.

The diffusion coefficients calculated by both methods are given in Table 4. In Fig 16, $\log D$ is plotted against the reciprocal of the absolute temperature. The agreement between points obtained by the two methods is gratifying.

The diffusion of carbon in alpha iron as a function of temperature can be represented by the equation:

$$D = 7.9 \times 10^{-3} e^{-\frac{18100}{RT}}$$

No significant difference exists in D values between deoxidized, fine-grained samples and undeoxidized, coarse-grained samples. The diffusion coefficient at 700°C calculated for deoxidized, fine-grained samples (experiments 1, 2, 3, 4, 6) using the Van Orstrand-Dewey method samples gave a value of 6.4×10^{-7} cm² per sec. The experimental D value at 700 for an undeoxidized large elongated grain sample (experiment 5) gave a value of 6.75×10^{-7} ; experiment 7 also on an undeoxidized sample should not be compared with

FIG 9—Carbon penetration at 700°C.

FIG 10—Carbon penetration at 700°C.

FIG 11—Carbon penetration at 700°C.

FIG 12—Carbon penetration at 723.5°C.

experiment 5 since the sample contained 0.38 pct cobalt. Reference to experiments 9, 10, 11 employing the Grube method indicates that no anomalies were observed due to differences in grain size (See Fig 3 for example).

Silicon up to 0.25 pct and cobalt up to 0.38 does not appear to affect the diffusion coefficient although it must be emphasized that the data are very meager and more work is necessary to establish the effect of these elements unequivocally. In the case of silicon (experiment 2) the calculation of D from the exponential relation derived from all the points gives a value of 2.7×10^{-7} at 606°C as against the experimental value of 2.8×10^{-7} . In the case of cobalt (experiment 7) the calculation of D from the exponential relation gives a value of 7.2×10^{-7} at 700°C as against the experimental value of 7.6×10^{-7} . These variations are both within 10 pct and no greater accuracy than this is claimed.

It has not been possible, as may be evident, to determine whether D varies with concentration as it does in the case of gamma iron.⁶

THE SOLUBILITY OF CARBON IN ALPHA IRON

The data on the solubility of carbon in alpha iron are given in Table 5. They have been obtained as the intercept carbon, C_0 , from the carbon penetration curves obtained by the Van-Orstrand-Dewey method (experiments 1-8), Fig 5 to 12, and from the concentration of carbon at the ferrite-austenite interface, C_i , as is obtained in ferrite layers by the decarburization of a medium carbon steel (experiments 12-17); typical decarburization curves are given in Fig 17 and 18 for 750°C and 875°C, respectively. The data are plotted in Fig 19 together with data obtained by other investigators. The maximum solubility of carbon in alpha iron was found to be 0.019 pct at 725°C. The lines joining the carbon solubilities obtained by the Van-Orstrand-Dewey method and the decarburization method intersect nicely at the same point indicating that both methods are complementary and that the assumptions made regarding them are justified.

Discussion

The diffusion of carbon atoms in alpha iron as well as in gamma iron is interstitial and hence one need not concern himself with the mechanism of the process as one does for the dif-

fusion of atoms in substitutional solid solutions.

The diffusion of carbon in alpha iron, however, is much more rapid than in gamma iron. Wells and Mehl⁶ report the diffusion of carbon (in the range of 0.01 pct) in gamma iron as

$$D_{\gamma} = 0.07e - \frac{32,000}{RT}$$

Using their equation and the one found here for alpha iron, comparisons in the $\frac{D_{\alpha}}{D_{\gamma}}$ ratios at various temperatures can be made. Snoek⁸ and Polder⁹ predicted that at 910°C the ratio should be 2600 and 3, respectively. Actually the ratio at 910°C is 39. At 725°C the ratio increases to 126 and at 500°C it is 835.

It should be pointed out that the activation energy of the diffusion process in alpha iron is 18,100 gram-cal per gram-mol or about half the energy for diffusion in gamma iron, that is, 32,000. This value of 18,100 is identical (18,000) with that obtained by Snoek⁸ from the theory of the magnetic after-effect and by Polder⁹ from the theory of the elastic after-effect.

THE SOLUBILITY OF CARBON IN ALPHA IRON

The solubility of carbon in alpha iron has been established between 535 and 910°C with the maximum solubility of

0.019 pct occurring at 725°C. The maximum solubility and the solubilities near it have been determined by several investigators. The present investigation is in agreement with Smith,¹⁹ Ham,¹⁰ and Dijkstra;²¹ all other determinations have tended to be high. Fig 19 gives the data of the present experiments and the data of other investigators.

The limit of solubility below 725°C is rather important because it may serve as a base line for subsequent work which is needed to determine the effect of alloying elements on solubility. Such basic information is required if progress is to be made in the study of such phenomena as quench, strain, and "magnetic" aging as well as temper and blue-brittleness.

Summary

The diffusion of carbon in alpha iron was determined by two methods. One, the Van Orstrand-Dewey method, consisted of diffusing the carbon from a high carbon iron containing 0.68 pct C—corresponding to fine pearlite—into an essentially carbon-free iron. The other or Grube method consisted of diffusing carbon from a "high" carbon ferrite into a low-carbon ferrite. The first method could be used only below 725°C (eutectoid temperature) but the second could be used above and below 725°C. Both methods gave equivalent results.

The diffusion of carbon in alpha iron can be represented by the equation:

$$D_{\alpha} = 7.9 \times 10^{-3} e^{-\frac{18,100}{RT}}$$

The diffusion of carbon does not appear to be affected by grain size, decarburization or small additions of silicon and cobalt. The present methods did not lend themselves toward determining if D varied with concentration.

At 725°C the diffusion of carbon is over 100 times as fast as it is in gamma iron.

The solubility of carbon in alpha iron below 725°C was determined by the Van Orstrand-Dewey method since the carbon leaving the pearlitic iron at

the diffusion temperature corresponds to the carbon solid solubility. The solubility above 725°C was determined by a decarburization method, the solubility being the carbon concentration where the carbon gradient in the ferrite intersects the carbon gradient of the austenite-ferrite region. Both methods of determining solubility gave lines meeting at the same point to give a maximum solubility of 0.019 pct carbon at 725°C. The solubility lines between 514 and 910°C were obtained.

Acknowledgment

The writer is most appreciative of the University of Pittsburgh-Westinghouse Electric Corporation Graduate Study Program through which this study was made possible. It was a privilege to be associated with such personalities as Dr. G. R. Fitterer, Head of the Department of Metallurgy, University of Pittsburgh, and Dr. T. D. Yensen, Westinghouse Research Laboratories; both were most helpful in the carrying out of this work.

The writer wishes to acknowledge the assistance of the following: Messrs. Julius Heuschkel (welding), R. Anderson (metallography), R. Darby (machining), and Miss Joan Von Hoene for assisting with the numerous carbon analyses.

Studies of Interface Energies in Some Aluminum and Copper Alloys

K. K. IKEUYE* and CYRIL STANLEY SMITH,* Member AIME

In an earlier paper¹ one of the authors called attention to the significance of the relative free energies of grain boundaries and interphase boundaries in alloys in determining the shape and distribution of micro-constituents.

The ratio of the interphase and intercrystalline boundary energies (that is, $\frac{\gamma_{12}}{\gamma_{11}}$, where γ_{12} is the energy of the interface between a crystal of phase 1 and a crystal of phase 2, and γ_{11} is the energy of the boundary between two crystals of phase 1) will be denoted by Γ . It is this ratio that determines, by the simple triangle of forces relation,[†] the dihedral angle, θ , of phase 2 where it adjoins a boundary between two grains of phase 1. On a metallographic sample various angles are actually obtained because of the random orientation of the plane of observation, but the statistically most frequent angle is the true one. These basic principles were discussed in detail in the earlier paper.

The experiments described below show the effect of both composition and temperature on θ and Γ for some alloys containing a liquid phase, and provide data on the rate of approach to the equilibrium angles in both solid and liquid phases.

Experimental Procedure

All the alloys were melted in a graphite crucible and cast into ingots $\frac{3}{4}$ by $1\frac{1}{8}$ in. cross-section. Some of the aluminum alloys consisted of two immiscible liquids from which uniform castings could not be obtained. The amount of liquid phase varied locally to a considerable extent and the analyses were meaningless. Nevertheless, the composition of the liquid would not differ from that in an alloy of the intended gross composition, and

the synthetic composition of the alloys was therefore used in considering the surface energy results. The ingots were given initial deformation by cold-rolling to 50 pct reduction, annealed, and given a second 50 pct reduction prior to cutting into small samples for heat treatment at the times and temperatures subsequently reported. The resulting micro-samples were carefully prepared metallographically and examined at magnifications of 650, 1280, or 2500. The objectives used were 21X, 0.40 NA (dry); 41X, 0.65 NA (dry); and 80X, 1.40 NA (oil emulsion). The appropriate angles were measured by rotation of the stage of a Bausch and Lomb metallograph to align the appropriate boundaries successively with a cross-hair in a micrometer eyepiece. About 250 angles were measured on each phase. Though the angles were read to 1°, the accuracy is probably not above 3°, because of uncertainty in setting the cross-hair tangent to the sometimes curved boundary. The corners of very small particles, particularly in early stages of adjustment after cold-rolling, were difficult to measure and the results were slightly dependent on the magnification used (compare Fig 1-C and 1-D). With particles of larger size and more nearly equilibrium shape, magnification made no difference (*vide* Fig 1-F and 1-G). The measured angles were grouped in 10° intervals (5° if θ was less than 20°) and plotted in bar

graphs, of which Fig 1 is an example. The most probable angle was estimated and taken to be the true dihedral angle.

The frequency curves of even well-annealed alloys showed a greater spread of angle than that resulting from random sectioning alone, which indicates that the energies of all interphase boundaries are not identical, but vary slightly, supposedly as a result of differing orientation between the grains. Though this is of great interest and importance, it is a minor factor as far as general microscopic features are concerned and, for the present, is ignored.

Rate of Approach to Equilibrium

The distribution of dihedral angles for the liquid tin-rich phase in an aluminum-tin alloy with 5 pct tin, cold-rolled and subsequently annealed for various times at 350 and at 450°C, is shown in Fig 1 and 2. In all of these alloys, the structure consists of nearly pure aluminum grains with a tin-rich liquid dispersed as a continuous prism-like network along the edges of the three-dimensional grains. In the two-dimensional metallographic section, the tin-rich phase (solid, of course, after quenching) appears most frequently as triangles at the junction of three grains of aluminum. In the annealed samples, these triangles are essentially equilateral and equiangular, but cold-rolling distorts them considerably, resulting in a much wider spread of angles; annealing causes rapid restoration of the angles to the values determined by surface tension equilibrium. Fig 3 shows the same data as Fig 1 (that is, from the 350°C anneal) grouped according to the orientation of the apices in relation to the direction of rolling. In the rolled alloy most of the angles in the quadrants lying in the direction of rolling are smaller than the equilibrium value, while normal to this the particles have been flattened out and the angles increased. Annealing for 15 min. at 350°C gives a well-defined angle-distribution curve with a maximum at the equilibrium value, although the abnormally large spread of angles has not entirely disappeared. Annealing for 1 hr at 350°C gives liquid areas showing no anisotropy of angles, and further annealing causes no change. At 450°C (Fig 4) even the 15 min. anneal gives a structure that does not subse-

quently change, except for the size of the liquid particles.

In the solid state, restoration of distorted grain junctions to equilibrium configuration would be expected to occur at a slower rate than for a liquid phase and to be highly dependent on temperature. Tests were made on an alpha/beta bronze containing 16 pct tin at 650°C, a normal commercial annealing temperature. Annealing was done in a salt bath. Fig 5 to 8 show the microstructures obtained, while Fig 9 is a plot of the distribution of the corner angles of the beta grains after

various times of heat treatment. The grains of beta had been flattened out by rolling, and in the initial condition there is a large number of small angles in the quadrant parallel to rolling, while the normal quadrants contain larger angles than the equilibrium value. After annealing for 4 min., as can be seen from Fig 6, the alloy has completely recrystallized and the beta phase has developed apices, each one meeting a contiguous alpha boundary. The angles still show considerable spread from the equilibrium values and the strong curvature imposed on local

surfaces by the long-range geometry prevents equilibrium.* After 1 hr (Fig 9-D) the angles in the longitudinal and normal quadrants are nearly the same, and after 16 hr anneal at 650°C (Fig 9-F) the peaks of the two curves are almost identical, indicating that surface tension forces have entirely overcome the distortion imposed by cold-work.

*Equilibrium at a higher magnification (2500 \times) as in Fig 9-G gave a considerably sharper distribution, but still showed a definite difference between those angles near the rolling direction and normal to it. It is possible that on an atomic scale the equilibrium angle is achieved immediately after recrystallization. Samples that have been annealed for a sufficiently long time to allow the particles to acquire smooth, simply curved, outlines show no variation with magnification—provided, of course, that the metallographic preparation and optics are such as to give good resolution of the boundaries.

FIG 12—Relative interface energy, Γ , as a function of the composition of the liquid phase in Al-Sn alloys at various temperatures.

The answer to the question as to whether the mechanism of adjustment is by diffusion or by plastic deformation must await further study.

Effect of Temperature on the Dihedral Angle in a Binary Alloy Containing a Liquid Phase

Fig 10 shows the temperature dependence of the dihedral angle of the liquid phases in a copper-lead alloy with 1 pct lead and in an aluminum-tin alloy with 5 pct tin. Samples of these alloys were first cold-rolled and then annealed at different tempera-

tures for sufficient times to obtain equilibrium. Fig 11 shows values of Γ (the ratio of interphase and inter-grain boundary energies) calculated from the dihedral angles.

In the copper-lead system θ is unaffected by temperature up to 800°C, but decreases somewhat at 900 and 930°C and drops sharply to zero at 960°C. In the aluminum-tin alloy θ and Γ decrease with increasing temperature in a more uniform manner. The difference in behavior is easily explained if the constitution diagrams² are examined. In the copper-lead system, the composition of the liquid phase in equilibrium with solid copper changes

only from 0.5 to 1.0 pct copper as the temperature rises from 500 to 800°C, and then changes with increasing rapidity to about 7.5 pct copper at the monotectic temperature, 953°C, whereupon it abruptly changes to about 60 pct copper. In the aluminum-tin system the liquid changes continuously and with increasing rapidity from 0.5 to 100 pct aluminum as the temperature is raised from that of the eutectic (229°C) to the melting point of aluminum (660°C). It seems obvious that the major effect of temperature in both alloys is to change the composition of the liquid. Although it would be expected that both γ_{allq} and $\gamma_{\alpha/\alpha}$ would decrease with temperature, though perhaps at different rates, it seems reasonable to attribute most of the change in θ and Γ to the solid/liquid interface rather than to the grain boundary.

If, as in Fig 12, the values of Γ for the aluminum-tin alloys are plotted as a function of the composition of the liquid phase, as read from the liquidus of the constitution diagram,² Γ is seen to be a smooth function of composition,* decreasing as the liquid approaches the solid in composition. This is not unexpected.

It has often been supposed that the presence of a liquid phase results in hot-shortness of an alloy. Though extreme brittleness at high temperatures is almost invariably associated with the presence of a liquid, the converse is not necessarily so, for drops of liquid with

FIG 20—Relative interface energies as a function of composition in Al-Pb-Cd alloys at 350 and 550°C. (Al constant at 95 pct.)

large dihedral angles are relatively harmless. An alloy will become hot-short immediately above the solidus only if the dihedral angle is nearly zero, causing the liquid to replace a large fraction of the normal grain boundary area and to give rise to sharp notches for stress concentration. The method of determining solidus temperatures by detecting the onset of hot-shortness is an excellent one when θ is zero, but is dangerous to use on alloys where this is not known to be the case.

Interface Energies in Ternary Alloys Containing Liquid

It has been shown above that the composition change resulting from variation of solubility with temperature affects the interface energy ratio in a binary two-phase alloy. The change of

composition caused by the addition of a third element at a fixed temperature can have a similar influence. The effect of zinc and bismuth added to copper-lead alloys was discussed in an earlier paper.¹ More complete data were obtained with series of ternary alloys of aluminum containing tin and either copper, bismuth, lead, zinc, or cadmium. Except for the copper series, which contained 94 pct aluminum, the alloys investigated contained 95 pct aluminum with the remaining 5 pct divided between tin and the other element in varying proportions. Typical microstructures are shown in Fig 13 and 14.

The alloys containing copper were measured after annealing at several temperatures to show the effect both of temperature and composition (see Fig 15). The other alloys were annealed at 350 and 550°C only (for 16 and for 6 hr respectively) and gave the values of θ and Γ shown in Fig 16 to 20.

Copper and zinc (Fig 15 and 16) are soluble in both the solid and liquid phases in aluminum-tin alloys and they act slightly in the direction of decreasing the value of Γ —whether by modification of the grain boundary energy or of the liquid/solid interface cannot be said. The other elements—cadmium, lead, and bismuth—are virtually insoluble in solid aluminum, and dissolve little aluminum themselves when molten. In their ternary alloys with aluminum and tin it is therefore possible to study the equilibrium angles between an aluminum grain boundary (which, to a first approximation, may be assumed not to change in nature or

* The vertical lines drawn through the experimental points in Fig 10 represent the range of Γ corresponding to an error of 5° in measuring θ . It is obvious that the smoothness of the curve is to some extent fortuitous.

composition), and the interface between aluminum crystals and liquid that is of varying composition. The data in Fig 17 to 19 show that the energies of the interface between solid aluminum and liquid cadmium, lead,* or bismuth in the binary alloys are all higher than that of the aluminum-tin interface, but that the interface energy is decreased rapidly by the first addition of tin and more slowly as the liquid becomes richer in tin. This parallels closely the variation of surface tension with composition in binary liquid alloys and doubtless arises from a similar cause—the preferential adsorption of the element giving lower interface energy at the interface.†

Summary

Studies have been made of the angles

* The liquid phase in the pure binary alloys of aluminum and lead did not aggregate to a sufficient size to permit θ to be measured, even after annealing for 6 days at 550°C. The alloys with minor additions of cadmium or tin behaved satisfactorily.

† The behavior of the copper-bismuth-lead alloys described in Ref. 1 is not in accord with this, for the Γ curve is convex with increasing bismuth content.

‡ In the ternary Al-Pb-Cd case, there is no variation of Γ with composition (Fig 20).

existing at the corners of various microconstituents in alloys after deformation and heat treatment. Liquid phases take relatively short times to reach the angles determined by surface energy equilibrium. Solid phases are slower to adjust, but commercial annealing practice for a bronze gives dihedral angles that are not appreciably changed by longer annealing.

The effect of temperature on the dihedral angle and the relative energies of grain boundary and interphase boundary in copper-lead and aluminum-tin alloys is slight except when the change of temperature produces a change in the composition of the phases in equilibrium. In general, it is predicted that alloys whose constitution diagrams show a nearly vertical liquidus will be substantially unaffected by temperature change, and that alloys with a sloping liquidus will present structures that vary considerably with annealing temperature. The dihedral angle decreases as the composition of the liquid approaches that of the solid. Alloys become hot-short when heated above the solidus *only* if the liquid phase has a small dihedral angle and so replaces a large part of the

grain boundary area.

Dihedral angles were measured for a series of ternary alloys of aluminum with tin and other low melting-point elements. If the third element is soluble in both solid and liquid phases the dihedral angle may be decreased (aluminum-tin-copper, aluminum-tin-zinc) but otherwise the ternary alloys possess relative interface energies intermediate between that of aluminum-tin and that of the binary alloy of aluminum with the other component. The first addition to a binary alloy of a third element that itself has a lower interface tension against solid aluminum will cause rapid reduction of interface tension, while further additions are less potent, paralleling the behavior of surface tension in liquid binary alloys.

Preparation and Casting of Beryllium Melts*

J. G. KURA,[†] J. H. JACKSON,[‡] Member, M. C. UDY,[§] Member, and L. W. EASTWOOD,[‡] Member AIME

Introduction

The melting and casting of any commercial metal depends upon the success with which the problems attendant to the handling of the specific metal are overcome. Common difficulties encountered in the handling of commercial metals are tendencies to burn or oxidize excessively, low fluidity, entrapment of dross, hot cracking, cold embrittlement, cold shuts, and unsoundness caused by gas evolution. Beryllium is not only subject to these same difficulties but is generally more sensitive to them than are the more common metals, thus necessitating more exact founding precautions.

Characteristics of Beryllium

Certain characteristics of beryllium which make it particularly difficult to handle in the plant or laboratory are as follows:

1. The melting point of beryllium is about 2400°F and pouring temperatures vary from 2600 to 2900°F, depending upon the degree of fluidity required. The extreme chemical activity, combined with the high temperatures, makes necessary the use of inert atmospheres, slags, or vacuum for protection during melting and pouring. Furthermore, beryllium tends to react with the melting crucibles, tools, and molds, thus requiring the selection of suitable materials and proper maintenance of these items.

2. The very marked absorption of gas by molten beryllium and the subsequent evolution of gas during solidification causes a great deal of difficulty with unsoundness. Beryllium castings may also be subject to unsoundness as

a result of gas formation by chemical reaction with the mold surface during solidification.

3. The very marked chemical affinity between molten beryllium and the normal atmosphere causes the formation of dross. On relatively quiescent melts, this dross forms a very tenacious film which, if carried over to the mold, can cause defects such as the formation of skins or dross in the interior or on the surface of the casting; folds or defects similar to cold shuts may also be found.

4. During the pour and attendant turbulence, the dross may be mixed into the metal and then carried to the casting. There it may be entrapped during freezing and cause internal defects, or it may float to the surface and cause severe dross defects on the cope side of the castings.

5. Solid beryllium is very weak at a temperature near the solidus line; brittleness is also a problem at lower temperatures. Thus, hot and cold cracking must be guarded against.

Scope of the Experimental Work

All of these problems have been given consideration in the work at

Battelle. Before the work was started at Battelle, it was customary to melt beryllium in a vacuum furnace or under flux in graphite-lined induction furnaces.

Because of the difficulty of preventing gas unsoundness in beryllium castings, an investigation was undertaken primarily to study this particular problem and, secondarily, to devise methods of overcoming the other difficulties encountered in the founding of beryllium. The objectives of the laboratory work were multifold: 1. To devise a practical method of melting, other than vacuum melting, by means of which consistently sound beryllium castings could be produced. 2. To obtain fundamental data which would promote a better understanding of the causes of gas unsoundness in beryllium. 3. To develop a casting technique which would permit low melt temperatures, minimize dross defects and hot cracking, and eliminate reaction with the mold surface.

Up to the present time, a considerable amount of progress has been made on the first and third objectives, with the result that it can now be safely stated that consistently sound castings can be made by the open-pot melting method, using argon as a protective atmosphere and a proper casting technique. There has been some progress on the second objective of the project, but it cannot yet be safely stated that the problem is completely understood.

Most of the experimental work has been conducted in an enclosed melting and pouring apparatus in which very close control of melting variables has been effected. Findings based on the results of the work conducted in this small experimental apparatus have been applied to large-scale melts which have been made by techniques suitable for duplication on a commercial scale.

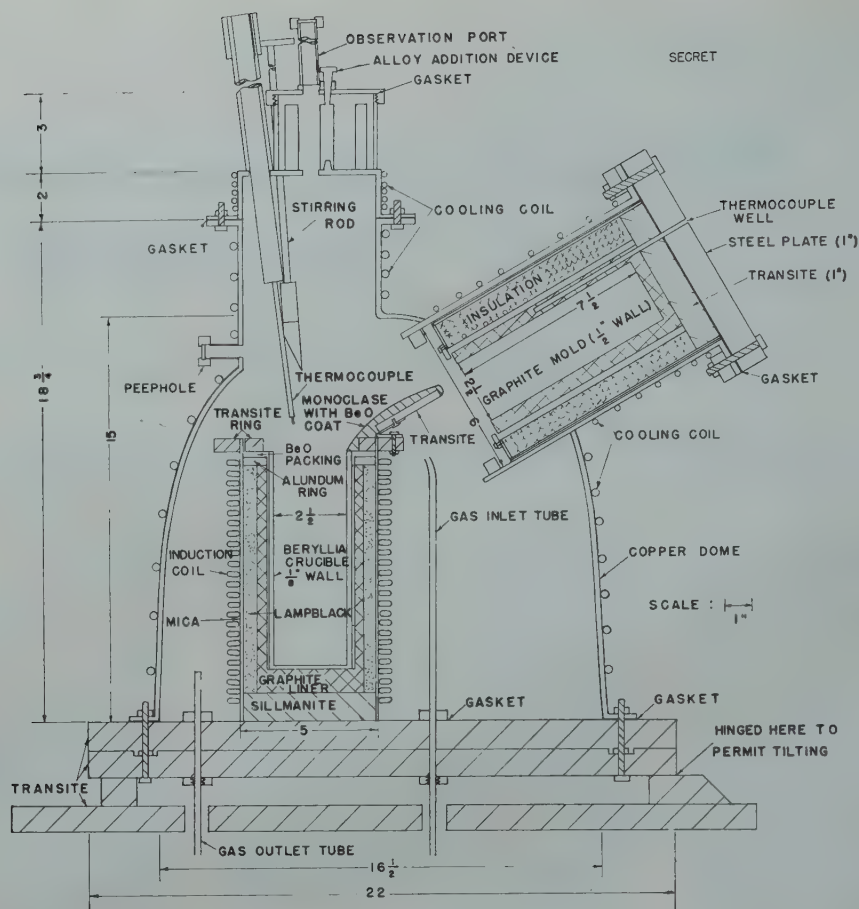

FIG 1—Sectional view of gas atmosphere induction furnace.

The Controlled-atmosphere Furnace

The experimental apparatus for melting and pouring under controlled conditions has been termed the small or controlled gas-atmosphere induction-melting furnace. A sectional view of this furnace is shown in Fig 1. The sketch shows the induction furnace lined with a beryllia crucible and equipped with a graphite mold. Other crucible and mold materials have been investigated in this apparatus, but those mentioned have been selected as the best for the work conducted to date.

As shown in Fig 1, the apparatus consists of a copper dome which fits over the induction furnace. The mold is integral with the dome. This arrangement permits the control of the composition of the ambient atmosphere used during melting and pouring. After putting the dome in place, the charge is melted in the furnace and then cast into the mold by revolving the entire assembly about the axis shown in the lower righthand corner of the drawing. Upon revolving the assembly, the

melt pours over the lip of the crucible and into the mold according to the Durville pouring method. This method of pouring is very desirable for easily oxidized or drossy metals because it permits the metal to be poured with a minimum of disturbance of the oxide film and thus prevents the inclusion of dross in the castings. The furnace assembly with the dome installed and in the melting position is shown by Fig 2.

The argon gas used as an atmosphere during melting and pouring is purified and dried, if a low humidity is desired, before it enters the dome. The rate of flow of the gas is closely controlled, its temperature inside the dome measured, and the humidity of the gas that leaves the dome determined. The temperature of the metal throughout the melting cycle is closely controlled, and the temperature of the graphite mold is also closely regulated. The dome is equipped with (1) a cooling coil through which various cooling liquids can be circulated, (2) peepholes for viewing the crucible and mold, and (3) a poking rod and an alloy addition device which permits these operations without open-

ing the dome.

Melting and Casting Large or Small Beryllium Heats

FURNACES AND FURNACE LININGS

The induction furnace is most suitable for the melting of beryllium. Graphite linings for the induction furnace have been used but are not very practical since, at a temperature of about 75° above the melting point of beryllium, the reaction $\text{Be} + \text{C} \rightarrow \text{Be}_2\text{C}$ takes place. Since the reaction is exothermic, the utility of a graphite crucible is limited by the necessity of an accurate control of the temperature of the melt.

Magnesia linings for induction furnaces, employed in melting beryllium, have been used in the past with some measure of success. The use of magnesia was abandoned when it was found that the fluxes used in melting beryllium attacked this refractory. Since fluxes are no longer necessary in the melting of beryllium, it may be possible to return to the magnesia lining. This possi-

bility should be investigated.

Large-scale melts have been made most successfully in induction furnaces lined with a graphite-bonded silicon carbide known commercially as Tercod. They are conveniently backed with lampblack for high thermal insulation. Tercod crucibles are available in a variety of sizes and shapes. In the experimental work, they have been used in the melting of heats ranging from about 3 lb up to about 85 lb.

Although Tercod crucibles have been successfully set in the large induction furnace with a silica sand backing, best results have been obtained using a lampblack (Norblack) backing. This material is rammed tightly around the crucible, the coils being protected with a layer of ramming mix next to the coil and a layer of asbestos paper between the ramming mix and the Norblack. With the 80-lb melts, melting time has been cut from $2\frac{1}{2}$ to $1\frac{1}{2}$ hr by the use of the insulating lampblack backing.

The Tercod crucible is ordinarily supplied with a borosilicate glaze. Tercod crucibles, having an aluminosilicate glaze on the outside and little or no glaze on the inside, are said to be available. Up to the present time, the glaze has been removed by melting a cryolite wash in the crucible. The cryolite is then removed by melting a wash heat of beryllium in the crucible. The wash heat may include scrap beryllium such as turnings, sawings, and others. Often, metal containing dross skimmed from previous heats is added to the wash heat which then forms a protective film of beryllium oxide on the inside of the Tercod crucible. Without this protective layer, the Tercod may be attacked by the beryllium.

The Tercod crucible does not appear to be suitable for use in the small gas-atmosphere induction furnace, because under such conditions of melting, the oxide film on the Tercod is not maintained and the melt reacts with the crucible. The use of cryolite for the removal of the glaze is undesirable from a health standpoint because, on subsequently using the crucible for melting beryllium, copious fumes of beryllium fluoride are formed as a result of the reaction between beryllium and the residual cryolite (Na_3AlF_6). It is possible that some means other than that which is used at the present time can be devised for the removal of the glaze and the attainment of a beryllia coating on the Tercod.

The development of beryllia crucibles for use in the small gas-atmosphere induction furnace (Fig 1) has been a

FIG 2—Photograph showing the small controlled-atmosphere induction furnace used to make melts of 1 to 2 lb each.

step of great importance in the experimental procedure. After a considerable number of trials of various materials, it was found that a beryllia crucible was satisfactory if it was fired by slow heating to 3300°F , and then held at this temperature for 4 hr before slowly cooling to room temperature. Without such treatment, the crucibles fail after each heat because they are subject to

considerable dimensional change during the heating and cooling cycle. After firing at 3300°F , the dimensional stability is very satisfactory and crucibles invariably last for 15 to 20 heats and fail through the formation of a skull of beryllium oxide on the inside of the crucible and not through cracking.

The spout of the experimental furnace is lined in such a way that during

FIG 3—Photograph of the large induction furnace with a graphite mold and tilting mechanism for making the cast 2-in.-round remelting ingots for the furnace illustrated by Fig 1 and 2.

the pour the metal contacts only the beryllia refractory.

New beryllia crucibles, even after preheating at 3300°F, are generally unsatisfactory for the melting of beryllium because the first melt made in a new crucible or in a furnace which has not been used for a considerable length of time is often very "gassy." In such instances, the use of a wash heat of beryllium for conditioning the crucible is recommended if sound castings are to be consistently obtained.

One disadvantage of the induction furnace for melting beryllium is that dross is often inductively stirred into the melt and results in dirty castings. When a Tercod crucible is used for the lining, the conductive crucible shields the melt from much of the electromagnetic field which would induce too violent agitation. A further advantage of the Tercod crucible is that it can be heated to a high temperature before the beryllium charge is added to it, thus permitting rapid melting if desired.

The stirring which occurs in the melt prepared in the controlled gas-atmosphere induction furnace (Fig 1) containing a beryllia crucible is of less importance because the use of the inert atmosphere eliminates the dross to a great extent. Furthermore, as shown in Fig 1, the beryllium melt is shielded to some extent from the inductive field by means of a graphite backer for the beryllia crucible.

Although induction heating has been used exclusively in the experimental melting of beryllium, it is conceivable that some other form of heating, such as electrical resistance heating, might be satisfactory. It is unlikely that gas-fired furnaces, unless mixtures other than city gas and compressed air were used, would be suitable because of the high-flame temperatures necessary for the melting operation and the gas absorption from the products of combustion. Arc melting probably would not be desirable because of the possible contamination of the melt by the electrodes.

SELECTION AND PREPARATION OF MELTING STOCK

Beryllium metal stock available for melting in the experimental work has ranged in purity from about 89 pct beryllium up to about 97 pct beryllium. The balance of this material has been, for the most part, fluoride flux remaining in the material from the refining operation. Very often it has also contained about 0.2 pct aluminum and up

to 1 pct magnesium. Melting this material by the open-pot method markedly reduces the content of fluoride and magnesium.

In order to prepare 1- to 2-lb charges for the experimental melts, the as-received beryllium is melted in large-scale heats weighing about 85 lb and is cast into 2-in.-diam bars. This melting is conducted in an open pot, using a Tercod-lined induction furnace with a stream of argon directed against the melt surface. The melt is poured in air into graphite molds, 4 bars per mold, using the Durville principle of pouring. Fig 3 shows the mold and apparatus used to prepare the 2-in. bars, the furnace being in a tilted position. The 2-in.-diam bars are cut to lengths weighing about 1.3 lb each. Such a bar makes an ideal material for melting stock in the experimental work because of its uniformity from piece to piece and its uniform surface area. Furthermore, during melting, the solid piece melts down uniformly with no opportunity for bridging which often occurs when lump materials are melted in the small, experimental induction furnace.

It is desirable that the beryllium melting stock, for large or small heats, be as clean as possible and dross should be removed by grinding the surface. The chances of obtaining an unsound

heat are greatly minimized by drying the stock thoroughly before melting it. This drying operation can be effectively carried out by holding the material at a temperature of 500 to 800°F for about 12 hr before melting. Naturally, the chance for gas absorption from the surface of the beryllium melting stock is minimized by using pieces as large as practicable.

MELTING TECHNIQUES

Because of the severe chemical reactivity of beryllium, it must be protected from reaction with oxygen and nitrogen during melting. Melting beryllium under a fluoride flux prevents drossing and, in a number of instances, successful castings have been poured by this method. On the other hand, the flux melting method is difficult to use because, during this type of melting, copious fumes evolve from the flux and these fluoride fumes are very toxic. A second disadvantage of this melting method is that the flux is very hygroscopic and, unless it is melted separately and added to the molten beryllium metal, a large quantity of hydrogen may be absorbed from the moisture in the flux. The flux is denser than the molten beryllium and, while it crusts over and is thus mechanically held on

FIG 4—Photograph showing a series of beryllium castings having a considerable range in unsoundness, made in the gas-controlled-atmosphere induction furnace.

FIG 5—Series of ingots showing the relationship of gas unsoundness to the humidity of the ambient atmosphere.

top of the melt, portions of the flux invariably sink and become entrapped in the metal during the pouring operation. This entrapment of flux occasionally results in flux inclusions in the castings.

Melting under a hydrogen atmosphere has been reported in accounts on the German beryllium industry. This method has not been tried, but melting under an inert atmosphere appears to be, by far, the most practical method for melting beryllium. Inert atmospheres of the argon or helium type are satisfactory. Argon has the advantage that, being denser than air, it forms a better blanket over the surface of the melt than helium which is lighter than air and has a greater tendency to rise. Attempts have been made to use dry nitrogen, but large quantities of beryllium nitride are formed which make this gas undesirable.

Investigations of the gas unsoundness in beryllium castings poured from melts prepared in the small, experimental gas-atmosphere induction furnace have shown that a high degree of purity and of dryness of the protective gas is necessary if sound castings are to be produced. In order to produce argon of high purity for the melting unit, the gas is passed first through copper

turnings at 1200°F to remove the bulk of the oxygen present, then through a copper coil which can be refrigerated to a temperature of minus 100°F to remove most of the moisture and, finally, through titanium turnings at 1200°F to remove nitrogen and the last traces of oxygen and water vapor.

Fig 4 illustrates the range of unsoundness which can be obtained in beryllium. Microporosity, such as occurs in copper-base alloys, was not a contributing factor to the unsoundness.

The effect of the moisture content in the argon atmosphere on the soundness of beryllium castings made in the small-scale experimental furnace is shown by Fig 5. For this particular series, it is believed that the other variables were held at values which, excepting for the humidity of the ambient atmosphere, are conducive to a high degree of soundness. The transition from sound to unsound beryllium castings appears to have occurred at a moisture level of about 3 grains per cubic foot. Other series made under similar conditions have indicated that the transition level is considerably lower. In one instance, it appeared to be at about 1.0 grain per cubic foot.

In general, the longer the time that a melt of beryllium is held in the molten

state, the more unsound the resultant ingot will be. The effect of increasing the holding time of beryllium melts at the pouring temperature in the gas-atmosphere induction furnace from 4 to 30 min. before pouring is shown in Fig 6. The humidity of the ambient argon atmosphere used for the heats from which these two ingots were poured was less than 1 grain of moisture per cubic foot. The graphite mold was held at a temperature of 300°F and a pouring temperature of 2800°F was employed. This increase in gas unsoundness produced by a prolonged holding at the pouring temperature is typical of some other metals also.

The effect of the length of the holding period at pouring temperature on gas unsoundness should not be confused with the length of time required to melt the metal. The effect of the speed with which the metal is melted and then brought to the pouring temperature has not yet been investigated. Since the rapid melting of beryllium may tend to increase gas unsoundness, it should be emphasized that Fig 6 shows the effect of holding at the pouring temperature. In other words, it is known that, once the metal has reached the pouring temperature, it should be poured without further holding. It does not necessarily follow, however, that the metal should be melted as rapidly as possible. Indeed there is some evidence that slow melting is desirable.

The typical effects of the pouring temperature on the gas unsoundness of beryllium castings are shown in Fig 7. All of these ingots were poured in a graphite mold at 300°F. The heats were made in an argon atmosphere at less than 1 grain of moisture per cubic foot. The tendency to increase gas unsoundness as the casting temperature increases is typical of most metals.

Fig 8 shows a typical example of the occurrence of unsoundness in a casting made from the first melt in a beryllia crucible preheated to 3300°F before using.

MELTING POINT DETERMINATION

The melting point of beryllium, as reported in *Metals Handbook*, is 1285 $\pm 40^\circ\text{C}$ (2345 $\pm 70^\circ\text{F}$). In the course of the melting of beryllium in the controlled-atmosphere furnace, one melt was allowed to freeze in the crucible and the cooling rate determined by a calibrated platinum, platinum-rhodium thermocouple protected by a beryllium oxide tube. The resultant curve, which is shown in Fig 9, shows a

FIG 6—The effect of holding time on the occurrence of gas unsoundness in beryllium.

Pouring temperature 2800°F, mold temperature 300°F.
 A-77. Melt poured as soon as the pouring temperature was reached.
 A-78. Melt held 30 min. at the pouring temperature before pouring.

melting point of 2400°F after some supercooling. This value is near the high limit previously reported. A melt-

ing point taken as the maximum temperature after supercooling can be considered only a minimum possibility

FIG 7—The effect of pouring temperature on the occurrence of gas unsoundness in beryllium.

A-66, held 16 min., poured at 2700°F, mold temp. 300°F. A-67, held 16 min., poured at 2800°F, mold temp. 300°F. A-68, held 12 min., poured at 2900°F, mold temp. 300°F. A-71, held 18 min., poured at 3000°F, mold temp. 300°F.

since it cannot be assured that the maximum temperature after supercooling is anything more than a balance between the heat released on freezing and the heat loss by natural cooling. Thus a value of 2400 + 20–10°F seems to be the melting point as determined in this test. The metal was remelted virgin beryllium. By spectrographic analysis it contained 0.10 pct Al, 0.08 pct Si, 0.10 pct Fe, < 0.05 pct Mg, and only traces of other impurities. Carbon was low, as judged by metallographic examination, but no estimate of oxygen content is available.

CASTING PRACTICE

Beryllium static castings can be produced with a minimum of difficulty from gas unsoundness and oxide and dross inclusions if they are poured directly from the furnace using the Durville method, as illustrated by Fig 1, 3, and 10. Ladling of the metal is obviously undesirable because it increases the contact of the metal with the atmosphere, makes higher melt temperatures necessary, and also increases turbulence and attendant included dross. Furthermore, ladles are often a source of gas pickup through unsatisfactory drying. In order to reduce the formation of dross, it is desirable that the molten metal be introduced into the mold with a minimum of turbulence. This can be accomplished by permitting it to run down a slight incline into the mold cavity. Although a mold can be tilted by hand to accomplish this end, the best practice is to design the mold for attachment directly to the furnace so that it tilts or can be separately tilted as the furnace is tilted. Fig 3 and 10 illustrate this technique showing the mold and method of pouring 2-in.-diam ingots and a slab about 2 in. thick and 18 in. square. The ingot mold is tilted by hand, using the special tilting mechanism, thereby permitting several to be poured from the same melt, whereas the slab mold is attached to the furnace and tilts with it, thereby permitting the pouring of one casting per melt. The metal is poured so that it runs down the slightly sloping surface of the riser and, as the furnace is tipped over, the mold is filled without causing undue turbulence. In both instances, the melt is poured direct from the furnace into the inclined mold. The end bells of the ball mill, shown by Fig 11, also illustrate castings made by this method. The end plates are sound, the dark spots being the individual coarse grain

revealed by the machining operation.

Centrifugal casting is an ideal method for producing beryllium castings when the size and shape of the casting are suitable. In order to pour a large-diameter casting, ladling metal is often necessary, though direct pouring should always be used if possible. The nature of the centrifugal casting process is such that it tends to reduce or minimize the difficulties with dross formation and gas unsoundness. A rapid pour into the mold is desirable to prevent cold shuts and to minimize the distance of travel of the metal. In the large-diameter castings, it is also desirable to pour the metal into the mold as near as possible to the periphery.

In order to cast an inside vertical wall centrifugally, it is necessary to use a rotating speed that gives a value of centrifugal force at the inside wall of the casting of at least 75 times the force of gravity. Thus the minimum speed of rotation is fixed and is dependent upon the casting diameter. Most of the centrifugal castings have been cast at this speed because it was feared that too high a speed might promote cracking. However, speeds somewhat higher than the minimum showed no harmful effects.

Some of the castings made successfully by centrifugal methods are as follows:

1. A cylinder 2¼-in. od, ¾-in. wall, 30 in. long, cast horizontally.
2. A ring 19-in. od, 1-in. wall, 5 in. high, cast vertically.
3. A ring 19-in. od, 7½-in. wall, 5 in. high, cast vertically, using a water-cooled steel mold. This casting after cutting and some machining of the inside surface is shown by Fig 12. The shrinkage on the inside periphery is to be noted.
4. A ring 52-in. od, 2-in. wall, 4 in. high, cast vertically. Fig 13 shows this casting as stripped from the mold.
5. A ball mill 9-in. od, 1½-in. wall, 8 in. long, cast vertically. This casting is illustrated by Fig 11.

A sound, fine-grained molded graphite makes an ideal mold material. It can be used successfully both in static and centrifugal casting. Although successful castings have been made in steel molds coated with acetylene soot, beryllia, or alumina, there is a tendency for beryllium metal to cut steel and, in general, the use of this material is not recommended. Baked, oil-bonded magnesite and zircon-base molds have been used, but the effects of these materials on gas unsoundness are not completely

FIG 8—The effect of the use of melting crucible on the occurrence of gas unsoundness in beryllium.

Both castings poured at 2800°F, using a mold temperature of 300°F. A-76, first heat in the crucible, namely, a wash heat. A-77, second heat in the crucible.

understood and they should be used with caution.

The extreme tendency for beryllium to hot crack must be guarded against when designing the casting. To accomplish this, the molds must be designed in such a way that the casting is not restricted during its solidification or cooling period. The development of a collapsible mold material for this metal

would be very desirable. Meanwhile, small, moderately intricate castings can be made by opening the graphite mold immediately after the casting is solidified so that the metal is subjected to a minimum of restriction as it cools.

All molds should be thoroughly dried before use. A desirable practice is to hold the graphite mold at 1000°F for about 1 hr and then cool it to not lower

FIG 9—Cooling and solidification curve, Heat No. A-14.

FIG 10—Photograph showing the graphite mold attached to the large induction furnace.

The mold is for a plate 18 inches \times 18 inches \times 2 inches, which is poured by the Durville method.

FIG 11—Photograph showing a cylindrical casting and end plates to form a small ball mill approximately 8 in. od.

than 300°F for use. In some instances, where a sufficiently large high-temperature furnace was not available, the molds were preheated to only 600°F and held for 16 hr. Graphite molds should not be allowed to cool below 300°F until all of the castings to be poured into them have been produced. If the mold is held for any length of time at room temperature, it should be reheated to 1000°F (or lower, if the higher temperature is not practicable) before subsequent use.

In the study of graphite as a mold material, it has been observed that the tendency toward gas unsoundness in the casting increases with repeated use of the mold. The reason for this behavior of the graphite is not definitely known, but to insure against the possi-

bility that the re-use of the graphite mold becomes a variable in the experimental studies, no mold is used for more than ten casting operations.

Discussion of Results

Since the experience with the founding of beryllium has not been extensive, it is difficult to evaluate the limitations of the art and science of producing high-quality castings. In this investigation, some consideration has been given to practically all of the founding characteristics of beryllium, and special attention has been given to that problem which has appeared to be the most troublesome, namely, gas unsoundness. The seriousness of the gas unsoundness problem in casting

beryllium can be appreciated by observing the range of unsoundness which may be encountered, as shown in Fig 4.

The unsoundness observed in Fig 4 is clearly caused by an evolution of gas during solidification of the metal. The precise type of gas evolution or the particular gas or gases involved is not definitely known. In general, there are two types of gas evolution, as follows: 1. Gas evolved during solidification of the metal because of the very marked decrease in solubility of the gas as the metal changes from liquid to solid. 2. The formation of a relatively insoluble gas by a reaction which occurs between two constituents dissolved in the melt. A typical example of such a phenomenon is the carbon monoxide gas evolved

FIG 12—Photograph showing a centrifugal casting 19 in. od, a 7½-in. wall, and 5 in. high.

The casting is shown after it was sawed and some machining done on the inside surface. The shrinkage on the inside periphery is evident.

in a rimming steel ingot as a result of the reaction between dissolved carbon and oxygen. A second example is the formation of steam in copper-base alloys as the result of a reaction between hydrogen and oxygen, or an oxide dissolved in the melt. In both of these instances the gases formed, as a result of the reactions, are relatively insoluble in the solidifying metal and thus precipitate or evolve from the melt.

There are many possibilities of these two types of gas evolution which might occur in beryllium. Hydrogen, carbon monoxide, carbon dioxide, nitrogen, and possibly other gases might evolve from the melt during solidification as Type 1 gas evolution. Type 2 gas evolution could occur as a result of the reaction of hydrogen and oxygen or oxide in the melt to form steam, or the reaction of carbon or carbon monoxide with oxygen or oxide in the melt to form either carbon monoxide or carbon dioxide. If oxygen or beryllium oxide is as insoluble in molten beryllium as is oxygen or the respective oxide in the light alloys, aluminum and magnesium, Type 2 gas evolution may not occur. There have been a few instances in the experimental work where unsound ingots have shown an increased carbon monoxide content. The samples for these tests were selected to include whole gas bubbles, so that evolved as well as dissolved gases would be determined in the vacuum-fusion analyses.

Except for a few instances where carbon monoxide has been found in the unsound ingots, practically all of the gas unsoundness observed in beryllium can be explained by the supposition that hydrogen dissolved in the melt evolves during solidification as a re-

sult of decreased solubility. The principal source of hydrogen is, of course, moisture. Experimental proof of the effect of the moisture content in the argon atmosphere on the soundness of beryllium castings made in a small-scale experimental furnace is shown in Fig 5. In addition to this experimental proof of the effect of moisture, there are many indications or circumstantial evidence which place hydrogen, absorbed from moisture, at the head of the list as the main cause of gas unsoundness in beryllium. These are: 1. The necessity for melting a wash heat in a crucible before consistently sound castings can be obtained from it. 2. The necessity, when using the flux method, to melt the flux before it is added to the metal. If the flux is not melted, a considerable amount of hydrogen may be absorbed from the water in the flux. 3. The necessity for drying molds thoroughly before sound beryllium castings are made in them. 4. Melting a charge previously wet with water has produced gas unsoundness in an application where such unsoundness was desired.

In addition, there have been many other indications which have shown that moisture should not be allowed to contaminate any of the tools used in the melting process which are likely to come into contact with the molten beryllium.

Summary and Conclusions

The success with which beryllium castings can be made in the plant or laboratory depends, to a great measure, upon how well certain difficulties attendant to the handling of this metal

are overcome. These difficulties, not peculiar to beryllium alone but encountered in the handling of many commercial metals, include a high degree of reactivity with oxygen and nitrogen; this characteristic is accentuated by the high pouring temperatures of 2600–2900°F and results in the formation of dross which, if carried over to the mold, can produce serious casting defects. Another characteristic of the metal is that it is very weak and brittle at high temperatures and, therefore, tends to crack easily when hot. Its low ductility when cold can also result in cracks if the normal contraction of the casting is restrained during cooling. Finally, and perhaps the greatest difficulty encountered has been unsoundness resulting from gas evolution during solidification.

Another characteristic of the metal which must be carefully considered is the apparently extreme toxicity of the fumes evolved during melting and of the dust formed during machining, grinding, sawing, and other procedures.

The problem of gas absorption has been studied by the use of a small, controlled gas-atmosphere induction furnace. It has been found that if reasonable care is taken to prevent the exposure of beryllium to moisture during the melting and casting operations, consistently sound castings can be produced.

The reason for the occurrence of unsoundness is not completely understood but it is apparent from the experimental work that hydrogen picked up from moisture accounts for a major part of the gas which causes the unsoundness.

The results of the present investigation have added considerably to the

FIG 13—Photograph of a cylindrical casting 52 in. od, with a 2-in. wall, 4 in. high.
This casting is shown as stripped from the mold.

knowledge relating to the proper handling of beryllium in the foundry. Techniques have now been developed which will permit the production of consistently sound beryllium castings from heats weighing up to 80 lb and limited in size only by the melting equipment available for this particular operation.

The following recommendations for the melting and casting of beryllium are based upon observations made in the course of the experimental work, including the preparation of heats weighing up to 80 lb:

1. Melts may be made in thoroughly preheated beryllia or graphite-bonded, silicon carbide crucibles (Tercod). Usually, a wash heat is desirable in a new crucible to insure complete removal of moisture. High-frequency induction heating is the most convenient.

2. The beryllium melting charge should be thoroughly dried out at a temperature between 500 and 800°F. Thereafter, in the melting process, the metal should not be subjected to any atmosphere or material which might be a source of moisture, or gas, particularly hydrogen.

3. No fluxes need be employed, but the metal should be protected from the atmosphere by means of argon of the lowest possible moisture content. This can be accomplished by covering the melting crucible and introducing argon at right angles to the melt surface so that it mushrooms out over the bath. The argon can be satisfactorily dried

by passing it through a coiled copper tube held at about minus 100°F.

4. The time that the metal is kept in the molten condition, especially at the pouring temperature, should be held to a minimum, and the casting should be poured as soon as the proper melt temperature has been reached.

5. The maximum temperature should be kept low, preferably less than 2900°F, and the pouring temperature should also be kept at a minimum, consistent with the degree of fluidity necessary to fill the mold cavity completely without cold shuts or misruns.

6. Where possible, the casting should be poured directly from the furnace in order to carry out effectively these recommendations. Ladling, while not desirable, may be useful when pouring centrifugal castings.

7. The mold material should be such that the metal will not react with it. Thoroughly preheated graphite which has not been used for more than ten casting operations appears to be satisfactory, though there are considerable differences among various grades of graphite.

8. Dross entrapment should be avoided. It has been found that this can be accomplished most effectively by introducing the metal into the mold gently by permitting the molten metal to run down a low incline into the cavity, using the Durville method or a modification of it.

9. Any undue restriction to the contraction of the hot casting, such as a fin

which would result in cracking, should be prevented by proper design of the mold cavity. As far as is known to date, this means that it is feasible to cast only relatively simple shapes which do not present problems of restriction to contraction. However, the precise limitation on complexity of design has not been established. The development of collapsible molds for beryllium casting is a definite possibility.

10. Beryllium castings having fairly thin sections can be made in a graphite mold if the surface areas are relatively small. The remarkable flowability of beryllium in graphite molds and the reproduction of minute detail in the mold design should not be overlooked.

11. The size of the castings, including the gates and risers, is limited only by the size of the available melting equipment. At the present time at Battelle, the maximum is about 80 lb of beryllium.

12. Within the limitations outlined, both static and centrifugal castings can be satisfactorily made.

Metallographic Examination of Beryllium Alloys*

M. C. UDY,† G. K. MANNING,† and L. W. EASTWOOD,† Members AIME

Introduction

Those who have examined beryllium and beryllium-rich alloys under the microscope have noted the results of the difficulties encountered when preparing these materials for examination. Hard constituents are readily chipped and pulled out of the matrix, and the soft ones are easily gouged out or embedded with abrasive or other material. The matrix is easily deformed, which makes it very difficult to remove the effects of scratches. Furthermore, the matrix and some of the constituents are also readily pitted during etching, which makes the structure difficult to develop.

The metallographic techniques designed to avoid these difficulties are neither radically new nor necessarily the best possible procedures. They were developed at Battelle to fill immediate requirements as part of a study of the preparation and pouring of beryllium melts as described in a separate paper.

A part of the research program on the causes of gas unsoundness in beryllium castings entailed a study of the effects of such gases or gas formers as oxygen or oxides, nitrogen or nitrides, and carbon or carbides. These gases or gas formers, if dissolved in the melt, might be an important factor in the study of unsoundness caused by gas evolution in beryllium. Because it was necessary to be able to distinguish these gases or gas formers, if present as alloy constituents, from metallic phases also present as alloy constituents, a series of alloys was prepared with additions of the various possible metallic and non-metallic constituent formers. It should be emphasized that the constituents

referred to as gases or gas formers are important in the study of gases in beryllium only if they form a part of the alloy, that is, if they dissolve in the liquid or solid metal.

During the first part of the development of metallographic techniques, the Massachusetts Institute of Technology, unpublished report (TC 3315, Nov., 1945) by Paul Gordon, describing various microconstituents in beryllium, was quite useful. Of particular interest in this report is the confirmation of one of the conclusions drawn from the present investigation, that is, that a distinct oxide phase apparently does not occur in beryllium.

The Preparation of Metallographic Specimens

GRINDING PROCEDURE

The original specimen is either sawed or cut on an abrasive wheel to a convenient size. For best results, the surface to be polished should not be more than about $\frac{1}{4}$ in. square, and it is convenient to mount the specimens in bakelite to facilitate handling. Two alternative grinding procedures have been developed. As one alternative, specimens are ground successively on

120-, 240-, and 400-grit, wet-or-dry metallographic discs. The abrasive discs are revolved at 1750 rpm on a conventional pedestal grinder. The coarsest disc (120 grit) is used either wet or dry, and in most instances, it can be eliminated from the procedure. Grinding on the two finer discs (240 and 400 grit) is accompanied by the application of kerosene. The technique consists of holding an oil can, containing kerosene, in one hand and the mounted specimen in the other hand. While the grinding is being done, several drops of kerosene are applied every few seconds close to the center of the disc. Carbon tetrachloride serves at least as well as kerosene as a lubricant; perhaps it is slightly better, but it volatilizes so readily that an additional health hazard is involved. Light oils and water are not satisfactory for the finer grinding operations.

The second procedure is perhaps slightly slower than the first and requires a more careful technique, but it eliminates the use of kerosene. The specimen is first ground wet on a 240-grit disc, followed by dry grinding on a 400-grit disc.

Finer grinding does not appear to be necessary with either of the two alternative procedures.

The pressures used throughout either grinding operation must be *extremely* light, that is, barely sufficient to hold the specimen in contact with the disc; otherwise, flow and chipping are almost certain to occur.

In both procedures, it is essential that the discs be sharp and that they be discarded as they show evidence of becoming dull or loaded. In general, not more than four or five specimens can be ground on a disc before the disc becomes dull enough to warrant discarding it.

Hand grinding of the beryllium alloys has not been successful, even though the grinding is done under kerosene.

The preparation of the specimen may be considered more than half done when a satisfactory fine grind has been obtained. The specimen should be examined at 500 magnification in the ground condition before starting the polishing operation. After some experience, the operator will be able to judge whether or not the grinding has been accomplished without either deforming the surface of the beryllium matrix or breaking out the hard, brittle constituents. If there is evidence that some constituents have been broken out or if there is evidence of flow in the beryllium matrix, it is well to start over again because it is a waste of time to attempt to polish an improperly ground specimen.

POLISHING PROCEDURE

After a proper grind has been obtained on a specimen, the final polishing can be accomplished in a few minutes. Two successful procedures have been developed. With either method, the specimen is slowly counter-rotated on a 4-in. polishing head rotating at 1750 rpm.

The first method is more rapid but

less reproducible. The polishing head is covered with worsted serge because the use of longer nap cloths seems to promote pitting and should be avoided. A solution of 5 pct oxalic acid in water is used in conjunction with an abrasive on the polishing cloth. This is an improvement over a more complicated, glycerine-containing solution which was used earlier and which seemed, in some cases, to promote pitting of the specimen. Fine alumina is used sparingly as the abrasive. However, when soft constituents occur, such as those formed by aluminum or tin additions, levigated CP-Fe₂O₃ is better though slower than alumina. When alumina is used as the abrasive, there seems to be a greater tendency for soft constituents to be gouged out. Actual polishing of the specimens apparently requires a proper balance between chemical solution by the oxalic acid on the one hand, with the abrasive action by the alumina on the other. This procedure requires rather careful manual manipulation which can be effected only after considerable practice.

The polishing procedure consists of applying a small amount of abrasive and oxalic acid solution at the beginning of the operation and, as the polishing continues, adding only the oxalic acid solution. As the polishing operation nears completion, the addi-

tion of the oxalic acid solution is discontinued and water is added a few drops at a time to keep the wheel slightly moist.

The alternate polishing procedure, slower than the one already described is based on abrasive action alone, and requires less judgment on the part of the operator. It was developed primarily to retain magnesium-rich constituents during the polishing operation. The small-diameter, high-speed wheel is covered with ordinary green billiard cloth, the usefulness of which appears to improve with use. Merck's CP heavy MgO, suspended in 30 pct hydrogen peroxide, is used as the polishing agent. Since this suspension does not "keep" well, it is best to prepare small amounts several times daily. During the polishing operation, a considerable amount of the suspension is used on the wheel, so that, actually, the polishing is done on a layer of MgO rather than on the cloth. The peroxide has two functions. It holds the MgO on the cloth more satisfactorily than does water, and it also appears to inhibit the reaction of water with some of the microconstituents of beryllium, particularly the magnesium-rich phase. Even with this "slower" procedure, polishing can usually be completed within a few minutes.

ETCHING PROCEDURE

No systematic study of etching reagents has been made. However, a number of the common metallographic etchants were tried and, of these, only one appeared to be universally successful on the alloys. This etchant is composed of 10 cc of 48 pct hydrofluoric acid and 90 cc of 190-proof ethyl alcohol. Etching times range from 10 to 30 sec. This etchant outlines and produces many color distinctions to the different alloy phases, and not infrequently develops fine lines in the beryllium matrix which appear to be faults in the lattice structure. The etchant seems to increase in activity after standing for several hours. In general, the other etchants which have been investigated have been found to cause some pitting of the polished surface.

Identification of Constituents

A number of alloys were made especially for metallographic study. In addition, a number of specimens have been

included from heats made for other purposes.

Black and white micrographs are included in this paper, and in addition, color transparencies have been prepared of a number of the microstructures. This color photography is of great assistance in preserving and describing the colors of the various constituents. Ansco daylight film was used with a light source consisting of a 6-volt, 18-amp microilluminator, containing a 3200°K ribbon filament. Various combinations of color-correction filters were necessary because of the different reflectivities of the different constituents and, in general, it was difficult to avoid a greenish cast to the background.

No microconstituent has been found which can be identified as an oxide or as a hydride. This, however, does not preclude the possible presence of oxygen (or an oxide) or hydrogen (or a hydride) in liquid or solid solution in the metal, or even as a second phase in the solid metal.

The carbide is a distinctive phase; it is hard, angular, usually gray, and when exposed to the atmosphere, it readily stains, first to all colors of the rainbow and, eventually, to brown.

Fig 1 and 2 are specimens containing a high proportion of carbide, which is the prominent, angular gray constituent. The shadowy, lighter gray phase seen in the background, particularly of Fig 2, is unidentified, but it is probably a silicon-bearing phase. The hydrofluoric etch has no effect on the color of the carbide constituent.

Fig 3 and 4 are specimens from heats to which 1 and 2 pct carbon, respectively, were added as graphite. The angular, gray carbide constituent is easily recognizable. The lighter gray constituent (actually a light blue-gray) is a silicon-rich phase, while the bright speckled phase (actually slightly yellow) is an aluminum-rich phase. Fig 3 and 4 should be compared with

Fig 1, a high-carbon specimen, and Fig 5, a vacuum-cast material which, in this instance, contains a small amount of carbon in the form of a small quantity of angular, gray carbides. Very little of the light blue silicon-rich phase is present, but with a relatively greater amount of the yellow speckled aluminum-rich phase. It is of interest that the silicon-rich

FIG 8 (below)—Heat A-2. Isolated nitride needle.

× 500. Reduced one-half in reproduction.

and the aluminum-rich phases can exist in the same "particle" as shown just below the center of Fig 5.

Fig 6 is a photograph of a poorly prepared specimen in which the cold-worked material was not completely removed by the polishing operation. It is of interest, however, that deep etching reveals the individual grains and also delineates the grain boundaries. This treatment is unsatisfactory as a means of revealing "second" phases, however, because the aluminum-rich, silicon-rich, and carbide phases are scarcely recognizable in the figure.

The nitride phase is distinctive. It is also gray, but a darker gray than the carbide, is not affected by the HF etchant, and is usually present in needle-like form. However, in large amounts, it may also have a more massive appearance. Fig 7 is a photograph of a specimen cast from a heat melted under nitrogen and represents a badly segregated part of the ingot. An angular, gray carbide particle is also evident somewhat to the right of the center of the photograph, but other phases are not readily identifiable.

Fig 8 is a photograph of an isolated nitride needle in a portion of the same ingot represented by Fig 7. Associated with the needle are the angular carbide phase, the speckled yellow

aluminum-rich phase, and the bluish silicon-rich phase. This latter phase is barely visible in the photograph. Again, the silicon-rich phase and the aluminum-rich phase are seen to occupy the same "particle," about halfway along the top side of the needle. The aluminum-rich phase is also present as an "inclusion" in the nitride and carbide phases. The black areas are holes and a crack is also evident across the lower right-hand corner of the photograph.

One phase found in practically all samples of beryllium studied is an aluminum-rich phase. It has already been noted in the descriptions of the preceding photographs. It is soft and difficult to polish; it is bright yellow and often appears to be speckled. This speckled appearance, revealed by careful polishing, may indicate a eutectic. The HF etch does not affect the color, but does outline the phase which may be present as a grain-boundary constituent or as isolated globules, as shown by Fig 9, a photograph of a 2 pct aluminum alloy. As mentioned before, a light-blue silicon-rich phase is often associated with the bright-yellow aluminum-rich phase. This is noted again in Fig 9, where several areas in the otherwise yellow stringers are occupied by the light-blue phase. It is also possible that the speckled constituent may be the bright-blue, silicon-rich phase, or some other phase attributable to silicon. Only a few carbides are present in the specimen, represented by Fig 9, and they appear about equally abundant in the matrix and in the aluminum phase. In this instance, over-exposure has blackened their appearance considerably as well as darkened the matrix in the photograph.

Fig 10 is a photograph of a heat to which 10 pct silicon has been added. The light-blue phase attributable to silicon is seen in the grain boundaries and as isolated particles. The angular, gray carbide phase is easily recognized, as is the bright-yellow aluminum-rich phase which is associated to some extent with the silicon phase. The light-blue silicon phase is intermediate in hardness between the aluminum-rich phase and the matrix, and is outlined but not stained by the HF etch.

There are probably other phases associated with silicon; one of these is probably illustrated in Fig 11, which is a photograph of a heat that had reacted with a silicon carbide crucible. The triangular-shaped gray phase with a crack running through it is beryllium

carbide. The grain-boundary constituent is the light-blue phase previously attributed to silicon. Associated with it are small amounts of the bright-yellowish aluminum-rich phase. The dark, irregularly shaped constituent in the center of the photograph is a hard, dark blue-green constituent whose color is not affected by the HF etchant. It might be silicon carbide, although no positive identification has been made. It also occurs in heats which have had no contact with silicon carbide crucibles, but it always appears to be associated with silicon in some form.

Fig 12 shows a sample to which 10 pct titanium was added. The phase attributable to titanium is slightly pink and generally angular and its color is not affected by the HF etchant. Angular gray carbides are readily identified in the photograph. Aluminum- and silicon-rich phases, if present, have been "absorbed" in the titanium-rich phase. The fine black dots, which seem to be real, have not been identified.

Fig 13 shows a sample to which 10 pct calcium was added. Only two phases other than the matrix appear to be present. One is the angular gray phase previously identified as beryllium carbide, while the second is a light-yellow, generally angular phase present in fairly large amounts which can be

FIG 9 (above)—Heat 162. Unetched. 2 pct Al alloy.

FIG 10 (below)—Heat A-32. Lightly etched. 10 pct Si added.

attributed to the calcium addition.

When tin is added to beryllium, a two-liquid system is formed which causes a two-layer ingot. The heavy tin-rich liquid settles to the bottom and mechanically carries the beryllium carbide along with it. Fig 14 shows a segregated area just above the interface between the two metals. Globules of the tin-rich phase are in evidence, and associated with them are the familiar angular gray carbides. The tin phase is yellow and similar in appearance and polishing characteristics to the aluminum rich phase previously described. It is soft and difficult to polish, as evidenced by the smeary appearance in the photograph. The beryllium layer, away from the interface, is remarkably free of inclusions. The beryllium-rich phase in the tin layer is present as a finely dispersed eutectic resolved only at × 2000 magnification.

Fig 15 and 16 are photographs of a sample to which 10 pct iron was added. Fig 15 shows the sample unetched and the phase attributed to iron appears in the grain boundaries almost entirely and is barely distinguishable from the background. The familiar gray carbides are present in the matrix and only occasionally in the iron-rich material. Other phases, if present, have been "absorbed" in the iron-rich phase. The

HF etchant (Fig 16) colors the iron phase to a reddish brown, thus affording a method of distinguishing it from other similar-appearing phases.

Ten per cent manganese was added to the specimen shown in Fig 17. The phase attributable to manganese is very similar in appearance to the iron phase. It appears in the grain boundaries and is slightly more pink than the matrix. The beryllium carbide seems to prefer the grain-boundary location in this alloy. Unlike the iron phase, the manganese phase is not stained by HF but only outlined by it.

Fig 18 shows a specimen to which 6 pct boron was added. The phase attributable to boron appears in the grain boundaries and is colored red, but is stained blue or purple by the HF etchant. The familiar carbides are present, away from the grain boundaries. The yellow aluminum-rich phase also appears as a distinct constituent which, in some locations, is closely associated with the red boron phase.

An attempt was made to produce an oxide phase in beryllium by adding silica to a melt. An increase in the light-blue silicon-rich phase was noted as well as the appearance of small amounts of the dark blue-green phase which has also sometimes been associated with silicon. Any oxide formed,

however, either went into solution and remained there, or was insoluble and separated by gravity from the melt.

FIG 15 (above)—Heat A-36. Unetched. 10 pct Fe added.
FIG 16 (below)—Heat A-36. Etched. 10 pct Fe added.
× 500. Reduced one-half in reproduction.

FIG 17 (above)—Heat A-37. Etched. 10 pct Mn added.

FIG 18 (below)—Heat A-39. Unetched. 6 pct B added.

× 500. Reduced one-half in reproduction.

FIG 19 (above)—Heat A-46. Slightly etched. 5 pct Mo added.

FIG 20 (above)—5 pct U alloy. Slightly etched.

× 500. Reduced one-half in reproduction.

FIG 21 (above)—Melting stock containing 0.75-1.00 Mg. Unetched.

FIG 22 (below)—5 pct Zr alloy. Slightly etched.

× 500. Reduced one-half in reproduction.

Five per cent molybdenum was added to the specimen, represented by Fig 19. Until it is etched, the phase attributable to molybdenum, like the iron-rich phase, appears to be about the color of the matrix. It first stains, on etching, to a chocolate color and then to a black. Carbides were substantially absent in this specimen, but the yellow aluminum-rich phase appears in small amounts.

A 6 pct copper alloy showed no phase attributable to copper. This is indicative of rather high solid solubility of copper in beryllium.

In a 5 pct uranium alloy, the uranium-rich phase was not distinguishable from the matrix in the unetched condition. However, the etchant stained the uranium-rich dendritic phase to a series of colors ranging from yellow to green. A photograph of this etched specimen is shown in Fig 20. The dendritic structure is easily seen and only a few carbides, largely in the matrix, are in evidence.

Materials containing as low as 0.35 pct magnesium have been shown to contain a phase attributable to that

material. In some of the early work, this phase was overlooked because it is soft and difficult to maintain during grinding. In addition, it is somewhat reactive to water and may disappear during polishing. Fig 21 shows this phase, believed to be a magnesium-rich constituent, in a specimen containing about 0.75 pct magnesium. It is bright "water white," very soft as compared to the matrix, and readily removed by the HF etch, leaving pits.

Fig 22 shows an alloy to which 5 pct zirconium was added. The phase attributable to zirconium is dendritic in appearance and, until etched, is barely distinguishable from the matrix, but the alcoholic HF etch outlines the phase and stains it a light blue. Further etching has no effect on the color.

Summary

Reasonably satisfactory metallographic techniques have been developed for beryllium and beryllium-rich alloys.

The following phases have been identified:

1. Carbide
2. Nitride
3. Aluminum rich
4. Silicon rich
5. Calcium rich
6. Titanium rich
7. Tin rich
8. Iron rich
9. Manganese rich
10. Boron rich
11. Molybdenum rich
12. Uranium rich
13. Magnesium rich
14. Zirconium rich

No second phase attributable to copper could be found in a 6 pct copper alloy. No phase attributable to oxygen or hydrogen has been found, but this does not preclude their presence in liquid or solid solutions.

Introduction

This report describes the progress made in the research work on the development of a new method for preparing lower-cost titanium tetrachloride and preparing titanium oxide pigment.

One of the requirements for the commercial production of ductile titanium in the process used by the Bureau of Mines is a source of lower-cost titanium tetrachloride.

The production of ductile titanium by a modification of the Kroll¹ process, recently developed by the Bureau of Mines, requires such a source of lower-cost titanium tetrachloride to make it commercially feasible. This report describes the progress of work done at the Mississippi Valley Experiment Station at Rolla, Missouri, on the development of a new method for preparing titanium tetrachloride. During the course of this research a new method for preparing pigment-grade titanium oxide was developed.

At present, the price of technical-grade titanium tetrachloride is \$0.32 a pound, which makes the price of the contained titanium \$1.28 a pound.² In addition, the titanium tetrachloride must be purified further before it is suitable for processing into metal, thus making its cost still higher.³

¹ References are at the end of the paper.

There were 8,562 tons of rutile produced in the United States in 1947, which was 900 tons in excess of that consumed. In addition there were 13,937 tons in various stocks, exclusive of the stocks in the Government strategic stock pile.

No estimates of the domestic production of rutile are given for any of the prewar years. However, in 1939, 442 tons of rutile were imported as compared to 14,307 tons in 1947.

One of the reasons for the large increase in the production of rutile is the working of the Florida beach sands for ilmenite, during which a considerable amount of rutile is produced as a by-product.

It would be of value to determine methods for utilizing the excess production of rutile.

The Arkansas titanium deposits in Hot Spring County produced commercial-grade rutile concentrates from 1933 to 1942. These were sold mainly to England, Germany, and Russia.

* N.D. means not determined because of lack of sample.

The ore dressing of low-grade titanium ores containing approximately 4 pct TiO_2 to a high-grade concentrate of 92 to 95 pct TiO_2 places an unusual duty upon any ore-dressing plant. A high recovery of rutile under these conditions is sacrificed to produce a high-grade product. Examination of the tailings from any rutile mill of this type operating on mine-run ore in the United States will confirm this statement. One purpose of the laboratory work on the matte smelting of titanium is to be able to utilize lower-grade titanium concentrates and thereby directly facilitate the conservation of titanium minerals. There is no present commercial use of rutile concentrates containing less than 92 pct TiO_2 . All of the laboratory work at Rolla on the matte smelting of titanium has dealt with a concentrate containing only 85 pct TiO_2 . The ilmenite concentrates treated for matte smelting were of standard grade and of the following composition: 58.4 pct TiO_2 , 25.0 pct Fe, 0.37 pct P_2O_5 , 0.11 pct V_2O_5 . It is necessary to mention that, in the production of ilmenite concentrates, the same general statement holds true in that considerable losses of ilmenite occur in the attempt to produce high-grade ilmenite mineral concentrates. The recent introduction of flotation for the recovery of fine ilmenite and rutile values has been of considerable assistance in improving these recoveries. The presence of clay minerals, however, interferes with the recovery of fine titanium minerals in flotation the same as in gravity concentration.

Preparation of Titanium Tetrachloride

GENERAL

Titanium tetrachloride is commonly prepared by one of the following processes: (1) Chlorination of titanium cyanonitride, which product is pre-

pared from pigment-grade titanium dioxide or high-grade rutile concentrate in the electric arc furnace, (2) chlorination of pigment-grade titanium dioxide at 400 to 900°C, and (3) chlorination of ilmenite or rutile concentrates at 500 to 1100°C. Methods 1 and 2 suffer from the disadvantage of requiring a relatively expensive starting material; that is, pigment-grade titanium dioxide, which has recently been quoted at \$0.19 per $\frac{1}{2}$ lb or high-grade rutile concentrates which cost approximately \$0.07 per lb.⁴ Method 3 requires a comparatively high chlorination temperature.

Chlorine is an extremely active chemical reagent at elevated temperatures. None of the common metals or alloys is resistant to its action although certain acid-resisting refractory brick and graphite are not affected by chlorine at the reaction temperatures used. In laboratory tests made on the chlorination of ilmenite-carbon mixtures several types of graphite retorts, coated with the refractory cements available, were tried. All of the tests showed that graphite was unsatisfactory because of its porosity and because of its tendency to oxidize rapidly at temperatures above red heat. None of the coating materials adhered to the graphite tubes well enough to prevent them from being oxidized.

It is believed that it would be extremely advantageous to develop a process for producing titanium tetrachloride by chlorinating a titanium compound at a temperature less than 300°C. In perusing the literature it was found that one of the most likely compounds of titanium for this purpose was the sulphide. M. Picon⁵ stated that all of the sulphides of titanium were attacked by chlorine at 175°C, titanium chloride being volatilized.

Little previous work has been done on the preparation of titanium sulphides. Some of the methods used were as follows: (1) Reaction between ti-

tanium tetrachloride vapor and hydrogen sulphide at 480 to 540°C,⁶ (2) reaction between a mixture of titanium dioxide and graphite with dry hydrogen sulphide,⁷ (3) reaction between carbon disulphide and hot titanium oxide,⁸ and (4) reaction between mixtures of iron sulphide, titanium dioxide, and carbon.⁹

Of these methods (1) is obviously unsuitable since one of the starting materials is titanium tetrachloride. However, during the course of this research some pure titanium disulphide was made by this method in order to prepare a standard X ray diffraction pattern and to determine some of its fundamental characteristics. Of the remaining three methods, a variation of (4) appeared to be the most attractive.

PREPARATION OF TITANIUM MATTES

In January 1947 a study of the reactions between rutile, pyrite, and coke, and ilmenite, pyrite, and coke was started. In the preliminary tests 200-g samples, charged in a graphite crucible, were smelted in a 3 kv-amp. high-frequency induction furnace. All of the constituents were ground to minus 200-mesh. The purpose of this work was to produce a matte containing all of the titanium in the form of the sulphide, while the reduced iron was separated from the matte in a metallic button at the bottom of the crucible. This metal should be a useful by-product as molten feed to a bessemer converter.

To determine the proper conditions for recovering the maximum amount of the charged titanium in the matte and at the same time produce a desirable titanium sulphide product, the composition of the charges, the smelting temperature, and the time were varied.

In one series of experiments the composition of the charge was varied from 20 to 60 pct ilmenite and 30 to 70 pct pyrite, and the coke was held constant at 10 pct. The results of these experiments showed that, as the pyrite in the charge was increased, the percentage of titanium in the matte decreased and the percentage of iron increased. As the percentage of titanium in the matte increased, its solubility in 10 pct and concentrated sulphuric acid decreased. It is believed that this was caused by the formation of suboxides of titanium as the amount of pyrite in the charge was decreased.

In a typical run a 200-g charge, con-

sisting of 60 pct ilmenite, 30 pct pyrite and 10 pct coke, was charged into the small induction furnace, heated to approximately 1500°C, and smelted for 45 min. at this temperature. After the smelting period the charge was allowed to cool in the crucible and the matte separated from the metal. The result of this run is shown in Table 1.

The results of these experiments were not entirely conclusive because of the large losses by "dusting" that occurred during the charging of the small induction furnace and during the reaction period. However, in larger-scale work when rutile was smelted with pyrite and coke, recoveries exceeding 90 pct of the titanium in the charge were obtained in the mattes. These initial experiments showed that it was possible to prepare titanium mattes by smelting mixtures of ilmenite, pyrite and coke at approximately 1550°C.

Several small-scale experiments were made in which mixtures of rutile, pyrite, and coke were smelted in the small induction furnace to determine whether there was any difference in the behavior of rutile in the matte smelting reaction as compared to ilmenite. No marked difference was found between the two minerals. However, rutile gave a distinctly less violent reaction than ilmenite, and the fusion temperature of the various mixes was somewhat higher. The rutile used in these and all of the following tests was an 85-pct TiO₂ mill concentrate which did not meet the specifications of commercial-grade rutile.

Little work has been done on identification of the various matte constituents and a large number of these remain to be identified. It is believed that some of the reactions which occur are as follows:

X ray studies of the mattes are being

made to determine the various constituents present in order to increase our knowledge of the reactions which occur during matte smelting.

CHLORINATION OF TITANIUM MATTES

In order to prepare a sufficiently large sample of titanium matte for chlorination experiments, several samples of matte were prepared in the 35 kv-amp. high-frequency induction furnace. This larger induction furnace was similar to the one previously described, except that the inside diameter of the graphite crucible was 3¼ in. as compared to 1¼ in. for the smaller furnace, and 1,500-g charges were smelted as compared to the 150- and 200-g charges melted in the smaller furnace.

In most of the experiments the charge was smelted for one hour at an approximate temperature of 1550°C, allowed to cool, and the matte separated from the metal. The charge compositions and chemical analyses of four typical mattes are shown in Table 2.

Table 2 . . . Matte Samples Used in Chlorination Experiments

| Sample | Analysis, pct | | | | Composition of Charge, Pct |
|--------|---------------|------|------|-----|--|
| | Ti | Fe | S | C | |
| 1 | 44.6 | 9.4 | 19.7 | 2.2 | 55 pct rutile, 35 pct pyrite, and 10 pct coke. |
| 2 | 37.2 | 14.8 | 27.2 | 2.5 | 45 pct rutile, 45 pct pyrite, and 10 pct coke. |
| 3 | 31.6 | 22.8 | 31.2 | 3.7 | 35 pct rutile, 55 pct pyrite, and 10 pct coke. |
| 4 | 37.3 | 19.3 | 28.1 | 1.5 | 45 pct rutile, 45 pct pyrite, and 10 pct coke. |

After spending considerable time in devising suitable apparatus for carrying out the chlorination experiments, it was found that a stainless-steel retort containing 25 pct chromium and 12 pct nickel was most satisfactory. A collecting system was devised that consisted of a short length of 1½-in. stainless steel pipe welded to the retort which was in turn connected by means of a length of rubber tubing to a length of 1¼-in. glass tubing that extended into a 4-liter filter flask serving as a collecting vessel. The flask was connected in series to three 500-ml Erlenmeyer flasks, the first of which contained hydrochloric acid and the other two, water. The purpose of the first Erlenmeyer was to keep the system free of water vapor, and the other two were to remove the volatile titanium com-

pounds in the exit gas. The retort was heated by a tube furnace held in a vertical position. The charge was supported on a carbon plug drilled with ⅛-in. holes, which in turn was held in position by means of the chlorine inlet tube which was flared at its end. A 1½-in. pipe cap was screwed on the bottom of the retort to make the apparatus airtight, and the cap was drilled and tapped to permit the chlorine inlet tube to pass inside the retort.

In order to keep the charge, which was ground to minus 200-mesh, from falling through the carbon plug, it had to be mixed with a binder. In several of the earlier tests fuel oil was used as binder. However, it was later found that benzol was more suitable for the laboratory work as it volatilized at a lower temperature. In some of the earlier runs activated charcoal was mixed with the titanium matte in the charge; but, as it seemed to have little effect on the chlorination reaction, its use was discontinued.

The reaction time and temperature were varied considerably during the earlier experiments. Temperatures from room temperature to as high as 400°C and reaction periods from 1 to 4 hr were used. However, in later runs, a reaction temperature of 200 to 220°C and a reaction time of 4 hr were used. After chlorination, the residues were generally leached with water to remove any of the ferric chloride formed, so as to provide an analytical sample that was not hygroscopic.

The initial experiments showed that it was possible to recover 60 pct of the titanium in the mattes by chlorination, when the charge composition of the matte contained 45 pct or more pyrite. Additional tests were made to improve the titanium recovery from mattes containing 55 pct rutile, as it was obvious that it would be more economical to prepare a matte of higher titanium content. These later runs showed that recovery could be increased and are described later.

The product obtained by the chlorination of titanium mattes was a yellow, hygroscopic, crystalline solid which fumed when exposed to the atmosphere. During the course of the reaction an amber liquid was first recovered, which was converted to the yellow solid by further reaction. The chemical composition of this solid, as determined in some 5 or 6 dozen cases was as follows: Titanium 17-21 pct, sulphur 4-6 pct, chlorine 67-75 pct. It is believed that chlorination proceeded according to the

following reactions:

1. $\text{TiS}_2 + 2\text{Cl}_2 = \text{TiCl}_4 + 2\text{S}$
2. $2\text{S} + \text{Cl}_2 = 2\text{SCl}$
3. $\text{TiCl}_4 + 4\text{SCl} = \text{TiCl}_4\text{SCl}_4 + 3\text{S}$

The product obtained from the various chlorination reactions was identified as a mixture of titanium tetrachloride and titanium sulpho-octochloride ($\text{TiCl}_4\text{SCl}_4$). It is apparent that this product must be treated further to remove the sulphur.

REMOVAL OF SULPHUR FROM CRUDE TITANIUM CHLORIDE

Several methods were tried for purifying the material obtained by the chlorination of titanium matte. Simple distillation was unsuccessful because titanium tetrachloride and sulphur monochloride have boiling points that are within 0.8°C of each other. A number of inorganic materials, that have an affinity for sulphur, were added to the crude titanium chloride, and the mixture was heated until distillation occurred. Some of the reagents used were sodium carbonate, sodium hydroxide, lime, aluminum powder, iron powder, and titanium wire and powder. None was satisfactory as the sulphur content of the product varied from 0.23 to 3.00 pct.

At the suggestion of O. C. Ralston, chief of the Metallurgical Division, Bureau of Mines, fixed oils, such as cottonseed oil, and fatty acids such as palmitic acid, coconut oil fatty acid, and oleic acid were mixed with the impure titanium tetrachloride and heated slowly for a short time until distillation occurred. The use of such an oil was to provide a material that could be chlorinated by the sulphur chloride present thus splitting the sulphur from the chlorine and forming elemental sulphur, which has a considerably higher boiling point than titanium tetrachloride.

These fatty acids and oils were more successful than the inorganic reagents which had been used previously. In several runs titanium tetrachloride with a sulphur content of as low as 0.02 pct was produced. The optimum

amount of oil used was 4 pct of the weight of the crude titanium compound charged.

In a typical run in which the charge consisted of 50 g of impure titanium compound and 2 g of soya bean oil fatty acids, three distillates were obtained. The first distillate contained 1.74 pct sulphur and consisted of 9.9 pct of the titanium charged, the second contained 0.02 pct sulphur and consisted of 52.5 pct of the titanium charged, while the third contained 0.09 pct sulphur and consisted of 24.0 pct of the titanium charged. The residue contained 13.6 pct of the titanium charged. The distillates which were high in sulphur could be returned to the still for further treatment. It should also be possible to reduce the titanium losses in the residue so that it may be safely assumed that 90 pct or more of the titanium charged should be recovered.

Further work showed that it was possible to replace the fatty acids and oils with tall oil, a cheaper material obtained as a by-product in the manufacture of paper.

At present, nothing is known of the amount of sulphur that may be tolerated in the titanium tetrachloride used in the Kroll process. It may be possible to use a product that is less pure than has been previously described, which would naturally lower the operating cost and probably increase the titanium recovery.

USE OF SILICON IN MATTE SMELTING

All of the titanium mattes prepared thus far contained a certain amount of iron, probably in the form of suspended metallics and as iron sulphide. During chlorination a considerable amount of chlorine is used in producing ferric chloride, as iron is attacked before titanium. The commercial value of this byproduct has not been investigated. Several methods were tried to lower the iron content of the mattes. Various reagents, including sodium carbonate, lime, aluminum, copper, and electrolytic manganese were added to

samples of matte in the molten condition. All of these reagents were ineffective. During a conference with Dr. William J. Kroll of the Albany, Oregon, Branch of the Bureau of Mines it was suggested by him that silicon be tried as a desulphurizer. It was believed that the silicon might react with the iron sulphide in the matte removing the sulphur in the form of volatile silicon sulphide thus forming metallic iron which would be collected in the metallic button.

Various methods of adding silicon to the charge were tried. One of the most effective ones appeared to be to smelt the batch of rutile, pyrite, and coke in the usual manner, hold it at the reaction temperature for 30 min. to one hour, then add the metallic silicon, stir the batch as thoroughly as possible and hold it for an additional shorter period, usually 15 to 30 min. at the reaction temperature, 1500 to 1550°C .

Many mattes were prepared in which silicon was added to the charge. The amount of silicon added was 2 to 4 pct of the weight of the charge. In general, the iron contents of the finished mattes were lower than those of corresponding mattes in which silicon was not used. However, all of the mattes contained some silicon, ranging from 0.11 to 8.7 pct, depending on the quantity of silicon added and the method of mixing it with the matte. In some instances, when the silicon was not thoroughly stirred into the matte it collected on the surface in the form of a slag.

Several of the silicon-containing mattes were chlorinated. In general, the titanium recoveries were somewhat higher when silicon was added to the matte. In one case, a titanium recovery in excess of 90 pct was obtained from a matte with a charge composition of 55 pct rutile, 35 pct pyrite, and 10 pct coke, to which silicon amounting to 2 pct of the original charge was added. In several other runs in which all of the experimental conditions of the previous test were duplicated, it was not possible to obtain a titanium recovery in excess of 70 pct. Apparently, this reaction of silicon with titanium matte is very sensitive and difficult to control. The function of silicon in the matte smelting reaction has not been ascertained. However, in most cases, the bulk of the silicon was not volatilized and remained in the matte, slag, and metal. Some of the metals had a silicon content of nearly 10 pct. More experimental work is necessary to determine the function

Table 3 . . . Matte Smelting in the Globar Furnace

| Product | Weight, Pct | Analysis, Pct | | | Distribution of, Pct | | |

of metallic silicon when introduced into molten titanium mattes.

SMELTING IN THE GLOBAL FURNACE

It was noted in the early work that an induction furnace was not entirely satisfactory for preparing titanium mattes because of its uneven heating caused by the difference in conductance of the metallics and the matte, and because of the dusting losses which occurred when the furnace was charged. The experiments made in the induction furnace, however, gave an indication of the results that might be obtained in larger-scale work.

A series of experiments was made in a global furnace to approach more nearly the hearth-type furnace and determine its suitability for titanium matte smelting. The furnace used had a hearth that was 18 in. deep and 25 in. wide. The roof was arched, and it was 17½ in. high on each side and 18½ in. in the center. There was enough room to charge four crucibles. The samples were charged into deep graphite crucibles to make a better separation between metal, matte, and slag.

In all of the experiments the charge weights were varied from 2000 to 2400 g. In the initial runs the samples were charged at 1200°C, heated to 1550°C, and held at this temperature for one hour, the total furnacing time being 7 hr. In later runs the samples were charged at 1550°C and the total furnacing time was 4½ hr. In two of the runs in which silicon was added to the samples, the charge was held at 1550°C for one hour previous to the addition. After the silicon was added the charge was stirred and held at the reaction temperature for another 30 min. The total time the samples were in the furnace was 6 hr. In some of the experiments the samples were held at the reaction temperature for 30 min.

A typical run consisted of mixing a 2000-g charge containing 55 pct rutile, 35 pct pyrite, and 10 pct coke, charging into the global furnace at 1100°C and heating for a period of 30 min. at 1550°C. The analyses of the matte, metal, and slag formed are shown in Table 3.

All of the mattes produced in the global furnace were chlorinated under various experimental conditions. The reaction temperatures were varied from 200 to 300°C, while the time was held constant at 4 hr. The results of these experiments showed that in most cases the titanium recoveries obtained from

samples made in the global furnace were approximately the same as samples made in the induction furnace. The smelts made in the global furnace, to which silicon had been added, showed that a considerable amount of the silicon was in the slag. This was probably caused by the difficulty of stirring these samples while they were being heated.

In runs in which the reaction time was reduced from one hour to ½ hr the titanium recovery was somewhat lower. In several of the samples in which the rutile was increased to more than 60 pct of the weight of the charge, the titanium recovery was markedly reduced when the sample was chlorinated. The titanium recoveries obtained by the chlorination of several mattes made in the global furnace are shown in Table 4.

SMELTING IN THE ELECTRIC ARC FURNACE

In order to prepare larger samples of titanium matte than had been made previously and also to study the smelting of these mattes in an electric arc furnace, several charges were smelted in a 100 kv-amp. single phase series arc furnace which had a carbon hearth.

In one run a charge weighing 100 lb and consisting of 55 pct rutile, 35 pct pyrite, and 10 pct coke was smelted. When the charge became molten at 1550°C, 2 pct by weight of silicon was added. After the silicon was added, the bath was thoroughly rabbled, and then poured. The total time between charging and pouring was about 2 hr, and the current and voltage were 900 amp and 70 volts, respectively. The rutile charge seemed to be ideal for smelting in an arc furnace, and the electrode consumption was considered normal. The matte from the fusion contained 42.6 pct titanium, 24.3 pct sulphur, 10.9 pct iron, and 0.11 pct silicon.

A chlorination experiment made on a sample of this matte in which the initial temperature was 150°C, the reaction time 4 hr, and the average chlorine flow 204 cc per min., gave a titanium recovery of 81.3 pct and an iron recovery of 95.0 pct. This was approximately the same titanium recovery as obtained previously in smaller-scale runs made in the induction furnace in which metallic silicon was added to the matte.

Preparation of Titanium Oxide Pigments

GENERAL

During the past 20 years the use of titanium oxide pigments has increased tremendously. Since 1939 titanium dioxide has been utilized in greater quantity than any other white pigment.¹⁰ Production and sales of titanium pigments established new high records in 1947, but the capacity production rate was inadequate by a substantial margin to fill the peak and still growing demand for the product. Because of its superior pigment properties it is reasonable to expect that the demand for titanium dioxide will continue to be strong.

During 1947, 473,154 tons of ilmenite, estimated to contain 248,231 tons of titanium dioxide, were used for making pigments in the United States.¹¹ As far as is known, no rutile was used. The reasons for this are the difficulty of extracting pigment-grade titania from rutile and the present higher cost of rutile concentrates, as compared to ilmenite. If our reserves of ilmenite should become depleted, it may become necessary to use rutile or other titanium minerals as a source of pigment-grade titanium dioxide some time in the future. The use of lower-grade rutile concentrates should lower the cost of producing titanium dioxide

Table 4 . . . Chlorination of Titanium Mattes Made in the Global Furnace

| Sample | Analysis, Pct | | | | Charge Composition, Pct and Remarks | Recovery, Pct by Chlorination | |

| Composite..... | 43.50 pct | 17.80 pct | 100.0 | 100.0 |

from this mineral.

In the earlier work it was shown that titanium mattes made from ilmenite were soluble in 10 pct and concentrated sulphuric acid solutions. A study of the solubility of titanium mattes made from ilmenite and rutile was undertaken to determine whether the mattes would be suitable starting materials for the production of titanium oxide pigments.

LEACHING WITH AQUEOUS HYDROCHLORIC AND SULPHURIC ACID SOLUTIONS

The usual method of extracting titanium from ilmenite is by digestion with concentrated sulphuric acid solutions at 150 to 180°C. Accordingly, in the initial runs the mattes were leached with sulphuric acid solutions of various concentrations. The leaching times and temperatures were varied. In a typical run a 50-g sample of matte made by smelting a mixture of 49.4 pct rutile, 38.0 pct pyrite, and 12.6 pct coke in the 35 kv-amp. induction furnace for one hour at 1600°C and containing 43.0 pct titanium, 16.1 pct iron, 20.2 pct sulphur, and 4.8 pct carbon was leached with 143.6 g of 97 pct sulphuric acid solution for a period of 4 hr at 160 to 180°C. The mixture, which was then quite viscous, was allowed to cool and agitated for an additional ½ hr with 300 ml of water at 60 to 80°C, filtered, and washed with 200 ml of water. The results of this run are shown in Table 5.

The results of the leaching experiments with sulphuric acid solutions showed that recoveries of 25 to 75 pct of the titanium in the mattes could be obtained, dependent on the reaction conditions. Higher titanium recoveries were obtained when higher leaching temperatures and more concentrated sulphuric acid solutions were used. Increasing the amount of sulphuric acid above a 10 pct excess had no effect on titanium recovery. Increasing the leaching time to a period greater than 4 hr gave slightly higher titanium recoveries. In several cases titanium

mattes that were made from charges containing 35 pct or less rutile gave recoveries that were greater than 90 pct when leached with sulphuric acid solutions.

Several experiments were made in which hydrochloric acid solutions were used to leach some of the titanium mattes. Concentrations of 10 pct, 20.24 pct (constant boiling mixture), and 37 pct hydrochloric acid solutions were used. In no case was it possible to obtain a titanium recovery greater than 30 pct. This was considerably less than had been obtained with sulphuric acid solutions. It is believed that leaching with hydrochloric acid removed only the TiS and subsulphide contents of the mattes.

BAKING WITH SULPHURIC ACID

In the earlier experiments, it was found that, when the mattes were leached with sulphuric acid, increasing the temperature increased the titanium recovery. A series of experiments was made in which titanium mattes were baked with sulphuric acid at temperatures varying from 200 to 400°C. The amounts of sulphuric acid used, the reaction temperatures, and reaction times were varied. The general procedure was to mix the acid and matte, bake at the required temperature, allow to cool, leach with water, filter and wash the residue. The optimum experimental conditions were baking for 1 to 2 hr at a temperature of 200 to 250°C with a 100 pct stoichiometric excess of sulphuric acid. With these conditions it was possible to recover 90 to 95 pct of the titanium from

mattes of high titanium content (40–50 pct titanium). Baking these mattes with sulphuric acid increased the titanium recoveries from 15 to 25 pct as compared to similar experiments in which they were leached with aqueous sulphuric acid solutions. It is believed that the higher temperatures used in the baking experiments put the suboxides of titanium into solution.

In a typical run a 50-g sample of matte made from a batch consisting of 55 pct rutile, 35 pct pyrite and 10 pct coke, and containing 42.8 pct titanium, 9.2 pct iron, 20.2 pct sulphur, and 1.78 pct carbon was mixed with 205.5 g of concentrated sulphuric acid and heated for 2 hr at 225 to 250°C. The sample was allowed to cool, leached with 300 ml of water, filtered and the residue washed with 200 ml of water. The result of this run is shown in Table 6.

There are several advantages in treating titanium matte, as compared to ilmenite. For one, the quantity of iron in the matte is considerably lower than in ilmenite, thus reducing the amount of ferrous sulphate in the leach solution. The leach solutions obtained from high titanium mattes contained one-sixth to one-eighth the amount of iron as compared to similar solutions from ilmenite. This will simplify the purification process by reducing the amount of ferrous sulphate to be handled. Another advantage is the fact that the matte has a higher titanium content than ilmenite thus reducing the handling cost. Although considerable acid (100 pct stoichiometric excess) is necessary in most cases for a maximum titanium recovery, a large amount of this acid can be recovered in the form of sulphur trioxide and elemental sulphur.

It has been shown that titanium recoveries in excess of 95 pct can be obtained by baking titanium mattes with sulphuric acid at 200 to 250°C. Very little work has been done, however, on the precipitation of titanium dioxide or the adjustment of the concentration of the leach solution. It is believed that a countercurrent decantation system

Table 6 . . . Baking Titanium Matte with Sulphuric Acid

| Sample | Concentration | | Recovery | |
|-------------------|------------------|-----------------|----------|-------|
| | Ti | Fe | Ti | Fe |
| Leach liquor..... | 37.6 g per liter | 8.6 g per liter | 98.6 | 99.0 |
| Residue..... | 2.6 pct | 0.44 pct | 1.4 | 1.0 |
| Composite..... | 45.0 pct | 10.24 pct | 100.0 | 100.0 |

of leaching can be developed for leaching the baked matte. A sulphur balance must also be made to determine the amount that may be recovered from the system.

**BAKING CHLORINATION
RESIDUES WITH SULPHURIC
ACID**

The residues from the various chlorination tests contained 30 to 60 pct of the titanium in the original mattes and analyzed 25 to 35 pct titanium. Several runs were made on samples of these residues obtained from the chlorination of mattes prepared in the electric arc, induction, and globar furnaces. The procedure used was similar to that described in the previous section and consisted of baking the chlorination residue with sulphuric acid followed by a water leach. In all cases titanium recoveries over 90 pct were obtained. The arc-furnace product gave a recovery of 98.4 pct, the induction furnace product gave 90.6 pct, and the globar furnace gave 94.7 pct.

In Table 7 are shown the chemical analyses and over-all distribution of titanium in the various products obtained by chlorination and sulphuric acid baking of a sample of titanium matte prepared in the electric arc furnace.

A recovery of 95.2 pct of the titanium in the rutile concentrate has been obtained in usable form. It is also believed that a major part of the titanium in the slag may be recovered by sulphuric acid leaching or baking.

**Preparation of Titanium
Sulphides by Reaction of
Rutile with Carbon
Disulphide Vapor**

Several experiments were made to determine whether titanium sulphides

could be economically prepared from rutile by reaction with carbon disulphide vapor at elevated temperatures. In these tests, 85 pct rutile concentrates and a sample of low-grade rutile middling were sulphidized. Work on the low-grade material was abandoned when it was found that the gangue mineral, ankerite ($\text{CaO} \cdot (\text{MgFe})0.2\text{CO}_2$) was sulphidized before the rutile, thus causing an excessive consumption of carbon disulphide.

The procedure and apparatus used in these experiments were as follows: A weighed sample was mixed with a binder and charged into a vertical tube furnace. The charge was supported on a carbon block which was drilled with $\frac{1}{16}$ -in. holes to permit the carbon disulphide vapors to pass through the sample. The alundum or fused-silica tube was heated by an electric resistance furnace controlled by a rheostat. A weighed sample of carbon disulphide was placed in a three-necked Pyrex flask and heated by a water bath. A current of helium gas was passed over the surface of the carbon disulphide to carry it through the charge. The gases issuing from the top of the retort were passed through a water-cooled condenser to condense any unreacted carbon disulphide. The carbon disulphide was collected in a separatory funnel and returned to the distillation flask, while the tail gases were bubbled through a water trap to the atmosphere.

In a typical run a 150-g sample of 85 pct rutile was mixed with 7.9 g of sawdust and 29 g of water and heated to 800°C for 15 min. to remove the water and the volatiles in the sawdust. The charge was then heated at 1100°C for 8 hr while carbon disulphide vapor was passed through it. During the run 272 g of carbon disulphide were used. Part of this was used to sulphidize the rutile while the remainder was decomposed to form carbon and elemental sulphur. The analysis of the product obtained was 42.2 pct

titanium, 26.4 pct combined sulphur, 2.4 pct free sulphur, and 0.54 pct carbon.

A 100-g sample of this sulphidized product was chlorinated for 4½ hr at 200 to 220°C. A recovery of 59.4 pct of the titanium in the rutile was obtained. The product contained 15.3 pct titanium, 0.5 pct iron, 7.8 pct sulphur, and 78.1 pct chlorine.

It is believed that a higher recovery of titanium may be obtained, but this will be at the expense of greater carbon disulphide consumption and longer reaction times.

Conclusions

The results of the laboratory research work done thus far indicate that it is possible to produce titanium tetrachloride and titanium oxide from rutile by means of smelting the rutile with pyrite and coke and then processing the titanium matte. An impure iron is recovered as a byproduct. Ilmenite may be treated in the same way as rutile.

Recoveries of from 65 to 81 pct of the titanium in rutile may be obtained as an impure titanium tetrachloride by chlorinating titanium mattes at 150 to 250°C. When titanium matte is baked with sulphuric acid at 200 to 250°C, recoveries of 90 pct or more of the titanium in the rutile are obtained in the form of a titanium sulphate solution which is suitable for the recovery of pigment-grade titanium dioxide.

Chlorinating the mattes, followed by baking the residues with sulphuric acid gave titanium recoveries greater than 90 pct.

Recovery of Zinc by the Dithionate Sulphur-dioxide Leaching Process

S. F. RAVITZ,* Member AIME, and A. E. BACK*

When manganese ores are leached with sulphur dioxide, a large part of any zinc in the ore usually is extracted with the manganese.¹ In the dithionate process,^{2,3} in which the manganese ore is leached with dilute sulphur dioxide gas and the manganese is subsequently precipitated by adding lime to the pregnant solution, the zinc is precipitated with the manganese. These facts suggested the possibility of applying the dithionate process to the recovery of zinc from oxidized ores or calcined sulphide concentrates. Accordingly, an investigation was begun, and preliminary tests were made on several ores and concentrates. The results were encouraging, but the need to devote available funds and personnel to other projects made it necessary to drop the work before the various factors involved in the process could be studied in detail. A brief mention of the process,⁴ however, elicited a number of inquiries, so that it appeared desirable to report the results of the preliminary work.

The dithionate process as applied to zinc may be summarized briefly as follows: The ore or calcined concentrate is leached with dilute SO₂ gas to dissolve the zinc, largely as zinc sulphate, in accordance with the following equation in which [ZnO] represents the "oxide zinc" in the ore or calcine:

If, in the leaching step, the ore or calcine is suspended in calcium dithionate solution, the sulphate ion, as it is formed, is precipitated immediately as calcium sulphate, which is subsequently filtered off with the insoluble ore residue:

An alternative procedure is to suspend the ore in water, filter off the insoluble ore residue after leaching, add calcium dithionate to the resulting zinc sulphate solution, and then filter off the calcium sulphate precipitate. In either event the zinc is obtained in the form of a pregnant solution of zinc dithionate, from which it can be precipitated as relatively pure zinc hydroxide by adding milk of lime:

The zinc hydroxide precipitate is calcined to form the final zinc oxide product:

Theoretically the process is completely cyclic with respect to dithionate ion, the calcium dithionate required for reaction 2 being replaced by that formed in reaction 3. In practice, of course, small amounts of dithionate would be lost in the various filter cakes, depending on the economic washing limits. In the leaching step, however, some of the SO₂ is oxidized to dithionate instead of sulphate, accord-

ing to the following overall reaction:

so that the dithionate losses are made up, at least in part.

Ores and Concentrates Tested

The analyses of the ores and concentrates tested are summarized in Table 1, which also includes the analyses of the calcines produced from the concentrates. The concentrates were roasted in a laboratory muffle furnace at the temperatures indicated until evolution of SO₂ could no longer be detected; shallow clay dishes ordinarily were used; but calcines 2a and 2c were prepared in iron dishes, with the result that these two calcines were badly contaminated with iron scale.

The "complex" concentrate, sample 1, consisted essentially of sphalerite grains containing inclusions of pyrite and other sulphide minerals too minute to be liberated by grinding within economic limits. In the "marmatitic" concentrate, sample 2, the iron was present largely as marmatite (that is, as iron sulphide in solid solution in zinc sulphide) rather than as pyrite inclusions. The zinc was present largely as the carbonate in the two "oxidized" ores, samples 3 and 4, and as the silicate in the "willemite" ore, sample 5.

Leaching Tests

The leaching cell was a 3-liter glass beaker placed in an electrically heated water bath manually controlled to maintain a temperature of 35°C in the leach slurry. The slurry was agitated by means of a flat paddle-type stirrer

rotating near the bottom of the cell at about 500 rpm. A mixture of SO₂ and air, containing approximately 3.5 pct SO₂ to simulate waste smelter gas, was introduced at a constant rate through two 1-mm glass orifices, the gas emerging in the direction of rotation of the stirrer at a point near the periphery of the cell about an inch above the bottom.

The material to be leached was suspended in water. In each test a quantity of minus 65-mesh ore or calcined concentrate containing approximately 50 g of zinc was placed in the cell, 1500 ml of water was added, the stirrer was turned on, and the 3.5-pct SO₂ gas was introduced at the rate of approximately 36 g per hr for the desired length of time, usually 6 hr. At the end of the leach the slurry was filtered, the residue was washed, and the products were analyzed. The results of various leaching tests are given in Table 2.

With 4.1 to 4.7 g of SO₂ per gram of zinc, 83 to 87 pct of the zinc was extracted from the calcined concentrates and from the Goodsprings ore; under similar conditions, 72 pct was extracted from the Leadville ore. Utilization of SO₂ was rather poor, since theoretically approximately 1.0 g of SO₂ would be required per gram of zinc to form zinc sulphate or sulphite and 2.0 g would be required to form zinc dithionate. The two tests on calcine 1b and the five on the Leadville ore indicate that SO₂ utilization becomes poorer as leaching progresses. The willemite ore gave an extraction of 61 pct with 2.7 g of SO₂ per gram of zinc, and it is probable that higher extraction would have been obtained with more SO₂. Extraction of silica from the willemite ore was 52 pct; the leach slurry filtered fairly well, but the filtrate sample, when examined some 46 days later, was found to have gelled. The calcine and Leadville ore slurries filtered rapidly, but the Goodsprings ore slurry filtered very slowly.

Extraction of zinc from the calcined concentrates agreed well with the percentage of zinc present as oxide, as determined by solubility in strong ammonium chloride-ammonium hydroxide solution; leaching tests with dilute sulphuric acid likewise gave approximately the same results. Microscopic, chemical, and X ray diffusion tests showed that virtually all the zinc in the leach residues was present as sulphide and ferrite, mostly the latter. Effect of ferrite formation is evident in tests 6, 7, and 8 of Table 2; when the concentrate was roasted at 940°C, zinc

extraction was 74 pct, whereas when the concentrate was roasted at only 600° to minimize ferrite formation, the extraction increased to more than 86 pct.

Extraction of iron was very low, amounting to less than 3 pct in most of the tests. Copper extraction, which was erratic, apparently depends on the extent of leaching and on the conditions of roasting. No lead and less than 3 pct of the gold or silver was extracted.

Dithionate formation ranged from 19 to 77 lb S₂O₅ per ton of ore or calcine (0.03 to 0.10 g per gram of zinc extracted). This would be ample, in most instances, to make up for washing losses in the process, which, it is estimated, would not exceed 30 lb per ton in practice. In the manganese investigation,^{2,3} however, it was found that dithionate formation depends on many factors, including size and shape of leaching tank, agitation rate, leaching rate, and method of introducing the gas, so that pilot plant tests would probably be required to determine whether dithionate formation would be adequate in leaching zinc ores or calcines under plant conditions. Dithionate formation was fairly constant in leaches 10 to 14, in which the leaching time ranged from 1 to 6 hr, indicat-

ing that most of the dithionate was formed during the first hour.

The ore and calcine samples lost a large part of their weight during leaching, so that the residues were substantially enriched in iron, lead, gold, and silver, as shown in Table 3, in which data for several typical tests are summarized. Compared with the original concentrate or ore, the increase in the iron, lead, gold, and silver assays was about threefold for the two concentrates and about twofold for the Goodsprings ore. The large losses in weight on leaching were due to the fact that the samples leached were suspended in water rather than in calcium dithionate solution; if the samples had been suspended in calcium dithionate solution, the leach residues would have contained considerable calcium sulphate formed by reaction 2, and the weight losses would have been much less.

Recovery of Zinc from Solution

Leach solutions for investigating the recovery of zinc oxide products were prepared from (A) the "complex" concentrate calcined at 600°C, (B) the "marmatitic" concentrate calcined at

† Includes zinc in wash solutions.

600°, and (C) the Goodsprings ore. A 200- to 300-g sample of each material was leached in 1500 ml of water with 3.5-pct SO₂ gas for about 12 hr, the residue was filtered off and the filtrate was treated as described below to precipitate calcium sulphate and zinc hydroxide successively. Each residue or precipitate was washed thoroughly, but to avoid dilution of the various solutions, the wash filtrates were discarded. The SO₂ contents of the solutions were not determined, but the odor of SO₂ was noticeable in the leach solutions and pregnant solutions, especially those from test B.

PRECIPITATION OF CALCIUM SULPHATE

To precipitate sulphate, leach solutions A and B were treated directly with finely divided crystals of CaS₂O₆·4H₂O assaying 13.3 pct Ca, 57.8 pct S₂O₆, and 0.35 pct SO₄ (theoretical

analysis: 14.7 pct Ca, 58.8 pct S₂O₆) Before adding the dithionate crystals to solution C, however, the solution was first treated with small additions of 20-pct sulphuric acid solution until the odor of SO₂ could no longer be detected and the pH remained constant at 1.9; 6.0 g of H₂SO₄ was required per liter of the solution. The quantities of calcium dithionate used per liter of leach solution were as follows:

| CaS ₂ O ₆ ·4H ₂ O Crystals Added Grams per Liter of Solution | |
|--|-----|
| A | 309 |
| B | 273 |
| C | 253 |

The analyses of the precipitates (dried at 110°C) and of the pregnant solutions are given in Table 4; the dried precipitates correspond closely to CaSO₄·½ H₂O, for which the theoretical analysis is 27.8 pct Ca and 66.1 pct SO₄.

PRECIPITATION OF ZINC

Freshly calcined lime containing 93.0

pct available CaO was used to precipitate the zinc. The lime was slaked in about 10 times its weight of water, and the milk of lime was added dropwise to the vigorously agitated pregnant solution over a period of about 45 min. Agitation was continued for several hours, after which the slurry was allowed to stand overnight, during which time the pH rose about two units. With pregnant solution B, sufficient lime was added to give a pH of 3.9, the resulting precipitate was filtered off, and the addition of lime was then continued as described. Theoretically 0.84 g of CaO is required to precipitate 1.0 g of zinc; the quantities actually used were as follows:

| | pH | Available CaO Used, Grams per Gram Zn |
|--------------|------|--|
| A | 7.4 | 0.83 |
| B—First ppt. | 3.9 | 0.10 |
| Final ppt. | 10.5 | 0.84 |
| C | 9.8 | 0.92 |

The precipitates were dried at 110°C, and portions of the final precipitates were calcined at 1000°C. The analyses of the precipitates, calcines, and barren solutions are summarized in Table 4.

The results show that virtually all the zinc in the leach solutions can be recovered as a calcine assaying nearly 70 pct Zn. No advantage appears to have been gained by acidifying the leach solution in test C. The double precipitation with lime in test B was detrimental, causing a loss of 9.5 pct of the zinc in the first precipitate. The lower grade of the product in test B compared with the other tests is due to the presence of considerable calcium sulphate as a result of the relatively high sulphate content of the corresponding pregnant solution. The reason for the differences in sulphate content of the pregnant solutions is not clear, however, since the three pregnant solutions have nearly the same calcium content. It may be that the solubility of calcium sulphate in the solutions varies with the sulphite content; pregnant solution B, which had the highest sulphate content, was known to be particularly high in sulphite, whereas pregnant solution C, which was lowest in sulphate, probably had the lowest sulphite content as a result of the acidification.

Discussion of Results

The dithionate process for zinc is similar in certain respects to two

processes investigated by Lyon and Ralston. In one of these,⁵ oxide ore or calcine is leached with sulphurous acid solution to dissolve the zinc as the hydrosulphite, the pulp is filtered, and the zinc is precipitated as the sulphite by either boiling the solution or adding zinc oxide. The precipitate is calcined to form zinc oxide and regenerate the sulphur dioxide. The reactions are as follows:

Lyon and Ralston tested several ores and calcines and obtained high extractions of zinc in solutions containing 0.2 to 4 pct SO₂. Precipitation of the zinc by boiling or by adding zinc oxide was incomplete, however, owing to the rapid air oxidation of zinc bisulphite to zinc sulphate and, in the case of calcines, to the presence of zinc sulphate formed in roasting.

In another process investigated by Lyon and Ralston,⁶ the zinc is extracted by leaching with sulphuric acid or by roasting with sulphuric acid and leaching with water. The zinc is then recovered from the zinc sulphate solution by a procedure similar to that in the dithionate process except that calcium chloride is used instead of calcium dithionate; that is, the solution is treated with calcium chloride to precipitate calcium sulphate and form zinc chloride solution, and the latter is treated with milk of lime to precipitate zinc hydroxide and regenerate the calcium chloride. Lyon and Ralston obtained precipitates assaying about 50 pct Zn, and calcination of the precipitates gave zinc oxide products assaying over 65 pct Zn. The main objection to the process, aside from the high acid consumption in leaching, was the fact that the treatment of the zinc chloride solution with lime resulted in the precipitation of basic zinc chloride

rather than zinc hydroxide, so that the precipitates contained 6 to 10 pct chlorine. This would involve a loss (in addition to normal washing losses) of 240 to 400 lb of chlorine per ton of zinc precipitated and would require 375 to 625 lb of make-up CaCl₂ per ton of zinc. Moreover, about 6 pct of the zinc was volatilized when the precipitates were calcined; this zinc would be lost unless expensive fume-collecting equipment were provided to recover it.

The present preliminary investigation of the dithionate process indicates that it may have promise for the treatment of oxidized zinc ores that cannot now be treated commercially and of off-grade complex zinc sulphide concentrates that can now be marketed with only relatively poor return for the values contained. Its advantages include (1) utilization of waste SO₂ gas for leaching; (2) possibility of forming enough dithionate during leaching to make up for losses; (3) separation of zinc from lead, gold, and silver; (4) recovery of zinc from solution by a simple precipitation with lime; and (5) production of a zinc oxide product assaying nearly 70 pct Zn. To determine the commercial feasibility of the process, however, would require a more extensive investigation. Among the factors that should be studied are effect of SO₂ concentration in the gas and of type of leaching cell on zinc extraction, SO₂ utilization, and dithionate formation; relative merits of leaching in water versus leaching in calcium dithionate solution; and effect of sulphite in the leach solution on the precipitation of calcium sulphate.

Summary

1. A new dithionate process for treating oxidized zinc ores or low-grade zinc concentrates is described. The ore or calcined concentrate is leached with dilute SO₂ gas, sulphate is precipitated by means of cyclic calcium dithionate, and the zinc is recovered from the solution by precipitation with

milk of lime.

2. In laboratory tests on several ores and calcined concentrates, 83 to 87 pct of the zinc was extracted, together with less than 3 pct of the iron, gold, or silver and none of the lead. Enough dithionate was formed during the leaching process to make up for losses. About 5 lb of sulphur dioxide was used per pound of zinc extracted.

3. Virtually all the zinc in the leach solution was recovered as a precipitate which, after being calcined, assayed nearly 70 pct Zn.

Acknowledgments

The authors wish to express their appreciation to S. R. Zimmerley, Chief of the Salt Lake City Branch, Metallurgical Division, Bureau of Mines, for his helpful interest in the investigation and for arranging to obtain the samples of ores and concentrates tested; to J. D. Prater, H. E. Ohn, and the late W. F. Wyman for their invaluable assistance in the experimental work; and to the staff of the chemical laboratory of the Salt Lake City station, under the direction of H. E. Peterson, for the analytical work.

Seminar on the Kinetics of Sintering

(With Discussion)

A. J. SHALER,* Member AIME

Introduction

The subject of the mechanism of sintering has received much attention in the past few years, particularly since the beginning of the series of AIME seminars in powder metallurgy of which this paper introduces the fourth. In the first of these, F. N. Rhines¹ brought together and discussed the available experimental data on the sintering of pure metallic powder, and succeeded in bringing to a sharp focus the attention of workers in this field on the established observations which a satisfactory theory must explain.

Several other authors^{3,5,6} have, in the last few years, studied the phenomena that occur when cold metallic powders, loose or in the form of compacts, are first brought to elevated temperatures. Some workers⁷ in the field of friction have recently studied the adhesion of solid metal surfaces when they are brought into close contact. These researches have indicated that several separate mechanisms operate simultaneously, at least during the first part of the sintering process. Some of them have been called *transient mechanisms*⁴ because they are in general not absolutely necessary to sintering. Powders may be so prepared and so treated that these transient phenomena do not take place during subsequent sintering. This does not mean, of course, that their industrial and scientific importance is any less than that of the *steady-state* phenomena. The latter are changes that go on during sintering no matter how the powders are made or treated; they cannot be divorced from sintering.

One way to analyze the process of sintering into its component parts is perhaps to distinguish between these

transient and steady-state phenomena. Some of the transient phenomena have been studied in the past few years. Hüttig³ has shown that, when the temperature of metallic powder is slowly raised, the following events generally occur in order: (1) physically adsorbed gases are desorbed; (2) there is an atomic rearrangement of the surface, a sort of two-dimensional "surface-recrystallization"; (3) there is a breakdown of chemically adsorbed surface compounds; (4) there is a recrystallization in the volume of the metal. All these changes are shown by Hüttig and his coworkers to be completed fairly rapidly at lower temperatures than those generally used in sintering and are therefore not a part of the mechanism whereby the density of a mass of powder continues to change after long heating at an elevated temperature. But the first and third of these changes release gases in quantities which may or may not help to control the steady-state mechanisms, depending on when the voids become isolated from the outside of the compact.

Among the phenomena studied by Steinberg and Wulff,⁸ there is the effect on sintering of residual stresses arising from the pressing operation. They found that the lateral surfaces of a green compact of iron are under a longitudinal residual tension-stress of the order of magnitude of half the yield-point for solid iron. If the outside surface is in tension, the core must be under longitudinal compression. When the compact is heated, the surface residual stress is thermally relieved

first, and the compact therefore initially expands in the direction of its axis. This is a transient phenomenon, if for no other reason than the possibility of sintering unpressed powders, as demonstrated by Delisle,⁹ Libsch, Volterra and Wulff¹⁰ and others.¹

The subject of recrystallization is dealt with further in a separate section, in view of its prominent place in sintering literature. It, too, is one of these transient phenomena.

Among the steady-state parts there may be distinguished the attraction between particles and its consequences, the spheroidization of voids in the compacts, and the densification or swelling of the compact.

There is considerable evidence^{4,7} showing that cold metallic surfaces, when brought to within a few interatomic distances of one another, are attracted to each other by forces of the order of many thousands of pounds per square inch. A calculation, discussed in greater detail in another section, shows that this force changes but slightly when the temperature of the surfaces approaches the melting point. Actual measurements of forces of adhesion of this magnitude have been made by Bradley¹² on some nonmetals, but none has yet been made on cold or hot metals. This force is of sufficient magnitude to cause some plastic deformation in powder compacts, as will be shown below.

A second force of steady-state nature is due to the surface tension, which probably has the same origin as the force of attraction between surfaces.^{16,4} A paper by Udin, Shaler, and Wulff¹³ gives the results of precise direct measurements of its value for solid copper. The demonstration of the tendency for the surface tension to shrink a pore was long ago given by Gibbs.¹⁷ He showed that its effect on a curved surface between two phases is equivalent to a pressure perpendicular to that

FIG 2—The progress of densification of compacts originally sintered in argon or nitrogen at one atmosphere, then subjected to heating variously in vacuo and in nitrogen.

surface and equal to twice the surface tension divided by the radius of the curvature. If the pressure of a gas within a pore is considered positive, then the pressure equivalent to the surface tension is a negative pressure directly opposed to it. Its magnitude depends on the size of the void. The interplay of this pressure and the pressure of the gases trapped within isolated voids has been described^{18,28} elsewhere.

An attempt will be made in this paper to show that the ordinary modes of plastic deformation (slip and creep) contribute appreciably only in the first-stage of sintering to the change of density of a compact, and also that surface diffusion and evaporation cannot make major contributions to the process of densification (or swelling) in most metals. Another mode of flow must be demonstrated to exist in order to account for the changes in density of a compact during later stages of sintering. The nature of this flow is at present one of the major incompletely solved problems in the theory of sintering. This meeting will probably have heard, before its close, more than one version of how surface tension and gas-pressure-differences can cause densification or expansion of compacts. After a brief discussion of recrystallization and of the contribution to sintering of surface-diffusion and evaporation, the steady-state processes will be analyzed in more detail.

Recrystallization

The term "recrystallization" has been used in two different senses. In the first, it has been applied to the reorganization of the lattice following its distortion by cold deformation; it pro-

ceeds by the diffusion of individual atoms from the distorted lattice to a nucleus; the nucleus, if it is big enough, grows into a new crystal having (despite its more perfect geometry) a lower free energy. In the second, broader, sense of the term, recrystallization means any change in crystalline shape brought about by a movement of individual atoms. If sintering takes place by a diffusion of atoms and not by slipping or twinning of blocks of atoms, then it is certainly a recrystallization in this second sense; but the term is then no more specific than "sintering" itself, and its use gives no more insight into the nature of the phenomena.

Balshin¹⁹ has advanced the hypothesis that recrystallization, presumably in the first, more restricted sense, begins at the points of contact between particles, where the greatest degree of cold deformation has been introduced during pressing, and that densification of the compact is a corollary of this recrystallization. But masses of powder need not be compressed in order to become more dense during heating. For illustration, Fig 1 shows the progress of densification of a mass of initially loose annealed copper powder (atomized, No. 4915 MD83A, Metals Disintegrating Co.) when it is heated in vacuo in a graphite container. According to this result, shrinkage does not require previous cold-working, and therefore requires no recrystallization. The converse, that recrystallization, in this sense of the word, does not result in shrinkage, can also be demonstrated. Smithells²⁰ reports that a cold-worked tungsten wire, coiled into an extremely fine coil, is recrystallized on heating in such a way that it becomes a single crystal whose orientation is independent of the direction of the axis of

the wire, as if the coil had been machined out of a single crystal in the first place. No change in shape or size occurs during this recrystallization. In the same way, it is not to be expected that a composite of particles in contact with one another should change in shape or size even if the entire mass becomes recrystallized into a single, porous, crystal.

To demonstrate further that recrystallization following cold-work cannot be responsible for changes in the density of compacts, loose masses of powder were heated in argon or nitrogen at one atmosphere (14.7 psi) until their final stable equilibrium-density was reached (this equilibrium is described below). They were then heated in vacuo, wherein a different relation existed between the driving forces of surface tension and differential gas-pressure; they were observed to expand to a new equilibrium-density, which thereafter remained relatively stable in spite of further heating in vacuo. These compacts, as detailed in Fig 2, were then reheated again in nitrogen at one atmosphere until they regained their first equilibrium-density. It is highly improbable that these changes of external stress of 14.7 psi could induce enough deformation to initiate new recrystallizations. These experiments support the conclusion of Rhines¹ that recrystallization, in this sense, proceeds no differently in powder-compacts than in more massive metals, and have nothing to do with the changes in density of these compacts during sintering.

Such simple experiments further show that the reactions between the gases within the pores and the metal surrounding them have at most an influence on sintering which is independent of the main mechanism

FIG 3—Micrograph at $\times 500$ of loose copper powder heated 24 hr in argon at 1 atm at 1000°C , then 54 hr in vacuo at 1025°C .

Deeply etched and repolished several times. Density 97 pct of theoretical. Note tendency of pores to become spherical. Note also recrystallized "bridges" between some particles.

whereby compacts become more or less dense. A change in the pressure of gas outside the compact can in no way influence the equilibria of reactions at the surface of pores sealed from the outside, provided the temperature is not changed. The phenomena of recrystallization and of desorption or adsorption of gases are therefore of transient influence on sintering, and their effect is not in evidence after the first heating-up period, during which they govern the amount of gas that will be trapped within the pores. After that period, the nature of the sintering process must be sought in other phenomena.

Surface Diffusion and Evaporation

Pines²¹ and more recently Ivensen²² have stated that surface diffusion and the process of evaporation from one place and condensation at another cannot change the density of a compact. This thesis has been further supported by Shaler and Wulff¹⁸ by the following argument. In a mass of powder particles, imaginary continuous lines may be drawn, passing through the centers of the particles and through the centers of the metallic "bridges" where they make contact with one another. These lines may be drawn in such a way that they never emerge from the surface of the metal

into the voids between the particles. The aggregate of these lines forms a skeleton. No process can be imagined whereby this skeleton is changed in shape or size unless there is flow within the particles themselves, or across the solid metallic "bridges." If recrystallization has permitted the lattices of the particles to be continuous through these "bridges," as countless micrographs, including that of Fig 3, have shown to be the fact in sintering, then these bridges are made of metal which is in general no different from the metal in the particles themselves. A change in size or shape of the skeleton—and hence of the compact as a whole—must involve flow in the volume of the metal. No redistribution of metal taking place at the surface of the voids between particles can cause any change in the skeleton, which never touches that surface.

If all the voids are connected by channels to the outside of the compact, of course, metal from the outside layers can proceed *via* the gas-phase or by surface-diffusion towards the interior. But this movement ceases as soon as the voids become isolated from the outside. There is other evidence to show that such a transient process can have little influence on the course of sintering—for instance, markings on the surface of compacts do not disappear during sintering.

On the other hand, surface-diffusion and vapor-phase transport do have a

function in sintering, but it is not that of changing the density. An aggregate of powder differs from a solid piece of metal chiefly in that it has a great deal more surface per unit of mass. Hüttig³ and the author⁴ show that metal powder made of micron-size particles has so much surface that its free-energy is of the order of 1000 cal per mol greater than that of solid metal. The mass of powder can reach an intermediate state of lower free-energy if the voids between the particles become spherical. Such a spheroidization of the pores has been observed, as pointed out by Rhines.¹ It can proceed by surface-diffusion or by evaporation and recondensation, for it involves only a redistribution of the metal at the surfaces of the voids. It can also proceed by a flow of the metal particles and bridges. A calculation⁴ has shown that, in nearly spherical pores (of radius 100μ) inside a copper compact at 850°C , the flow process is more rapid than the evaporation process and probably also than the surface-diffusion process. At the beginning of sintering, however, when the contact areas between the particles are small and the voids have sharper corners, the reverse may be true.

In brief, then, surface-diffusion and vapor-phase transport have a function in sintering, in that they assist the flow process in leading to a spheroidization of the pores. But these mechanisms cannot effect a change in the density of the compact, a change which requires a flow of the metal within the particles themselves.

The First Phase of Sintering

During the first phase, in the sintering of loose powder masses, the particles preserve to a great extent their original shape, and the voids are interconnected. In the second phase, which may best be studied separately, the pores are disconnected entities, and the compact may be considered a porous, but continuous, medium. Sauerwald²⁵ has shown that the mechanisms in sintering loosely pressed compacts resemble those found in sintering loose powder, whereas heavily compressed compacts already contain disconnected pores in the green state.

If the pores are all joined together and have passage to the outside, there is evidently no difference in gas pressure between the pores and the atmosphere, so that no force is to be expected

FIG 4—Two spheres, partly coalesced, separated by a minimum distance δ , and subject to attraction across cylindrical elements of length r and of thickness dy .

from this source. The surface tension exists, but it is perhaps more convenient to treat it in this phase as the force of attraction between particles. It has been shown^{4,29} that this procedure is justified, since the two forces stem from the same origin.

The force of attraction has been calculated⁴ on the following basis: according to the Sommerfeld¹¹ model of a metal, it is made up of positive ions of infinitesimal size, regularly distributed at the intersections of a geometric lattice; around the ions there is a cloud of fast-moving electrons. The electron density varies, but it is assumed to be uniform as a first approximation. The surface of the metal may be defined as the last layer of ions. The electron cloud does not stop abruptly, however, although its density falls off rapidly outside this layer. The presence of another surface nearby causes the density of the cloud to increase considerably, beyond the surface, and to fall off more gradually. If the surfaces come to within several interatomic distances of one another, there is an appreciable number of electrons moving about throughout the space between them. Each of these electrons is attracted to both the opposing surfaces, so that in effect the two surfaces are attracted to one another because they are both attracted to the electrons between them. The calculation of this force of attraction has yielded, as a first approximation, the following results: two copper surfaces, 30 Å apart, attract each other with a force of approximately 120,000 psi; this force drops to about 55,000 psi if the separation increases to 60 Å, and to about 30,000 psi when the distance is 120 Å. A rise in the temperature from 20 to 700°C decreases these values by only about 15 pct. Cleanliness of the surface is not a serious factor unless thick layers of compounds are formed. The

electronic work-function of copper, which depends on cleanliness, can vary from 1 to 5 electron volts without changing the force of attraction more than 10 pct. The calculation cannot be extrapolated to distances less than about 15 Å, because when the surfaces come that close together, the ions begin to repel one another, and the attraction falls off again. The expression is also not valid at great distances, where the presence of foreign ions and atoms interferes with electron movement. An approximate expression can be made to fit the data given above, and the unwieldy equations from which they were calculated are not necessary for practical use. If the distance r separating the surfaces, or elements of surface, is given in inches, then the force in pounds per square inch between them is given, within 10 to 15 pct, by the formula

$$f(r) = 1.4 \times 10^{-2} \frac{1}{r}$$

With this as a quantitative basis, the force of attraction between two coalescing spherical particles may be calculated. Fig 4 shows such a system. The distance δ between them is a region where, as a first approximation, the metal may be considered solid; in this disc-like region the force of attraction

becomes balanced by the ionic force of repulsion. Outside this disc, the surfaces gradually fall away from one another, and are under the influence of the force of attraction. The force pulling together the ends of the cylindrical element of thickness dy and height r at a radius y from the center-line is then

$$2\pi y f(r) dy$$

Integrating from $y = d$ to $y = R$, and remembering that δ is much smaller than R , an expression is found for the total force acting in such a way as to pull the spheres together and compress the disc between them. This expression is

$$F = 4.4 \times 10^{-2} \sqrt{R^2 - d^2} \ln \left(\frac{2}{\delta} \sqrt{R^2 - d^2} \right)$$

Since the area of the disc is πd^2 , the compressive stress acting on it is $\sigma = F/\pi d^2$. The spheres are assumed to remain spherical and to preserve their radius, a good approximation for small values of d . Fig 5 shows the values of this stress as a function of the radius d of the disc, that is, of the degree of coalescence of the two spheres, for copper spheres 0.01 cm in radius (200μ in diam). At first contact, when d is

FIG 5—Plot of the compressive stress on the contact area, and of the angle subtended by the radius of that area at the sphere centers, for various degrees of coalescence of copper spheres of radius 0.01 cm.

FIG 6—The growth of the area of contact of copper spheres, 0.01 cm in radius, with time at various temperatures. The ordinate is the square of the angle subtended at the sphere centers by the radius of the constant circle. Stresses corresponding to these angles, from the previous figure, are shown at the right.

FIG 7—Plot of stress vs. strain-rate for copper wires 0.005 and 0.003 in. diam at various temperatures. Data from Udin, Shaler and Wulff.

small, the stress of compression on the contact area is very large, and unless there is interference from oxide films or layers an immediate cold-welding occurs, as it does in the friction experiments⁷ mentioned earlier, and in those of Bradley on some nonmetallic spheres.¹² Plastic deformation under this stress leads to an increase in the area of contact, and the compressive stress on that area falls off until it becomes less than the least stress necessary to cause plastic flow. But at elevated temperatures, which do not appreciably decrease the force involved, the metal is still able to creep conventionally at these lower stresses. The time factor now enters into the picture, as it does in creep. Soon the compressive stress has fallen to a value lower than the stress-limit for creep, and the first stage of sintering is at an end. By this time, the pores are disconnected, and a new type of flow becomes predominant.

Experiments on the coalescence of spheres have been carried out by the author with the assistance of H. Bernhardt. Copper spheres were selected from a commercial grade of atomized powder (described below) by first sieving for the $-70 +100$ mesh fraction, then sorting out the particles by rolling them down a narrow ground-glass plate 4 ft long, and inclined at about 4° . The few particles that rolled down the whole length of the plate were selected for the experiments. These particles were packed in carbon-black and heated for 5 hr at 750°C in an atmosphere of dry deoxidized hydrogen at 0.5 mm pressure. After slowly cooling them to room-temperature, the spheres were separated from the carbon-black in an air-classifier. Several

particles were then placed in contact with each other in a deep groove in a graphite block. After heating for various periods of time at various temperatures in an atmosphere of dry deoxidized hydrogen, the strings of spheres were observed in a microscope equipped with a micrometer eyepiece. The diameters of the areas of contact and the distances between the centers of the spheres were measured. The angle θ subtended at the center of the spheres by half the radii of the contact areas were plotted against the time at various temperatures. There was some scatter due to the fact that many of the particles were not sound throughout, and that their surfaces, after deoxidation, were not perfectly spherical. The mean deviations from the mean values of θ were of the order of 10 pct. Each point in Fig 6 is the mean of from 5 to 24 spheres, plotted on coordinates of θ^2 and time t . According to Frenkel's analysis,²⁶ if the coalescence of spheres takes place by a purely viscous flow, the points on such a plot should lie on a straight line passing through the origin, since θ^2 is then directly proportional to the time ($\theta^2 = \frac{3\gamma t}{2\eta r^3}$ where r is the sphere radius, γ is the surface tension, and η is the viscosity coefficient). In these experiments the curves are straight only at larger values of the time, and no straight line, however fitted to the points, passes through the origin. Rather, the slope of the line initially decreases rapidly with time at heat, showing that the coalescence starts with a rapid mode of flow (first stage of sintering by creep or even normal slip) and gradually becomes slower until a

viscous flow becomes dominant (the line straightens out). Experiments² reported recently by Jordan and Duwez agree with this view. Others⁵ may not.

In Fig 6, the stresses corresponding to the various values of θ^2 are given on the right-hand scale. These have been taken from Fig 5 ($\sin \theta = d/R$). Note that the linear portion of the curves, representing the second stage of flow, begins at approximately 5000 psi at 800°C , but that non-linearly continues at 950°C until the stress has fallen as low as a few hundred pounds per square inch. Flow in the first stage is thus a process which appears to begin at a critical stress-limit, decreasing as the temperature rises, as in conventional creep. The type of flow required in second-stage sintering cannot have a critical stress-limit, for flow must occur under infinitesimal stress, at a correspondingly small rate, in order to account for experimental results.

Until more is known about the creep of copper at high temperatures under stresses of the order of hundreds of pounds per square inch, it is not possible to predict the rate of this first stage of sintering, when the particles coalesce and the voids between them become disconnected. In highly compressed compacts and in the later stages of sintering of loose or lightly compressed powders, the first stage is by-passed or ended, and the mechanism of sintering involves the slower, viscous, flow described below.

The first stage of sintering is further complicated by all the transient effects described in previous sections, some of which may tend to expand the compacts, some others to shrink it.

FIG 8—Artificial pore in a short length of copper wire.

Flow in the Second Phase of Sintering

In the second stage, the pores are in general disconnected, and any change in density of the compact involves a change in pore-volume and therefore in the pressure of the gas trapped within the pores. The force of shrinkage, previously manifested as the attraction between surfaces, can now be more conveniently considered as the surface tension.

Surface tensions and pressures of gas such as are encountered in powder metallurgy can form high stresses at the surface of very small pores—stresses great enough to induce plastic flow by the well-known modes of slip, twinning or creep. But it was shown that there can be no density-changes in compacts unless flow takes place inside the particles away from the surface of the pores. Here the effects of the surface tension and of the gas pressure are diluted because they act over a larger area. In the compacts described below, in which marked densification takes place, the pores have an approximate radius of 100 microns. At a distance of only 10 microns away from the surface, the stress induced by the surface tension is less than 3 psi. In the hollow tubes, whose densification is also described below, the radius of the hole is of the order of 2500 microns (0.01 in.), and the stress, even at the surface, is less than 1 psi.

• The mechanism of flow at these low stresses has not been extensively investigated. Chalmers²³ has observed the flow of tin at small stresses, and found a viscous flow at room temperature. Udin, Shaler, and Wulff¹³ measured the rate of flow of copper at elevated temperatures, under stresses of up to 6 psi on wires 0.005 and 0.003 in. in diam. Fig 7 reproduces their data in terms of stress and strain-rate. These results are consistent with a viscosity, independent of stress, expressed by the relations

$$\eta = 5.94e \frac{66490 \pm 1000}{RT}$$

for 5 mil wire, and

$$\eta = 1.32 \times 10^3 e \frac{53756 \pm 1000}{RT}$$

for 3 mil wire.

Kanter²⁷ and Frenkel²⁶ predict on theoretical grounds that the phenomenon of self-diffusion should lead to a viscous flow whose heat of activation is the same as that for self-diffusion (57,000–61,000 cal per mol for copper). The viscosities given above have a heat of activation near that range (66,000 and 54,000 cal per mol). Kê²⁴ has observed a room-temperature grain-boundary flow having the heat of activation for self-diffusion, in both iron and alpha brass. Little can be said with certainty about flow at these stresses save that it is of a viscous nature. Newtonian viscous flow is characterized by the fact that the stress vs. strain-rate curve is linear and passes through the origin. The flow is further complicated by the fact that there is evidently a dependence of viscosity on size. Possibly the self-diffusion coefficient also varies with size.

To show whether a viscous flow of this nature could be responsible for the shrinking of closed pores in sintering, a direct measurement was made. Since the artificial creation of a spherical hole of very small size in a piece of metal entails mechanical difficulties, a cylindrical hole was used. Such holes were drilled (diameters *ca.* 0.02 mm) lengthwise in three short lengths of copper wire. The drilled tubes were then heated overnight at 1000°C in dry deoxidized hydrogen at 0.5 mm pressure, and furnace-cooled. The outside diameter of the tubes was 1/8 in., and their length 1/2 in. The ends of the holes were tapered to a depth of 3/64 in., and tapered plugs were made to fit. One end of each was firmly closed by

FIG 9—The relative change in radius of cylindrical "pores" in copper, compared with calculated from viscosities of copper wires.

pressing-in the plugs. In the other ends, the plugs were left loose, so that, during heating in vacuo, the holes would be evacuated before becoming sealed. A sketch of such a tube is shown in Fig 8. Being closed, as shown in a previous section, it cannot shrink by surface-diffusion or by evaporation, although by these processes the radius of the hole may expand at the expense of the length (spheroidization), but the radius and length of the hole may both decrease by flow under the action of surface tension. To heat the tubes, they were placed vertically into wells drilled in a graphite block, loosely-plugged ends uppermost. An undrilled 1/2 in. length of the same wire, similarly annealed and mounted, was used as a control. The heating chamber in which heating was carried out was a long quartz tube, sealed at one end, and fitted at the other with a waxed-in rubber stopper. Two glass tubes, fitted into the stopper, led respectively to a mechanical vacuum pump and gauge and to a source of hydrogen. The quartz tube could be evacuated and then inserted into a chromel-wound furnace. In this way, high-temperature seals were avoided, and heating and cooling-times would be cut to a minimum. The same furnace technique was used in the experiments on the coalescence of spheres and on the sintering of compacts, described elsewhere in this paper. The source of hydrogen was a commercial cylinder, from which the pressure was reduced by a conventional reducing valve to about 15 psi. The gas went to a purification train consisting of four tubes containing respectively heated copper gauze, indicating Drierite, palladium-alundum, and activated alumina. From this train, the

hydrogen passed through a constriction-flowmeter, and then through a 4 ft length of 1.2 mm capillary tubing before entering the quartz furnace-chamber. The capillary furnished a pressure differential such that atmospheric pressure could be maintained in the reducing train and flowmeter, whereas a vacuum of 0.5 mm could be easily obtained in the furnace-chamber.

The small copper tubes were first subjected to a series of three 2-hr heats at 930°C, and thereafter, since density measurements showed the metal had nearly reached stability under these conditions, to a series of 24-hr heats at 1000°C. After each heat the tubes were radiographed; their external dimensions were measured with a micrometer caliper, and their density was determined to four significant figures pycnometrically. The dimensions of the holes were found from the density determinations, and were checked by measuring the radiographs on a film-reader.

The function of the hydrogen leak at 0.5 mm pressure was to insure the reduction of any oxygen leakage and also to reduce all oxide in the metal, without introducing into the "pore" enough gas to provide appreciable pressure until the shrinkage had become considerable. Fig 9 shows the relative radius of the cylindrical "pores" plotted against time-at-heat. Also plotted are the slopes of the calculated curves to be expected if the mechanism of flow is the same as that found in wires by Udin, Shaler, and Wulff.¹³ These two curves are plotted for the viscosities observed on 0.005 and 0.003 in. wires at 1000°C. It is expected that the size-effect on the value of viscosity should disappear rapidly at larger sizes. In the tubes, the wall thickness is about 0.050 in., so that the slope should be somewhat greater than that given for 0.005 in. wires. The calculation of these curves was done as follows (see Fig 9): The incompressibility of the metal requires that the same weight enter into and flow out of a cylindrical shell of thickness dA at radius A from the pore centerline. The outermost and innermost shells yield the equations

$$\frac{dA}{dt} = \frac{R_2}{A} \frac{dR_2}{dt} = \frac{R_1}{A} \frac{dR_1}{dt}$$

The strain-rate at any radius A , in terms of the rate of decrease of R_2 , is

$$\frac{d\epsilon}{dt} = \frac{d}{dA} \left(\frac{dA}{dt} \right) = -\frac{1}{A^2} R_2 \frac{dR_2}{dt}$$

Since the stress-strain relation for viscous flow is

$$\sigma = \eta \frac{d\epsilon}{dt}$$

the heat dissipated by flow per unit volume per unit time, at radius A , is then, after Frenkel²⁶

$$dE_F = 2\sigma\epsilon = 2\eta\epsilon \frac{d\epsilon}{dt} \\ = 2\eta \left(\frac{d}{dA} \left(\frac{dA}{dt} \right) \right)^2$$

In a length l of the tube

$$E_F = 2\eta \int_{R_2}^{R_1} \left(\frac{d}{dA} \left(\frac{dA}{dt} \right) \right)^2 2\pi A l dA \\ = 2\pi\eta l R_2^2 \left(\frac{dR_2}{dt} \right)^2 \left(\frac{1}{R_2^2} - \frac{1}{R_1^2} \right)$$

The loss in surface energy per unit time, due to the reduction of both inside and outside surfaces, is, if γ is the surface tension,

$$E_s = -\frac{d}{dt} (2\pi l \gamma (R_2 + R_1)) \\ = -2\pi l \gamma \left(1 + \frac{R_2}{R_1} \right) \frac{dR_2}{dt}$$

Equating E_F to E_s , and simplifying,

$$\left(1 - \frac{R_2}{R_1} \right) dR_2 = -\frac{\gamma}{\eta} dt$$

Using the incompressibility condition, and integrating from the initial radii R_{10} and R_{20} , there results

$$(R_{20} - R_2) - (R_{10} - R_1) = \frac{\gamma}{\eta} t^*$$

from which the curves of Fig 9 are drawn, using the values of γ and η at 1000° from Udin, Shaler and Wulff.¹³

It is clear from these curves that the hollow cylinders do shrink under the influence of surface tension and it is probable that the size effect is real, and must be taken into account in sintering theory; the particle-size as well as the pore-size is a variable affecting the sintering rate of a compact.

Rate of Sintering in Second Stage

The same calculation as that made for a cylindrical pore has been made for a spherical pore by Frenkel.²⁶ In a vacuum, according to him, the energy dissipated in viscous flow becomes, if R is the pore radius at any time,

* The right-hand member should be $\frac{1}{2} \frac{\gamma}{\eta} t$ (see Discussion by Eshelby) and Fig 9 has been redrawn with the correct value.

FIG 10—Change in average pore-radius during sintering of unpressed copper powder at 850°C.

FIG 12—The changes in the radii of pores of various initial radii, under conditions of vacuum sintering of compacts in which noble gas is trapped at an initial pressure of one atmosphere.

After Shaler and Wulff.

$$E_F = \frac{32\pi\eta R}{3\rho} \left(\frac{dR}{dt} \right)^2$$

where ρ is now the density of the porous metal surrounding the spherical void. Since the compact is usually very large compared to the void, its external radius is neglected. The density ρ varies with time during shrinkage of the compact, and therefore the rate of sintering must be measured by a parameter which combines both the time and the changing density. One such parameter, which greatly simplifies the calculations, is

$$F = \frac{3}{8\eta} \int_0^t \rho^2 dt$$

* Fig 10, 11 and 12 are reproduced from Fig 2, 3 and 4 of "Mechanism of Sintering" by A. J. Shaler and John Wulff, *Ind. and Eng. Chemistry*, May 1948. Reprinting is by permission of the copyright owner, the American Chemical Society.

Here the density ρ is introduced as a fraction of the density of solid metal. Equating E_F to the loss in surface energy E_s , as before, leads in the case of a spherical pore to

$$F = \frac{R_0}{2\gamma} - \frac{R}{2\gamma}$$

where R_0 is the initial pore radius.

Unpressed masses of powder particles, closely sized by sieving, were heated in vacuo at 850°C. The initial radius of the pores, R_0 , was calculated by assuming that the number of pores was equal to the number of particles. This assumption is valid in the case of a regular geometrical packing of the particles. Since the density of the loose mass was 0.51 of that of copper, and a simple cubic array would have a density of 0.52, this condition was judged to be fairly well obeyed. The effective radius of the pores was consequently found from the volume of voids divided by the number of particles. Since the average radius of the particles was 0.011 cm, that of the pores was 0.0103 cm. The validity of assuming that the voids are spherical is discussed in detail by Shaler⁴ and by Shaler and Wulff,¹⁸ and found to be satisfactory for voids which are not needlelike or flake-like. From Fig 6 it is observed that the end of the first phase of sintering is reached at 850°C when the contact-area radius is less than $\frac{1}{10}$ the radius of the particle. The densification corresponding to this point is very slight, so that in studying the progress of sintering of such copper compacts at this temperature, the first phase may be neglected. At higher temperatures it would have to be taken into account. After heating these compacts for various periods of time, their densities were measured, and the time and density values were combined to give values of the parameter F . When these were plotted on logarithmic paper against the changing radii of the pores, also found from the density, the points of Fig 10 resulted. The calculated curve in the figure corresponds to a coefficient of viscosity with a heat of activation near 66,000 cal per mol.^{4,18} The viscosities obtained in Udin, Shaler and Wulff¹³ have heats of activation of 66,490 cal per mol for 0.005 in. wire, and 53,756 cal per mol for 0.003 in. wire. The diameter of the particles used in the compacts was 0.008 in.

So far no account has been taken of the pressure of gas trapped within the pores. Three kinds of gas may be present: those which dissolve in the metal

or form a compound with it; those which diffuse through the metal at an appreciable rate; and those which neither diffuse, dissolve, nor react. The first kind have a pressure P_e dictated only by the temperature; when the pore shrinks, the gas is not compressed, but instead more of it goes into solution or reacts; the pressure does not change, and is constantly opposed to the stress introduced by the surface tension. Accordingly, if there is a pressure P_0 outside the compact, the pore shrinkage obeys the expression

$$\frac{dR}{dt} = \frac{3}{8\eta} [(P_0 - P_e)R - 2\gamma] \rho^2$$

Solving for F leads to⁴

$$F = \frac{2.3}{P_0} \log \frac{(P_0 - P_e)R - 2\gamma}{(P_0 - P_e)R_0 - 2\gamma}$$

If P_e is larger than P_0 , it is observed that pores initially of large size do not shrink, but expand on heating; that is, the compact swells. In copper, where γ is of the order of 1400 dynes per cm, pores larger than 5×10^{-3} cm in radius swell if $P_e - P_0$ is one atmosphere.

Gases of the second kind are more troublesome. The pressure of such gases depends on two factors: how fast the pore is shrinking; and how far inside the compact the pore is situated. No simple expression for the rate of sintering can be found except for particular cases. For instance, in the case of a very rapidly diffusing gas, the pressure stays generally low and may be neglected.

The third kind, the noble gases, are of more general interest, because all compacts pressed in air contain oxygen and nitrogen. The oxygen is generally removed during the first stage of sintering, either by the reducing atmosphere of the furnace, or in the form of compounds having a low equilibrium pressure. The nitrogen remaining behind is noble to many engineering metals. The expression for the parameter F is, in the case of a noble gas,

$$F = \int_{R_0}^R \frac{dR}{\frac{P_0 R_0^3}{R^2} - 2\gamma - P_0' R}$$

The labor of solving this equation is great, and it has been performed⁴ for one particular case only; namely, for pores 0.01 cm in radius, containing a noble gas initially at one atmosphere, the compact being sintered in a noble gas also at one atmosphere. Fig 11 compares the progress of sintering under these conditions with the prog-

ress in the case of vacuum sintering of compacts with and without any trapped gas. The limiting case where $P_0' = 0$ is easier to treat and yields:

$$F = -\sqrt{P_0 R_0^3} \left[\frac{1}{2\gamma x} + \frac{1}{2\gamma} \left(\frac{1}{2\sqrt{2\gamma}} \ln \frac{x - \sqrt{2\gamma}}{x + \sqrt{2\gamma}} \right) \right] x \sqrt{\frac{1}{R}} \sqrt{P_0 R_0}$$

where

$$x^2 = \frac{P_0 R_0^3}{R^2}$$

The curves corresponding to this expression, for P_0 equal to one atmosphere, are given in Fig 12. Pores larger than a critical size (2.4×10^{-3} cm radius) are seen to expand; finer pores shrink.

Fig 11 and 12 show another phenomenon: the change in pore-size takes place most rapidly during a relatively short time-range. The time range depends only on the pore-size, not on the conditions of gas pressure. Thus in Fig 11, the change, whether of expansion or shrinkage, is most rapid in the range of $\log F$ from -6 to -7 for pore-radii of 0.01 cm. From Fig 12 it is evident that the finer the pores are, the sooner they change. A compact pressed in air containing an assortment of pores ranging in radius from 0.0001 cm to 0.01 cm, would, upon sintering in vacuo at 850°C, first begin to shrink, in a very few minutes; and later, after an hour or more, it would expand again, and finally reach a stable density. Such a sequence is clearly shown in the work of Drapeau in cylindrical copper compacts.²⁸

In heavily pressed compacts of ductile metal powders, the voids, originally isometric, are compressed to a flake-like shape. The radius of curvature in the direction of pressing is then much larger than it is in a direction perpendicular to the pressing direction. Although the gas pressure is hydrostatic, the surface-tension force is not, and the pores may at first shrink in the lateral direction, while axially they are effectively larger and do not yet change. At a later time they may expand in the direction of pressing while remaining unchanged laterally. The final length of a cylindrical compact so compressed would be unchanged after a short sintering period, but the radius would have decreased. After a longer time of sintering the length might be greater, the diameter having suffered no further change. In such a case a short sintering time would yield a denser product than

a long sintering time, and the shrinkage of at least one dimension could be held to a minimum.

The porosity of a compact is not a direct measure of its fracture strength, as Sauerwald has often pointed out.²⁵ The shape of the voids is an important factor, because spherical pores are not as effective in concentrating stresses as are shapes containing sharper curvatures. Furthermore, long times of sintering favor conventional grain-growth, which may have a deleterious effect on strength. A more exact knowledge of the changes in shape and dimensions of pores and grains could be acquired by further study along the lines described here, and might permit powder metallurgists to select, on a more scientific basis, the proper pressures, temperatures, and times necessary to treat a compact to its best possible physical properties.

Conclusions

There remain many unsolved problems. For instance, it would be useful to know the atomistic nature of the viscous flow observed to take place at high temperatures under low stresses. In particular, the size effect observed by Udin, Shaler and Wulff¹³ and its relation to particle-size require more study. The role of oxide-films, of the thickness commonly found on metal powders, needs quantitative treatment. Such films undoubtedly affect the surface tension, the force of attraction, and govern in a large measure the pressure of gases trapped within the pores. In view of the extensive use of hydrogen-containing sintering atmospheres, the kinetics of sintering in the presence of diffusible gases is a field in which more work must be done. Finally, a great deal more experimental work must be done to test the hypotheses brought out in this paper regarding the force of attraction and the flow of metals under small stresses.

The sintering process is an extremely complicated one. In addition to the changes known to occur during the heat-treatment of massive metals—recrystallization, grain-growth, and others—the presence of a large surface-to-volume ratio increases the effects of transient phenomena such as the reactions and desorptions that occur at the surfaces of metals.

This study has given a more quantitative evaluation than any heretofore carried out of some of the mechanisms that are in operation during sintering.

Among these are the force of attraction between metal particles, the role played in the first stage of sintering by plastic flow or creep, and the nature of the last stage of the process, in which a viscous flow takes place under the combined action of surface tension and gas pressure.

Considerable attention has also been given to the part played in sintering by the transport of metal through the mechanisms of recrystallization, flow, surface-diffusion, and evaporation.

It has been shown that copper, and by inference, other metals, possess in the solid state a surface tension not widely different from that of the molten metal, and that this force alone is capable of bringing about changes in density in powder compacts. The question of why some compacts shrink, others swell, and still others do both simultaneously in different directions and at different times has been discussed. Methods of calculation have been outlined wherewith a powder metallurgist can evaluate the best conditions of time, temperature, particle-size and pressure required to meet his specifications.

In a limited range of cases it is now feasible to predict the course of sintering with some precision, and some observations, which until now have been puzzling to students in this field, can now be interpreted with less difficulty.

Discussion

(F. V. Lenel presiding)

H. H. HAUSNER*—I am surprised that Shaler in his excellent study on sintering does not apply electrical test

* Sylvania Electric Products.

methods in order to determine and distinguish the various stages of sintering. Electrical resistance or conductance measurements on sintered compacts permit a deeper insight in the process of sintering and especially in the earlier stages—or as Shaler calls it in the first phase of sintering, than any other methods.

The electrical resistance of a sintered material is composed of two different types of resistances: the particle resistances and the resistances between the particles which we call contact resistances.* In a general way (and before recrystallization) the total of the particle resistances will be the same whatever the particle size is, or whatever the respective degree of sintering of the compacts is. The contact resistances between the particles however will greatly change with the bond between the particles and will therefore be an indicator for the respective stages of sintering.

It is not only the electrical resistivity which permits conclusions on the bond between particles but also the temperature coefficient of resistance. Oxide layers, impurities or other material on the grain boundaries will greatly affect the contact resistance and especially influence its change with the temperature.

The results of a comprehensive study on the electrical properties of sintered material, especially describing the effect of the degree of sintering on the electrical resistivity of compacts will be published in the near future.

A. J. SHALER (author's reply)—I should like to thank Dr. Hausner for his excellent suggestion. I look forward with interest to the publication of his results. Owing to the complexity of the sintering process and the number of variables changing simultaneously during heating, I prefer, whenever possible, to simplify the problem by studying such models as a string of small perfect particles, or a synthetic pore. If, at some time in the future, I understand fully what is going on in these simple models, then I shall feel free to carry out experiments on the enormously more complicated problems existing in compacts made of irregular particles of various sizes and of different compositions. The state of the science concerning contact resistance and the passage of the electric current through complex surfaces in contact with one another is not yet such as to permit me to use it with much confidence as a research tool.

E. F. SWAZY† and L. S. BUSCH†—Generally, the powder metallurgist is concerned with the space between metal powder particles more than the particles

themselves. In making structural parts, he is concerned with minimizing pore space or eliminating it. In making bearings, filters, or any parts in which the pores are later filled, he is concerned with the shape, size, and degree of continuity or discontinuity of these spaces between the powder particles. Any work deserves great praise which sheds light upon the behavior of these spaces during the treatments usually afforded articles made from metal powders. Dr. Shaler's paper describes such work.

In the treatment of fine copper powder to reduce the oxides formed during storage, appreciable sintering occurs even at very low reduction temperatures. If the cake so formed is broken up, then changes which have occurred during the reduction (which can be considered a step in the elimination of the so-called transient phenomena) will affect the subsequent states through which a compact goes during sintering. We feel that any attempt to divorce completely the "steady state" and "transient phenomena" is a dangerous one and might lead to oversimplification of a difficult problem. One can consider these phenomena separately but cannot separate them finally.

We believe that the question of change in pore discontinuity during sintering deserves some discussion. It seems very dubious to us that the pores, resulting from the pressing of a compact from any metal powder particle which is not flat, ever become discontinuous.

Consider a three dimensional figure similar to Fig 4; that is, a closely packed group of spheres. It is difficult to imagine a complete discontinuity of the pores until the compact becomes completely dense, particularly if the particles retain some measure of their spherical shape on all surfaces forming a pore wall.

If the particle shape is changed before complete densification, as by repressing, it is conceivable that the pores might become discontinuous. But, as shown by the table that follows, porosity is still continuous even after severe repressing. It is conceivable then, that surface diffusion and evaporation can be considered part of the steady state phenomena. Certainly the rate at which both of these proceed would increase rapidly with increasing temperature and would also increase with time at a high temperature.

In the following table is shown the relative degree of porosity of copper compacts made from a minus 100 sieve, hydrogen reduced, copper powder sintered at 900°C for one-half hour and repressed at various pressures. The pressed density was 7.5 g per cc and the sintered density was approximately 85.5 pct of absolute in each case.

The degree of permeability was measured by noting the time required for a pressure of 90 lb of air on one side of the compact to fall to atmospheric pressure

| Final Density g per cc | Pct of Absolute Density | Relative Permeability to Air |
|---------------------------|----------------------------|------------------------------------|
| 8.00 | 89. | 5 |
| 8.25 | 92.8 | 5 |
| 8.32 | 93.5 | 1 |
| 8.40 | 94.4 | 3/4 |

on the other. The figures indicate that the pressure fell 6.6 times as fast in the 89 pct dense specimen as in the 94.4 pct dense one, but the important point is that the pores did not become discontinuous in any case. Neither do the pores in materials which develop a liquid phase become discontinuous. Porosity as low as 0.5 pct can be detected by liquid absorption methods in such materials as carbides or other high density materials and also in some materials which are pressed, sintered, and repressed to densities as high as 96 pct of absolute.

A. J. SHALER—Mr. Busch has brought up an interesting question concerning the closing of cavities. I think evidence exists that in pressing, a large proportion of the voids become isolated, and contain trapped gas at a pressure somewhere near the pressure with which the compact has been compressed. Some very thin compacts have even been observed to explode. I see no explanation unless the gas is trapped in sealed-off voids at high pressure. If Mr. Busch has made a three dimensional model of a group of spheres close-packed or otherwise, he cannot have failed to notice that in between them, on certain planes, there is a definite neck through which the passage of a gas or liquid is limited. The area of such necks must decrease in the first stage of sintering when the contact areas between spheres increase. If the sphere centers approach one another the neck is also gradually throttled down. It does not take very much increase in contact area or decrease in the distance between centers to close them completely. In later stages of sintering I cannot see any other explanation for the swelling of compacts than the presence of a force directed outward and acting on the void surface; that force to my mind can only be a gas pressure.

Other evidence in this connection is shown in the experiments reported on Fig 2, in which I was able to heat up compacts of spherical copper particles under isothermal conditions in a gas at a pressure of one atmosphere. The density of the compact increased at a gradually decreasing rate until, after a prolonged period of heating, an equilibrium density was obtained. These compacts were then heated further in vacuo. By thus forming a differential in pressure between the gas inside the voids and the gas outside the compact I was able to bring the density gradually down to a lower equilibrium value.

The reason for the residual permeability in carbides or in copper compacts

* H. H. Hausner: The Effect of Particle Size on the Electrical Properties of Sintered Materials. Powder Metallurgy Bull. (1948) 3, 4-8.
† P. B. Mallory & Co., Inc.

must be that there is a wide initial variation in the void sizes. That might in turn be due to a wide variation in the particle size or to an irregular distribution of the particles.

In that case, regions containing large pores take a considerably longer time to reach the end of the first phase of sintering than those containing only small ones. I think if regular geometrical patterns of equal spherical particles could be put together and sintered you would find the permeability reaching zero after long heating.

F. N. RHINES—If I remember correctly, Mr. Busch's sintering conditions were one hour at 900°. We have made some observations on changes in pore shapes at various temperatures and times. In the specimens that we used, the pores were definitely still connected and far from being spherical in one hour at 900°. However, as time goes on, the pores do spheroidize and by 1000 hr at 900° they are very close to being spherical and quite obviously not connected. I think that the observation under discussion is to be associated with too short a time to get into the condition of the samples to which we refer.

J. D. ESHELBY*—There are slight numerical errors in the formulas given by Dr. Shaler for the rate of closing of both cylindrical and spherical cavities. In view of the importance of these results it may be of interest to show how they may be derived by elementary, if rather tedious, methods.

In the case of the cylindrical cavity it is clear that a square of unit side with a diagonal pointing towards the center of the cavity suffers a pure shear $2\,de/dt$ per unit time. The work required to produce this shear is $\eta(2\,de/dt)^2$, twice Dr. Shaler's value.

In more complex cases this simple argument cannot be applied. We may start from the basic law of viscosity in the form: a unit surface normal to the direction of the velocity gradient has a tangential force acting on it of magnitude $\eta \times$ velocity gradient and directed parallel to the velocity. For any particular problem a volume-element can be chosen all of whose faces are subject only to shear stresses. If we choose a system of reference in which the center of the volume-element is at rest the work done on each face in unit time is then the product of η , the velocity gradient, the area of the face and the velocity of the surface in its own plane.

For the cylindrical case the appropriate volume-element is the cube, one of whose faces is the square ABCD, with BD along a radius. After unit time it has the shape A'B'C'D'. If AB = 1, then AA' = BB' = $\frac{1}{2}\sqrt{2}\,de/dt$. AB has undergone a rotation and a displacement Aa = bB'

FIG 13—Sketch to illustrate calculation of rate of closing of a cylindrical cavity.

= AA'/ $\sqrt{2}$ = $\frac{1}{2}de/dt$ which is its velocity in its own direction. The shear strain is, as before, $2de/dt$: it is the velocity gradient normal to AB. The work done on the face AB per unit time is thus $\eta(de/dt)^2$. There are equal contributions from the other three faces so that the rate of dissipation of energy per unit volume is $4\eta(de/dt)^2$ as before. The corresponding value for the rate of closing of a cylindrical cavity is

$$dR/dt = -\frac{1}{2}\gamma/\eta.$$

For the spherical case the appropriate volume-element is a regular octahedron with the line joining a pair of opposite vertices pointing along the radius (Fig 13). The medium suffers an extensional strain de/dt per unit time in the radial direction. To preserve constancy of volume there must be a contractional strain $\frac{1}{2}de/dt$ in directions at right-angles to the radius. The three diagonals of the octahedron are thus parallel to the principal axes of strain: in such a case it is known* that its faces are subject only to shear stresses. The velocity gradient between opposite faces is easily shown to be $\sqrt{2}(de/dt)$. Suppose that the previous figure now represents a section of the octahedron with B,D as opposite vertices and A,C the mid-points of a pair of opposite edges. If the edge of the tetrahedron is 1 then BD = $\sqrt{2}$, AC = 1. Aa now becomes $(de/dt)/4\sqrt{3}$ and bB', $(de/dt)/\sqrt{3}$. The component along AB of the velocity of the face of the octahedron varies linearly between these limits on passing from A to B. The mean value over the face is found to be $(de/dt)/2\sqrt{3}$. The area of the face is $\sqrt{3}/4$. This leads to $\sqrt{2}\eta(de/dt)^2/8$ for the work done on this face per unit time. There are eight such faces and the volume

of the octahedron is $\sqrt{2}/3$ so that the rate of energy dissipation per unit volume is $3\eta(de/dt)^2$.

For a spherical cavity in an infinite medium $de/dt = -2(dR/dt)R^2/A^2$ so that the total rate of dissipation of energy is

$$\begin{aligned} E_F &= 12R_0^4\eta\left(\frac{dR_0}{dt}\right)\int_{R_0}^{\infty}\frac{4\pi}{A^6}A^2dA \\ &= 16\pi\eta R_0\left(\frac{dR_0}{dt}\right)^3 \end{aligned}$$

that is, $\frac{3}{2}$ times the value given by Frenkel. The error in Frenkel's paper* is the following, using his notation: with spherical polar coordinates the non-vanishing components of his v_{ik} are v_{rr} , $v_{\theta\theta}$ and $v_{\phi\phi}$, not merely v_{rr} , as he states. The condition of incompressibility gives at once $v_{\theta\theta} = v_{\phi\phi} = \frac{1}{2}v_{rr}$. In his integral v_{rr}^2 must therefore be replaced by $v_{rr}^2 + v_{\theta\theta}^2 + v_{\phi\phi}^2 = \frac{3}{2}v_{rr}^2$.

The rate of closing of the cavity is

$$dR/dt = -\frac{1}{2}\gamma/\eta$$

It is interesting to note that this is the same as for the cylindrical cavity.

These and other results can also be obtained directly from an analogy between viscous and elastic problems pointed out by Goodier.† Suppose that an incompressible elastic solid (that is, one with a Poisson's ratio $\frac{1}{2}$) is deformed by the application of surface or body forces, and that the components of elastic displacement at a point are u, v, w . If the shear modulus μ is replaced by a coefficient of viscosity η then u, v, w are the velocities of flow of a viscous liquid under the same forces. The rate of dissipation of energy is found from the elastic energy by replacing μ by η and multiplying by 2, since we require stress \times rate of strain instead of the familiar $\frac{1}{2}$ stress \times strain.

Thus, for example, the rate of contraction of the spherical cavity is equal to the displacement of the surface of a spherical cavity in a medium with shear modulus η when the same surface-tension forces are applied. The energy need not be introduced, since the solution of the elastic problem is known. As a matter of fact the elastic energy per unit volume is $\frac{1}{2}Ee^2$ where E is Young's modulus ($= 3\mu$ for an incompressible solid) and e is the radial strain. The dissipation in the viscous case is thus $3\eta(de/dt)^2$ as before.

Summary

There is an error in the formula given by Frenkel for the rate of energy-dissipation round a closing spherical pore. This has the effect of replacing the numerical factor $3\frac{2}{3}$ by 16 in Dr. Shaler's expression for E_F . For the corresponding cylindrical problem the rate of dissipation should be $4\eta(de/dt)^2$, not $2\eta(de/dt)^2$.

† *Phil. Mag.* (1936) (7), 678.

It is shown how these results may be obtained by elementary methods.

A. J. SHALER—I thank Dr. Eshelby for bringing up this point and for his elegant demonstration. He is entirely correct as I discovered some three or four weeks ago when I recalculated this entire problem by yet a third approach, namely the Rayleigh equations of hydrodynamics. The correction, as you see, alters the constant factor in the result. I have recalculated the curves of Fig 9 accordingly, and have also added some experimental points obtained since the time of writing. The results are not precise enough to show any different agreement with the corrected curves, which are shifted by a small amount. Further experiments are in progress.

R. SHUTTLEWORTH*—Goodier³⁰ has pointed out that the problem of the steady flow of a viscous fluid and the elastic displacement of an incompressible solid are mathematically identical. Suppose that two isotropic homogeneous bodies of the same shape—one purely elastic and incompressible, the other purely viscous—are loaded in the same way; the displacement of the elastic body is given by the product of μ and a function of position, while the velocity in the viscous case is given by the product of η and the same function, where μ and η are the shear modulus and the coefficient of viscosity.

It is useful to apply this correspondence to the calculation of the rate of shrinkage of a viscous fluid that contains a large number of equal spherical pores, of radius R , due to surface tension (Dr. Shaler's model of sintering). The elastic problem is the deformation of the corresponding body formed from an incompressible but shearable material, due to a hydrostatic pressure $-2\sigma/R$ inside all the pores and zero pressure outside the body, where σ is the surface tension. Because the material is incompressible the deformation depends only upon the pressure difference between the inner and outer boundaries (this immediately follows from principles of superimposition of strains and the proportionality of stress to strain); the problem thus reduces to the deformation due to a hydrostatic pressure $+2\sigma/R$ outside the body and zero pressure inside the pores.

The hydrostatic pressure produces shears in the walls separating the pores, which cause a reduction in volume of the pores (the volume of the solid, of course remains constant). It is possible to treat the body as a homogeneous continuum, and every element of volume V (supposed so large that it contains many pores) has a simple dilatation strain dV/V which is independent of the size and shape of the body, and of the position of the element. The displacement be-

FIG 14—The increase at relative density with time at sintering.

tween any two points is proportional to their initial separation.

To make the theory quantitative it is necessary to find a relation between the dilatation and the pressure $2\sigma/R$. Here the approximation is made that the decrease in volume of a porous sphere is the same whether the pores are uniformly distributed or are all collected together at the center of the sphere. Love³¹ gives an expression for the radial displacement μ of the outer surface of a solid shell with internal and external radii a and b , due to an external pressure, from this expression

$$\frac{dV}{V} = \frac{3u}{b} = -\frac{3}{4\mu} \frac{a^3}{b^3 - a^3} \frac{2\sigma}{R}$$

A more accurate calculation could perhaps be made along the lines indicated by Bruggeman.³²

The relative-density ρ is defined by, $\rho = V_m/V$ where V_m is the volume of metal in an element of volume V , therefore

$$\frac{dV}{V} = -\frac{d\rho}{\rho}; \frac{a^3}{b^3 - a^3} = \frac{1 - \rho}{\rho}$$

If there are n pores per unit volume of metal, then

$$\frac{1}{R^3} = \frac{4\pi}{3} \frac{\rho}{1 - \rho} n$$

n can be calculated from the initial density and the initial pore radius; it does not change with time. And so

$$d\rho = \frac{3}{2} \left(\frac{4\pi}{3} \right)^{1/3} \frac{\sigma n^{1/3}}{\mu} \rho^{1/3} (1 - \rho)^{2/3}$$

In the viscous case each element of volume (together with its pores) flows towards the center of the spherical specimen with a velocity which is proportional to its distance from the center. The rate of decrease $-dV/dt$ of an element of volume V , corresponds to the decrease of volume $-dV$ in the elastic case:

$$\frac{d\rho}{dt} = \frac{3}{2} \left(\frac{4\pi}{3} \right)^{1/3} \frac{\sigma n^{1/3}}{\eta} \rho^{1/3} (1 - \rho)^{2/3}$$

The density increases uniformly throughout the whole body, at a rate which is independent of the size and shape of the body. When the last equation is integrated the relative-density is obtained as a function of time t ,

$$\frac{\sigma n^{1/3}}{\eta} t = \frac{2}{3} \left(\frac{3}{4\pi} \right)^{1/3} \int_{\rho_0}^{\rho} \frac{\rho}{\rho^{1/3} (1 - \rho)^{2/3}} d\rho = \Phi(\rho) - \Phi(\rho_0)$$

where ρ_0 is the relative-density at time $t = 0$. I am grateful to my colleague Mr. J. K. Mackenzie for evaluating the integral $\Phi(\rho)$, which is plotted in Fig 14. With the substitution $x = (1 - \rho)^{1/3} / \rho^{2/3}$, the integral can be expressed in terms of known functions. If Dr. Shaler's model is correct this equation enables the ratio σ/η to be found from the variation of the density of a powder compact with time.

Dr. Shaler, in his treatment of this problem, ignored the fact that all the pores in the body are closing simultaneously; and found that the velocity of flow decreased with the distance from a pore. This is not correct. An observer situated at the center of a pore and moving with the pore, who smooths out the change in direction of flow around the other pores, will observe that, at distances larger than the separation at pores, the velocity of flow increases in proportion to the distance.

Summary

Dr. Shaler's treatment of the rate of increase of density of a porous body is not valid, because he does not take account of the simultaneous closing of all the pores. A treatment based on the solution of the corresponding elastic problem shows that the relative-density ρ increases with time t according to the equation,

$$\frac{\sigma n^{1/3}}{\eta} t = \Phi(\rho) - \Phi(\rho_0)$$

where n is the number of pores per unit volume of metal (that is, it does not change with time) and the function $\Phi(\rho)$ is shown in Fig 14.

A. J. SHALER (author's reply)—I thank Dr. Shuttleworth and his colleague, Mr. Mackenzie, for the excellent discussion and for providing us with an explicit solution to the function F which I have left unintegrated. The possible skin effect, or size effect, described in the Udin, Shaler and Wulff paper¹³ may make it necessary to alter both Dr. Shuttleworth's model and my own. In the case of Dr. Shuttleworth's model, the change would lead to a more serious drawback, for it would be necessary to evaluate in a new light the validity of the approxima-

* H. H. Wills Physical Laboratory, Univ. of Bristol, England.

tion of a porous compact by a solid body with a single cavity at the center, and also the validity of extending his solution to other than spherical compacts, two unnecessary evaluations in the case of my analysis, in which the relative density is introduced into the graphical integration of F as an experimental value. A second drawback to the use of Dr. Shuttleworth's explicit solution is that the value of ρ_0 at the end of the first stage of sintering is not known, so that the value of the constant $\Phi(\rho_0)$ must in any case be deduced from experimental results.

Dr. Shuttleworth's criticism concerning the velocity of flow decreasing with distance from a pore is not in accord with the condition of continuity. For the same volume of porous material must cross each concentric spherical shell centered at any pore or at any point in the compact in the same differential time interval, during which the density is changing by the same amount throughout the compact, as he demonstrates. Hence, the velocity of any element towards the center of the shells is inversely proportional to the square of the distance. It is also inversely proportional to the density, a factor which was not left out of my equations, and appears in the function F for that reason. Dr. Shuttleworth's observer situated at the center as a pore is subject to much the same illusion as the astronomer on earth observing the recession of nebulae in an expanding universe.

G. F. HÜTTIG* (*Condensed version of translation*)—The first part of Hüttig's discussion is concerned with Shaler's distinction between "transient" and "steady state" phenomena or mechanisms in the sintering process. Hüttig considers possible different definitions of the words "mechanism" or "phenomenon," investigates whether the distinction between "steady state" and "transient" is possible on the basis of each of these definitions and comes to the conclusion that the distinction cannot be justified.

Hüttig further takes issue with Shaler's interpretation of his own theory: "I cannot agree that all the phenomena which form the basis of my theory can be considered transient for the following reasons:

"1. Even if the phenomena which I have considered are followed at higher temperature by other phenomena which complete the sintering process, this in itself would be no proof that the phenomena considered by me are transient." Hüttig argues that Shaler does not observe the final result of the sintering process, namely, a single crystal, and that it is therefore conceivable that at sintering times even longer than those employed by Shaler new phenomena are observed.

"2. It is not correct that my theory is based only on processes which are 'sub-

*Inst. f. Anorg. u. Phys. Chem. d. Tech. Hochschule, Graz, Austria.

FIG 15—Representing atoms in lattice.

stantially completed in a matter of hours at temperatures considerably below those generally used in sintering.' I have taken into account all the sintering phenomena which were described in the literature up to 1941. There were 85 publications not including my own. Data on the sintering process of the metals Cu, Fe, Sn, Pb, Au, Ni, Mo, W and Al were found. Also the literature on the sintering process in oxides and other materials was collected, including data on the oxides Fe_2O_3 , ZnO , BeO , CuO , Fe_3O_4 , NaCl , organic materials and glasses. Of the properties by which the progress of sintering was measured, the following may be mentioned: electromotive forces, solubilities and chemical reactions with various liquid media, adsorption isotherms of methanol vapor and data calculated from them, densities in the vacuum pycnometer, apparent density, catalytic effects, electrical resistivities, gas evolution, strength, hardness, grain growth measured microscopically and by X rays, adsorption of dissolved dyes, and so on. All observations are presented in graphical form, in such a way that they can be compared with one another, in *Kolloidzeitschrift*, (1942) 98, 6-33. On the basis of these data a theory which takes into account all the sintering phenomena was developed in *Kolloidzeitschrift*, (1942) 98, 263-286. Other investigations based on the same methods concerned systems of two components, that is, mixtures of powders. This finally led to a theory which covers not only the sintering of single metals, but all types of chemical reactions in the solid state. These results are presented systematically in *Handbuch der Katalyse*, Vienna (1943) VI, 318-577.

"I wonder is it possible that a theory which takes into account such extended material can find its rightful place in Shaler's section on transient phenomena, which comprises only 34 typewritten lines."

Regardless of his criticism of Shaler's distinction between steady state and transient phenomena, Hüttig states: "The paper contains so much new material and new ideas, that I believe it may become a turning point in powder-metallurgical research. The ideas are not always easy to comprehend and the following is therefore meant more as com-

ment than as criticism.

"1. The paper by Sackmann, Burwell and Irvine⁷ is closely connected with the results of Thirsk and Whitmore (*Trans. Faraday Soc.* (1940) 36, 862. Other papers which concern the same phenomenon are quoted in *Handbuch der Katalyse*, VI, 474-479 and 539-544.

"2. With regard to Shaler's concept of the electron density distribution on the surface of a metal I wonder whether the method of Grimm, Brill, Hermann and Peters who determined electronic densities by means of Fourier analysis of X ray diffraction data could not be applied also to the surface layers, perhaps on the basis of electron diffraction measurements. This may result in a direct confirmation of Shaler's concept.

"3. In order to provide experimental support to the ideas about the role which a gas plays in sintering I should like to suggest the following experiment: The progress of sintering should be investigated (a) in a vacuum, (b) under a pressure of one atmosphere, (c) of 10 atm. (d) of 100 atm. of an inert gas such as argon or helium. What differences are observed, if the other experimental conditions are held constant?

"4. I am trying to develop a simple model in order to visualize Shaler's concept of the energy and force relationships in a capillary. (Regarding the use of such models see my paper together with Joos on the energy of crystal lattices (*Ztsch. Elektrochem.* (1926) 32, 294); W. Biltz and H. Grimm's calculation of the lattice energy of ammonia compounds (*Ztsch. anorg. Chem.*, 145, 63; and Pfeiffer and Goldschmidt's application of the idea of coordination number to the systematics of crystal lattices. Such a picture may possibly serve as a basis of discussion.

"Every atom tends towards a minimum free energy content. No important error is introduced when, in this statement, total energy is substituted for free energy. Fig 15, representing the atoms in a lattice, is drawn in two rather than in three dimensions and my discussion refers to this simplified two dimensional model. The heavy line represents a cross-section through the surface of a crystal.

"The atoms in the interior, A, have a minimum of energy. They therefore represent the most stable arrangement. All four positions of nearest neighbors are filled. Next in line with regard to increasing energy content are the B-atoms whose three nearest-neighbor positions are occupied (subdivided into B_1 , B_2 , B_3) then C with 2, D with one nearest-neighbor position occupied, and finally E, a freely diffusing atom with the highest energy. In a three dimensional model the coordination numbers (numbers of nearest neighbors) have to be changed accordingly.

"The surface energy is that energy which has to be expended to bring an A

atom into a B position (in general a B₃ position). The same amount of energy is given off when a surface atom becomes an atom in the interior. The surface tension in dynes per cm is identical in numerical value and dimension to the surface energy in ergs per cm². The pressure which is exerted is always directed towards the mass, that is, in the direction which tends to fill the nearest neighbor positions and never in the direction of the empty space of the capillary. The entire system reaches a minimum in free energy, that is, the most stable state, when all geometrically possible movements in the sequence E-D-C-B₃-B₂-B₁-A have taken place. This process must be connected with the filling up of the capillary. All ideas which cannot be brought into agreement with this simple picture are to me very difficult to comprehend.

5. I should like to underscore three times the sentence in the conclusion: "The sintering process is an extremely difficult one."

A. J. SHALER—I thank Dr. Hüttig for his able and kind discussion, and regret that it could not be given in full. Doubtless it is dangerous, as he and others taking part in this discussion have stated, to try to dissect the interrelated parts of the sintering process without great care; it is nevertheless a very necessary part of the scientific method, and one of which Dr. Hüttig has made full use in the papers he quotes. The separation of the process into "steady state" and "transient" "mechanisms" and "phenomena" can be debated on semantic grounds, a debate which loses as much value through the imperfection of definition in our own tongue as through the additional loss of clarity attendant upon translation. That I have dealt with Dr. Hüttig's work in but a few lines in no way reflects on my part poor judgment of its importance, but rather an acceptance of the fact that he has given as final a treatment of some of the "transient" mechanisms as I had hoped to do with some of the "steady-state" phenomena. Dr. Hüttig's suggestions concerning further refinements are welcome. Some are even now being explored. His picture of the surface energy is oversimplified. It is more useful in dealing with ionic inert-gas crystals than with metals as Dr. Shuttleworth has pointed out (The Surface Energies of Inert-Gas and Ionic Crystals. *Proc. Physical Soc.* (1949) A 62, 167) in his statement: "In metals the surface energy is best regarded as arising from the change in kinetic energy of the free electrons due to the presence of the surface."

F. N. RHINES*—One matter that I would like to mention concerns the classification of the various steps in sintering. As a process in the scientific thinking, we very properly try to break up complex

processes into small parts in order that we may look at them one at a time and thereby gain an understanding of the whole process through more simple steps. In so doing, however, I think that we should be very cautious about naming the individual steps, or about intimating that one step occurs at one time and another at another. It seems to me that the steps that Dr. Shaler has mentioned really overlap so much that all of them are going on, to some extent, most of the time. This is rather a case of one process being predominant at one moment and another being predominant later so that, perhaps, we would confuse ourselves less if we referred to the several processes without intimating so definitely that each one is associated with a specific time.

The data that I want to present are from what was to have been a paper for this meeting. Unfortunately the work was not completed in time but it is so definitely on this subject that I would like to put some of it before you.

We at Carnegie Tech have, over a period of some years, been studying the sintering process by observing the change in size and number of pores in lightly pressed compacts sintered at various temperatures and for various times in various atmospheres. I shall confine what I have to say mainly to sintering in hydrogen and at the higher temperatures, because the effects that are observed are most obvious under these conditions. Density measurements, made at intervals from 10 min. to 1000 hr at 800, 900 and 1000°C, exhibit a progressive increase, at a diminishing rate, at each temperature, the change being most rapid at 1000°C. From this observation one must conclude, as Dr. Shaler has done, that the *total volume of porosity* in the samples has been decreasing progressively. I emphasize this point to make it clear that, so far as the density measurements are concerned, there is no difference between his results and ours, because, beyond this point, our paths diverge. Our microscopic observations show very clearly that one should not further conclude that, individually, the pores are diminishing in size.

Microscope counts of the number of pores as a function of size, in single samples, show that the number rises from near zero at the smallest discernible size (of the order of 100Å in diam) to a maximum number at some intermediate size, then decreases, rapidly at first, in progressing to larger size and, then, more and more slowly, a zero number is approached just above the largest size present. With increased sintering time, the total pore count (including all sizes) diminishes and the maximum count shifts to larger pore sizes, but there is an actual increase in the number of pores of sizes greater than that at the size of the maximum count and there are a few pores of larger size than the largest observed at shorter sintering time. In other

words, the larger pores are all growing at the expense of their smaller neighbors, while the smallest pores are vanishing altogether.

This is the experimental evidence. I have given just one example out of a good many that were studied, but they all follow this same pattern. We have made an effort to devise a mechanism to describe what happens to account for these observations and I would like to outline this rather briefly.

Taking a somewhat different, but I am not at all sure that it is a fundamentally different viewpoint from that of Dr. Shaler, we have assumed that the transfer of vacant space required to bring about the changes in pore diameter is accomplished by the diffusion of vacant lattice sites. We assume that the number of vacancies present in the lattice varies from place to place in the piece of metal under the influence of the surface tension at the boundaries of the pores and at the external surface. Adjacent to a small pore the number of vacant lattice sites will be large, because the higher surface tension of the small pore will increase the probability of the birth of vacancies at its bounding surface; similarly the concentration of vacancies will be less next to a large pore and still less near the external surface of the sample. This gives rise to a complex pattern of lattice vacancy concentration gradients, such that the vacant sites will tend to diffuse away from the smallest pores and toward larger pores and the external surface.

Using the surface tension value for copper, found by Udin, Shaler and Wulff, and applying conventional assumptions with regard to the variation of the lattice vacancy concentration with surface energy and with regard to the rate of diffusion of vacancies, Dr. Birchenall has succeeded in computing the change in the number of pores of each size during a stated time interval at 1000°C. His results agree very well with the observed changes. This encourages us to believe that the mechanism that I have outlined may be reasonable.

The mathematical method that Dr. Birchenall has been forced to use is, unfortunately, very cumbersome. (It is similar to the well known analysis of the growth of water droplets in equilibrium with water vapor.) For this reason, it is taking a rather long time to test the theory on all of our observations; this work is currently in progress.

I would like to add to what I have said a few comments with regard to what all this means in connection with Dr. Shaler's paper. The main conclusion that we seem to have reached is this: all except the smallest pores grow during sintering, but the rate of the disappearance of the smallest pores is such as to produce an over-all reduction in porosity. This may be hard to understand unless it is appreciated that all outdoors is a pore too and

* Carnegie Institute of Technology.

there is diffusion of vacant space into the space surrounding the sample. That is, the increase in density must be due to the diffusion of vacant lattice sites through the external surface. This would lead us to the conclusion that the rate of density change depends upon the initial number and size distribution of the pores, the amount of external surface and the thickness of the compact. I believe that it is often observed, commercially, that the smaller compacts do reach maximum density more rapidly than large compacts. My impression is that if we had a compact of infinite size the only thing that would happen would be that there would be a tendency for all the pores to agglomerate into one great big one of the same volume as the total porosity. There would be no change in density whatever. When we have an external surface some of the vacant space goes to the external surface and is lost; that gives us our densification. The more the external surface per unit of volume, the greater the rate of densification. In a compact of small size there would be, after many hours of heating, many more pores in the interior than near the surface.

Further, it seems to me that our observations are telling us that it is risky to assume, as Dr. Shaler has done in his experiments, that the pore size obtained by piling up sorted powders is really what one would compute on the assumption that there are always the same number of pores and that the change in density results from their decrease in size. I think that is not right. Some of the pores are disappearing altogether all the time, while others are growing.

Finally, I should like to make brief mention of another interesting case: that of sintering in argon. When we observe the changes in pore diameter on sintering in argon we find that, in the early stages, the process looks just like sintering in hydrogen, as described here, but at the highest temperatures and after a long time, we found a reversal in the trend of density change. That is, there was an increase in the total porosity late in the sintering process.

We think that the explanation may be this: not only must we take account of the movement of vacant space, when we are sintering in an atmosphere rather than a vacuum, but there must be movement of the gas within the metal. This is also a diffusion process, and the rate of diffusion of the gas may be quite different from the rate of diffusion of the vacant lattice sites. If the rate of diffusion of the gas is high, we may expect that the gas will get away, (disappear through the surface of the specimen), because of the squeezing down of the pores, with a consequent building up of the pressure. But if the rate of diffusion of the gas is slow, it is much less likely that the gas will reach the external surface at a rate corresponding to the change in total pore volume. Now,

suppose that we transfer a given amount of gas from a given volume of little pores to the same volume of big pores. The little pores will have high surface tension; the big pores low surface tension. The little pores can sustain a higher pressure of the gas so that when the gas is moved on into the larger pores it will cause them to expand.

A. J. SHALER—We are all anxious to read the full account of the work of Drs. Rhines and Birchenall, and I am grateful to Dr. Rhines for presenting so much of it here. I should like to comment on some of the points he has made with a view to discovering if and where important differences exist between his views and mine.

I appreciate his very valid criticism of my attempt to separate the sintering process into steps, which in reality overlap one another to a great extent. In my model, which is only a first approximation to reality, two assumptions are made: (1) the pores are assumed to be far apart, and (2) they are assumed to be all of the same size. In my synthetic cylindrical pores I have tried to proceed according to the first. In the experiments on compacts I have tried to use spherical particles all of the same size in order to approach the second assumption.

F. N. RHINES—May I say, in connection with this, that you would have to be a micro-olive packer to get that condition experimentally; when you pile up spheres you are going to have some bridging, and it is inconceivable to me that, experimentally, you could even have, initially, all one size of pore; this situation would get progressively worse as you went on in sintering.

A. J. SHALER—That is correct. You have in that respect carried out the refinement, which I have not yet wanted to make, of dealing, not as I have with an impractical simple system, but with a practical and very complicated one, judging from the complexity of your equations.

The observations given by Dr. Rhines concerning the pore-size changes in copper sintered in hydrogen and in argon are not in disagreement with my results, although I have not carried out a quantitative analysis of the case of a diffusing gas—hydrogen—trapped in the pores. In both cases, the smallest pores first shrink to a small size, stable in the case of argon, but, with hydrogen, subsequently decreasing at a slower rate depending on the diffusion path of the hydrogen. At later times, successively larger pores shrink by lesser and lesser amounts. Later still, pores larger than a critical size swell instead of shrinking, and again, in argon, reach stable equilibrium sizes. In hydrogen, the swelling of pores of these sizes is followed by shrinkage as the gas diffuses out. Such developments should give the same qualitative change in pore counts

as those observed by Dr. Rhines, although in my analysis I have neglected the effect on each pore of the presence of neighboring pores of greater and smaller sizes. My results indicate that, in argon sintering, there should be observed a fairly large stable pore count at very small sizes. The absence of these in Dr. Rhines' observations may be due to their being too small to be seen in the microscope; alternately, the surface tension may be sufficient to drive the residual argon into solution in the metal, notwithstanding the low solubility of this gas in copper.

F. N. RHINES—I do not think there is any evidence of a large pore count at submicroscopic size. As observed with a microscope, the pore count is decreasing at an accelerating pace all the way down to the smallest visible size. The larger pores are not shrinking; they are all growing, but the smallest pore is vanishing. I am not sure that I have got my point across yet. The point that I am trying to make and the way that I see this thing is that every pore must receive vacancy from outlying space so long as there is any pore around it that is smaller, so that we observe only growth of pores, or their total disappearance.

A. J. SHALER—Not in argon.

F. N. RHINES—No, but in hydrogen.

A. J. SHALER—The mechanism whereby pores change in size and compacts change in density by the movement of lattice vacancies is not quite the same in Dr. Rhines' view as in mine. He first establishes a gradient of vacancy concentration, then states that vacancies will diffuse down the gradient. In his treatment, as in those of Pines and Kuczynski, vacancies are treated very much as if they were atoms of matter soluble in the metal, present in mass inside the pores and outside the compact, and diffusing through the metal. Shrinkage of the compacts follows if it is shown that the vacancies are more highly "concentrated" in the small pores than in the large ones; the outlying space being the largest pore of all. Such concentration differences are ascribed to the radius-sensitivity of the pressure due to surface tension.

In my view it is not necessary to have vacancy-concentration gradients. A mechanical flow takes place by motion of vacancies under the influence of mechanical stresses due to surface tensions and gas pressures. The rate of this flow was calculated by Frenkel on the approximation that no vacancy-concentration gradients exist. In criticism of Frenkel's analysis, Nabarro (private communication) has pointed out that a single vacancy cannot be persuaded to move under a unilateral stress, but a way out of this difficulty was suggested (*Physical Rev.*, 73, 8, 926, Apr. 15, 1948).

I should like to inject a note of caution in evaluating attempts to explain mechanical behavior purely on a diffusion basis. Dissolved atoms or vacancies require an activation energy before they can diffuse. It is not sufficient, as it is in the diffusion of tenuous gases, that there be a concentration gradient. If external causes, such as the presence of surfaces of various curvatures, require local readjustments of vacancy concentration in order to minimize the free energy, then the concentration gradients are not in themselves driving forces for diffusion, because a decrease in gradient would increase the free energy. It is conceivable that a region of metal near a pore has the same flow characteristics as one far from a surface, although the former may contain many more vacancies.

It appears preferable to try to solve mechanically the mechanical problem of metal flow under stresses due to surface tension and gas pressures. The growth of large pores, which standing alone would shrink, when they are surrounded by many small ones, may be simply due to the addition of a radial tension, due to the shrinkage of the small pores, on the stress field. The system is equivalent to a hollow sphere with externally applied hydrostatic tension. That Dr. Birchenall's calculations agree well with observation is evidence that in this case the distinction between a direct mechanical solution and a diffusion solution is a semantic one only, and that our explanations are not fundamentally so different as might at first appear. The approach of Drs. Rhines and Birchenall is probably on safe ground, but that of Drs. Pines and Kuczynski is not, in my opinion, as I shall try to show in answer to the latter's remarks.

Dr. Rhines' conclusion that the rate of shrinkage depends on the size of compacts is probably true, but in both his and my model the effect must be limited to a very thin skin; it should be observable only on very tiny compacts. The commercial observations to the contrary can be better explained on the basis of the size-sensitive outward diffusion of hydrogen compressed within the pores, as described above. It should not be observed on compacts in which vacuum or a noble gas only is present within the pores.

I am happy that Dr. Rhines has found experimental evidence that pore shape has little influence on kinetics of sintering, a fact deduced theoretically in my doctoral thesis (Mass. Inst. of Technology, June 1947).

E. OROWAN*—Dr. Shaler's conclusion that the attractive force between metal surfaces has a range of several hundred Angstroms is difficult to accept. During his lecture I have calculated, on the basis of his formulas, the critical diameter for which the long-range attraction between two equal copper spheres in

contact would just balance their weight; in other words, the maximum size at which we could lift up a copper sphere by means of another similar sphere in contact with it. I have repeated the calculation in another way, with the same numerical result, that is, that the critical size would be between 5 and 10 mm. If both Dr. Shaler's and my calculations were correct, therefore, metal balls of $\frac{1}{4}$ in. diam could be picked up with another similar ball as with a magnet.

A. J. SHALER—The calculation I have made for the attraction between two surfaces indicates forces greatly in excess of the technical fracture stress of copper, but not in excess of the theoretical cohesive strength calculated by the physicists for a perfect lattice. There is some experimental evidence in support of this result. Notably, Sackmann, Burwell, and Irvine (reference in paper) brought riders of copper, containing radioactive copper, gently down onto steel surfaces, and then removed them, as carefully as possible in order to prevent lateral movement. Copper could then be detected on the steel surface, indicating that the attraction between the two surfaces was greater than the fracture strength of the copper.

E. OROWAN—This can be the result of a short-range force; a short-range attraction alone, however, would not lift a copper ball by another copper ball because the force would be restricted to an extremely small circle of contact.

A. J. SHALER—I believe we are verbally performing two separate experiments. The first of these is to allow the two balls to come within a few hundred Angstroms of one another. The force of attraction will then bring the two balls into contact. The second experiment is to separate them, by allowing the weight of one to exert a tensile stress on the area of contact. As in the tensile test, the tension required to cause fracture is very low (ca. 10,000 psi for copper) compared with the strength of the bond between lattice nets. The reason for the discrepancy is still the subject of debate among fracture-theorists, but it may well reside in defects brought into being by plastic flow. A recent analysis and calculation made in our laboratory of a tensile test under pressure performed by Bridgman indicates that a stress of over 170,000 psi normal to an inactive slip plane was insufficient to cause fracture in copper, whereas fracture occurs in this metal when a stress of only 8500 psi is exerted in a direction normal to active slip planes. The two balls, one suspended from the other, are very much like a tensile specimen, and one would expect slip to take place first, followed by fracture at the consequently lowered stress value. The second experiment does not, then, invalidate the result of the hypothetical first experiment.

E. OROWAN—We can assume that the experiment with the two copper balls can be carried out so that there is no plastic deformation in either.

A. J. SHALER—Can we so assume? If the fracture problem were solved, I think it would be possible to analyze the problem of the two balls more adequately; I am not sure that it reduces the result of my calculation to absurdity. In the meanwhile, I should be embarrassed to have to lift one $\frac{1}{4}$ in. ball with another!

E. OROWAN—The assumption of forces that act over distances of several hundred Angstrom units is not only unlikely from the theoretical point of view; it also leads to immediate difficulties of which I have already mentioned one (the very large attractive forces that would act between spheres in contact). Another difficulty is this. When fracture occurs between two parts of a brittle solid, the work of the cohesive forces between the fragments must be of the order of the total surface energy of the surfaces of fracture. So long as these cohesive forces are small, they are determined by Hooke's law; in order to obtain the correct order of the surface energy, however, we have to assume that they cease to obey Hooke's law and begin to diminish when the increase of the atomic spacings between the two fragments becomes a substantial fraction of the initial interatomic spacing. If the cohesive forces continued to act over hundreds of Angstroms, the resulting work of separation would be several powers of 10 higher than the surface energy.

A. J. SHALER—The departure, which you describe, of the cohesive force from Hooke's law is shown by the well-known Morse curve, which is made up of a repulsive term, becoming negligible at a separation of several Angstroms, and an attractive term, extending to much greater distances. The resultant curve ceases to rise linearly and then reaches its maximum very nearly at the point where the repulsive term disappears; thereafter the contribution of the attractive force to the surface energy falls off. It is this part of the curve which I have calculated, making the usual simplifying assumptions. It may be that the surface energy calculated on this model is not so much greater than the observed value as Dr. Orowan believes. It is not possible to perform the calculation without a knowledge of the remainder of the curve.

E. OROWAN—That would amount to the assumption that the area below the Morse curve up to its maximum was a tiny fraction of the total area below the curve. This is only another way of postulating attractive forces of extremely long range.

G. C. KUCZYNSKI*—Dr. Shaler, what kind of an approximation did you use to calculate your forces?

* Sylvania Electric Products.

* Cavendish Laboratory, Cambridge, England.

A. J. SHALER—The electron density is calculated from the Fermi equation; the potential falls quadratically from a value at the surface equal to the work function.

G. C. KUCZYNSKI—I am afraid there is something wrong in these calculations. The electron wave functions do not extend very far. After few atomic distances they are overlapping and therefore the exchange forces are negligible.

A. J. SHALER—Dr. Kuczynski states that there is a considerable difference between the viscous flow mechanism and what he calls the volume diffusion mechanism. Since Frenkel's analysis is also based on volume diffusion, I fail to see how Dr. Kuczynski reaches this answer. I should like to see more of the calculation. For the coalescence of strings of spheres, treated as a one-step viscous flow process, I found an unreasonable value of the heat of activation for self-diffusion of some 30,000 cal per mol for copper. I do not see why Dr. Kuczynski should get 55,000 instead of 30,000.

G. C. KUCZYNSKI—I beg to differ with you, but the mechanism described in Frenkel's treatment of this problem is clearly stated as viscous flow and not diffusion flow.

The difference between the viscous flow and diffusion flow mechanisms is the following: In the case of the former mechanism no concentration gradient is required. The atoms move preferably in the direction of applied stress. In the case

FIG 16—The variations of the coefficient of self-diffusion of copper with absolute temperature T , plotted on the semi-logarithmic scale. The points calculated from the data obtained by Dr. A. J. Shaler as represented in figure.

of diffusion flow on the other hand there has to be a gradient of vacancy concentration (or interstitial atoms). These two mechanisms represent different types of flow and their rates are different.

The relationship between the radius of the interface x and time t will be:

for viscous flow $-x^2 \sim t$ and
for diffusion flow $-x^5 \sim t$
The decrease of the radius of the spherical void r with time will be:

for viscous flow $-r = r_0 - \alpha t$ and
for diffusion flow $-r^3 = r_0^3 - \beta t$
where r_0 is the original radius of the void and α, β functions of temperature only.
On the basis of the relationship for diffusion flow the heat of activation equal to 55,000 cal per mol was obtained using your data. The plot of self-diffusion coefficient as the function of $\frac{1000}{T}$ on the semi-log scale is given in Fig 16.

A. J. SHALER—My reasons for breaking the process into two steps are given in detail in the paper. These reasons are supported by the results that Dr. Duwez presented to us this morning, in which sintering-rate curves for copper could by no stretch of the imagination be extrapolated continuously to the origin; to do so may introduce an unwarranted simplification. The fact that experimental points fall more or less on a straight line when one coordinate is a high power of one of the variables is a dangerous spring-board from which one can easily jump to arid conclusions.

G. C. KUCZYNSKI—There is no reason to separate your parabolic curves into two portions. If the correct functions were found, as I have shown in the case of the diffusion flow, these curves can be plotted as the straight lines which pass through the origin (Fig 17).

FIG 17—The plot of $\theta^5 = \left(\frac{x}{a}\right)^5$ where x is the radius of the interface and a the radius of the particles against the time of heating t in hours. The values of θ were taken from Dr. A. J. Shaler (Fig 6). It should be noted that straight lines are obtained instead of parabolic curves indicating that diffusion flow is responsible for bonding of the particles together.

FIG 18—(a) Round copper particle sintered to nickel block at 950°C for 24 hr in hydrogen. Mag 700 X. (b) Round nickel particle sintered to copper block at 1020°C for 48 hr in hydrogen. Mag 200 X.

Both specimens were nickel plated after heating. Black spots inside the particles were blow holes caused by reduction of oxides in the hydrogen. Reduced one-half in reproduction.

A. J. SHALER—Dr. Kuczynski has shown a photograph of changes in shape during sintering of a copper sphere on a nickel plate, and also of a nickel sphere on a copper plate. I fail to see how these changes can help us to distinguish between a viscous flow based on diffusion or any other kind of flow based on diffusion.

G. C. KUCZYNSKI—I only showed this picture (Fig 18) to demonstrate clearly that the bonding of the metallic particles is not a result of viscous flow. Only diffusion phenomena can account for the peculiar shape of interfaces.

H. UDIN*—Dr. Kuczynski uses as a model for his sintering calculations a sphere on a plane, and then as sintering progresses material fills in at the fillet. I do not understand where this material comes from. I should like to ask Dr. Kuczynski if he is positive that his fifth power relationship comes from the actual mechanism of sintering, not from the geometry of the model.

G. C. KUCZYNSKI—Of course, the material comes from the particles.

F. N. RHINES—Do I understand that, in your derivation, you are saying that the copper that is filling these fillets is coming from the center of the sphere?

G. C. KUCZYNSKI—Some.

F. N. RHINES—You will develop a shell.

G. C. KUCZYNSKI—There will be

no shell. The atoms move from the body of the particle to the “neck” and the holes are diffused out to the surface.

F. N. RHINES—Eventually you must then be taking the copper from the external surface. The question in my mind is whether you would get the same mathematical expression if you wrote it on the basis of picking your copper atoms out of the surface and transferring them through the center and out to the fillet. You seem to have left the second element of the process out of the computation, the element of moving the atom from the surface into the vacated space.

G. C. KUCZYNSKI—No, it was taken care of by the diffusion coefficient.

A. J. SHALER—In Dr. Kuczynski's model the flow of material to the neck from the surface of the particle may take place by one of two paths. Either the atoms diffuse along the surface, in which case the flow of material cannot lead to densification of the compact, but only to an increase in the area of contact (spheroidization of the pores). Or the atoms diffuse through the metal in two steps; first, along a vacancy gradient, to the neck from a region inside the particle near the neck; and, second, from the surface to that region. For the second step there exists no vacancy gradient to accelerate diffusion. It is therefore the slower and the limiting step, so that the kinetics of the process should be based on a flow mechanism requiring no vacancy gradient; that is, something similar to the viscous flow we have been discussing. Furthermore it is questionable to base

the mechanism of flow even for the first step on the existence of a forced vacancy gradient; for in this case the vacancy gradient exists only in order to remove the free-energy gradient which would otherwise exist by virtue of the surface tension acting on the curved neck surfaces. A vacancy gradient alone is not sufficient for diffusion; if there is no free-energy difference between one end of the diffusion path and the other, the units of flow cannot acquire the activation energy required for motion. Therefore the first step of Dr. Kuczynski's volume diffusion process is not valid, and we must return, for a solution to the spheroidization step in sintering as well as to the densification (or swelling) stage, to a mechanical approach. In fine powders, as Dr. Kuczynski has shown, the surface-diffusion mode of spheroidization may be dominant, but densification of the compact must still occur by flow under the stresses described in my paper.

G. C. KUCZYNSKI—The process here is controlled by the slower reaction, namely self-diffusion throughout the main body of the particle. The high concentration of vacancies near the “neck” does not accelerate the rate of diffusion appreciably on the overall scale. Some variations should be noticed in the coefficient of self-diffusion (increase for the vacancy mechanism, and decrease for the interstitial atoms mechanism) during sintering of particles of only a few hundred Angstroms in diameter. But probably even in such an experiment the volume self-diffusion would be completely masked by surface diffusion.

Relative Deoxidizing Powers of Some Deoxidizers for Steel

(With Discussion)

C. E. SIMS,* Member, H. A. SALLER,* and F. W. BOULGER,* Member AIME

Introduction

Most of the data on equilibrium constant and the deoxidations potentialities of those elements, considered to be stronger deoxidizers for steel than is silicon, have been calculated from thermodynamic data. The reason for this is, primarily, the obvious difficulty of obtaining direct experimental evidence of equivalent accuracy. This is an excellent use of the principles of thermodynamics and has given valuable data not otherwise available. Such results, of course, can be no more accurate than the physical constants used in the calculations, and one can never be sure that the basic data are either complete or accurate.

In fact, as in the case with silicon,¹ there are not only discrepancies among the calculated theoretical values of the equilibrium constant for deoxidation of steel but also between the theoretical and experimental values. It is highly desirable, therefore, to obtain experimental values for checks on calculated results whenever possible. If they disagree, both cannot be right, but if there is good agreement, their value is enhanced.

The present work was done in an effort to obtain experimental evidence in regard to some of the common alloying additions but more particularly the so-called "strong" deoxidizers for steel. The method used was to determine the minimum concentration of the deoxidizer that would effect a certain definite degree of deoxidation in steel. The criterion of deoxidation was the change from the large globular Type I sulphide to the eutectic Type II as described by Sims and Dahle.² This change is sharp and definite, and inasmuch as it can be produced with equal facility by aluminum, zirconium,

and titanium, it is considered a manifestation of a certain degree of deoxidation and not an alloying effect.

Ostensibly such a procedure could give only a comparison of deoxidizing powers and no absolute values. Nevertheless, repeated observations have shown that, when increasing increments of aluminum are added to a steel, the residual aluminum content begins to increase simultaneously with the appearance of Type II inclusions. Thus it seems warranted to postulate that the Type II inclusions appear coincident with the virtual elimination of FeO as an active constituent of the steel.

Experimental Procedure

The data obtained were primarily from the microexamination of polished and unetched specimens and from chemical analysis. Experimental heats weighing 200 to 250 lb were made in a basic-lined high-frequency induction furnace. The base composition was nominally that of a medium-carbon casting steel to which the appropriate additions were made. Specimens were poured into sand-cast ingots 3 in. in diam as shown in Fig 1. Sand-cast ingots were used to prevent chilling and to allow sufficient time in freezing for normal inclusions to form of a size large enough to be studied readily. In the first few heats, the tapered wall ingot was used, but in the majority, the

extra large riser was used to prevent piping in heavily deoxidized steels. Specimens for microexamination were taken from the location shown in Fig 1, and drillings for chemical analysis were taken from a similar location.

The procedure was to melt the base composition and deoxidize with the usual manganese and silicon additions and then to pour an ingot. The furnace was then tilted back, and the first increment of strong deoxidizer or special alloy was added and allowed to disseminate through the melt, with enough power on to hold the temperature constant, for 45 sec. Then a second ingot was poured. After this, another increment was added, and after the same holding time another ingot was poured. In this way from 9 to 12 ingots were poured from each heat, each successive ingot having progressively larger total additions of alloy.

Eighteen heats were made altogether, and the range of alloys used and additions made are outlined in Table 1. The three principal types of sulphide inclusions found are illustrated in Fig 2. The globular Type I sulphides are characteristic of silicon-killed steels, the eutectic Type II are characteristic of steels deoxidized with a small amount of aluminum, while the larger, angular Type III are usually found in steels with a residual aluminum content above about 0.02 pct.

In all specimens studied, the transition from Type I to II either did not occur at all or was very abrupt and clear cut. There never was any doubt as to just which increment produced the change, although the individual additions were small, in the order of 0.01 pct. The change from Type II to Type III was considerably less sharp, and, in some cases, both types were found together. Inasmuch as the formation of Type III sulphides is apparently not a deoxidation phenomenon, they will not be discussed here.

INEFFECTIVE ADDITIONS

Manganese

When manganese was varied from 0.63 pct to 17.7 pct, the globular Type I inclusions remained unchanged. In the higher manganese steels, there was a greater abundance of duplex inclusions containing both silicate and sulphide, but there was no hint of a eutectic formation. This confirms common knowledge to the effect that manganese is at best a weak deoxidizer, and that it is incapable of lowering FeO to the point that Type II inclusions can form.

It was noted that, as the manganese increased, the phosphorus content also increased from 0.009 pct to 0.040 pct, while the sulphur content decreased from 0.026 pct to 0.014 pct. The phosphorus can be accounted for as an impurity in the manganese, but the loss of sulphur is from a real desulphurizing action. This was confirmed by several analytical methods. Apparently the solubility limit for manganese sulphide was reached with high manganese contents and some manganese sulphide precipitated and floated out. It is not considered a practical desulphurization method, however.

Silicon

In Heat 1467, silicon was increased in steps up to 4 pct, but no trace of Type II inclusions was observed. Silicon is apparently a stronger deoxidizer

FIG 1—Sketch of experimental ingots and location of metallographic specimen.

than manganese but probably could not produce eutectic sulphides in any concentration. It was noted that the silicate inclusions increased both in size and in number as the silicon increased. They also became more transparent, indicating a higher SiO₂ content. Thus, the total silica content of the steel seemed to increase with higher silicon.

Vanadium

In Heat 1673, vanadium was added up to a content of 1 pct. The recovery of the added vanadium was practically 100 pct, indicating that it is not easily oxidized. There was no observable change in the type of sulphide inclusions. These observations plus the fact that vanadium oxide is readily

reduced by silicon warrant the conclusion that vanadium has no notable deoxidizing power in steel and does not rate a position higher than silicon.

Calcium

Although calcium has been widely regarded as a deoxidizer for steel, the present tests confirmed all previous experiments of the authors in giving completely negative results. In the tests, calcium silicide was added to the bare surface of the steel in amounts up to 0.4 pct. No change in the shape of silicates or sulphides was noted, although "birds-eye" sulphides, that is, sulphides with small, round, black spots were more prevalent after the calcium additions. Spectroscopic analysis did not show any residual calcium.

Manganese added as an 85 pct manganese, low-carbon alloy.

Silicon added to Heat 1467 as 77 pct ferrosilicon.

Vanadium added to Heat 1673 as ferrovanadium, 51 pct vanadium.

Calcium was added to Heat 1701 as a calcium-silicon alloy to the surface of the melt.

Boron added to Heat 1503 as ferrobore.

Magnesium added to Heats 1702, 1997 in the form of a powdered iron-silicon-magnesium alloy.

Titanium was added to Heat 1674 as a pure metal powder.

Zirconium added to Heat 1741 as pure metal powder and as a silicon-zirconium alloy to 1998.

Aluminum added in the form of wire to last eight heats.

* Acid-soluble aluminum—others are total aluminum values by wet or spectrographic analysis.

Calcium is reputedly insoluble in steel, and in molten steel, it is above its boiling point. Thus, it is under a severe handicap at best, but whether it would be a deoxidizer if it could be made to remain in contact with steel is purely hypothetical. Practically, it seems to have no deoxidizing effects.

STRONG DEOXIDIZERS

Of the elements tried, those which accomplished sufficient deoxidation to change the type of the sulphide inclusions were boron, magnesium, titanium, zirconium, and aluminum. There is some doubt regarding the deoxidation with magnesium as will be discussed later.

Boron

Boron was added to a carbon steel as 18 pct ferroboration. One effect of boron was to increase the size of the sulphides over those for similar steels containing no boron. Steels containing 0.030 pct boron, or less, were characterized by Type I sulphides and large globular silicates.

The typical sulphide inclusions in steels containing 0.034 pct or more of boron occurred as thick films in the primary grain boundaries. These inclusions have many of the characteristics of Type II sulphides in that they tend to form intergranular films, and yet they differ from those shown in Fig 2b in an important respect. Instead of being very small and forming a

fairly continuous network, they are concentrated in even larger masses than the Type I and therefore will be fewer in number and further apart. For this reason, they should not have the adverse effect on ductility that usually is associated with Type II inclusions. Typical examples are shown in the micrographs of Fig 3.

Magnesium

Magnesium is similar to calcium in being insoluble in steel and in volatility. It also has a similar position in the electromotive series. In order to add it to steel, it was made up as a master alloy by dissolving it in molten 75 pct ferrosilicon to a content of 10 pct. The first such alloy also con-

FIG 4—Typical sulphide inclusions found in Grade B steels with different titanium and magnesium additions. 500 X.
a. 0.003 pct Mg. b. 0.003 pct Mg, 0.005 pct Al. c. 0.024 pct Ti. d. 0.27 pct Ti.

tained 0.76 pct aluminum. When this alloy was added in increments to steel, the sulphides progressed from Type I to Type II and to Type III, the last being obtained with a total addition of 0.30 pct magnesium. Inasmuch as spectrographic analysis indicated less than 0.01 pct magnesium retained, but an aluminum content of 0.02 pct, it was considered that the latter element was responsible for the deoxidation.

Another series was made, using a similar alloy containing but 0.2 pct aluminum. The sulphides remained Type I up to a total addition of 0.30 pct magnesium at which point they changed to Type II; they remained Type II up to a total addition of 0.5 pct magnesium. Spectrographic analysis showed the residual magnesium never got higher than 0.003 pct, and the aluminum did not exceed 0.005 pct. This aluminum was high enough, however, to leave doubt as to whether the magnesium was effective as a deoxidizer.

Titanium

Titanium was added to Heat 1674 in

the form of pure metal pellets placed in a hollow tube fastened on a steel rod. The tube was plunged into the bath of steel where it melted off, and the titanium was dissolved. The titanium additions were made to the furnace in amounts varying from 0.01 to a total of 0.50 pct; the recoveries ranged from 50 to 60 pct. In this series of carbon steel castings, the sulphide inclusions changed from Type I to Type II at about 0.024 pct titanium. Film or eutectic sulphides were found in all samples containing more than this amount of titanium; the last ingot showed 0.27 pct titanium by analysis. Typical micrographs of titanium-bearing steels are shown in Fig 4. Data from this series suggest that titanium contents in steels should be kept below about 0.01 pct in order to avoid embrittlement by Type II distribution of sulphides.

In the steels containing comparatively large amounts of titanium, the sulphides occurred as extremely thin films, their color tending toward tan in reflected white light. These characteristics of the sulphide inclusions were noted previously in examining a medium-manganese steel with

0.16 pct titanium which had been added as low-carbon ferrotitanium. Such sulphides are presumed to contain a large proportion of titanium sulphide.

Zirconium

A silicon-zirconium alloy was used for adding zirconium to Heat 1998 after poor recoveries resulted from using pure metal powder in an earlier trial. Seventy per cent of the zirconium present was reported as being combined with oxygen when five samples were analyzed for both total zirconium and acid-soluble zirconium. This is puzzling considering that the total zirconium contents of these samples ranged from 0.01 to 0.32 pct. If the proportion of zirconium combined with oxygen was actually quite constant, it means that the oxygen content of the steel increased or that the composition of the oxide varied. In any event, the analyses agree with the metallographic examination which showed that the quantity of oxide inclusions increased with the total zirconium contents.

The micrographs in Fig 5 show the

FIG 5—Typical sulphide inclusions found in Grade B steels with different zirconium contents and characteristic oxides in samples with large amounts of zirconium. 500 X.
a. 0.01 pct Zr. b. 0.03 pct Zr. c. 0.32 pct Zr. d. Oxides.

typical appearance of sulphide inclusions in three castings from the zirconium series. Eutectic film distributions existed in samples reported to contain 0.005 to 0.026 pct total zirconium. The specimen containing 0.005 pct total zirconium was found to contain 0.002 pct acid soluble zirconium and 0.003 pct was presumed to be present as oxide. Samples containing 0.03 to approximately 0.07 pct of this element were characterized by angular sulphides. As illustrated by the micrographs, the sample containing 0.32 pct zirconium indicated a reversion to film sulphides at high contents of this element. The fourth micrograph shows the inordinate number of oxide inclusions present in an ingot poured after an addition of 0.15 pct zirconium had been made to the furnace. Clouds or clusters of oxide inclusions have been found in many experimental steels treated with large quantities of zir-

conium. Such oxide inclusions have been determined, by electrolytic extraction followed by chemical analyses and petrographic examination, to be mainly zirconium silicate.

Aluminum

The last eight heats listed in Table 1 comprise the series made to study the effects of aluminum in steels of different compositions. The samples were analyzed for aluminum by three of the methods in common use. The first eighteen ingots were analyzed by wet methods to determine the acid-soluble and acid-insoluble (Al_2O_3) aluminum contents, because both fractions were considered important. This practice is cumbersome and occasionally gave erratic values. The spectrographic determination appeared to be much more reliable, and it is definitely faster and simpler. Only total alu-

minum is determined in this way, however.

Previous studies have indicated that the acid-insoluble aluminum of aluminum deoxidized steels tends to be constant, and the present data go far to verify this concept. These data for thirty samples, listed in Table 2, show that even though the total additions and the acid-soluble aluminum vary widely, the insoluble content stays close to the average value of 0.006 pct. Only three of the values varied from the average by more than 0.002 pct, and one was in a sample which contained no acid-soluble aluminum. This is within the range of precision of most wet methods of analysis. The eight heats from which these samples were taken varied in composition, but all were poured at about the same temperature of 2950°F. It appeared justifiable, therefore, to consider the insoluble aluminum a

constant at 0.006 pct and to simplify the determination by wet analysis for soluble aluminum only, or to use the spectrographic method and subtract 0.006 pct from the total.

In the different heats, residual aluminum contents, varying from 0.002 to 0.005 pct, were required to initiate the formation of eutectic sulphides in the various steels except for the two low-carbon Heats Al278 and Al465. In these steels, Type I sulphides persisted with an aluminum content of 0.008 pct. The Type III, angular sulphides, were readily obtained with aluminum contents of about 0.015 pct or more with all steels except those very low in silicon or carbon.

COMPARISON OF DEOXIDIZERS

Only those elements which can lower the FeO content enough to cause formation of Type II sulphides are amenable to comparison by the presently proposed method. The elements tested which fall into this category are aluminum, zirconium, titanium, and boron. None of the others apparently is a stronger deoxidizer than silicon.

FIG 7—Comparison of deoxidizing powers at 2900°F (1600°C) for calculated and experimental values.

Solid lines Chipman's calculated values. Subscript E refers to present experimental work; subscript G refers to Gurry's calculated values; subscript D refers to Derge's experimental value.

for aluminum the change took place with a residual content of 0.002 pct for three cases, but in the steels containing 0.07 and 0.09 pct carbon, it required about 0.01 pct. In the high-carbon steel (0.51 pct C), the transition is a bit uncertain, but there was no change at 0.003 pct aluminum.

With zirconium, the transition was definite at a residual content of 0.002 pct which places it at least the equal of aluminum. In the case of titanium and boron, no distinction was made between soluble and insoluble portions, and the values given are determinations of total contents. From these it is deduced that they are considerably weaker than aluminum and zirconium.

For comparison with calculated values, the experimental values for the medium carbon steels are superimposed on Chipman's chart as it appears in "Basic Open Hearth Steel-making," 1944, p. 498, in Fig 7. No absolute values were obtained in the experimental work, and Chipman's value for aluminum was chosen as the standard, and the experimental value for aluminum made to coincide with it. Gurry's³ calculated values for aluminum, zirconium, titanium, boron,

and vanadium are also plotted as is Derge's⁴ experimental value for boron. The experimental values for titanium and boron are plotted on the basis that oxygen level is the same in all steels, regardless of deoxidizer, at the transition from Type I to Type II sulphides.

It is notable that Gurry's values for aluminum and zirconium have nearly the same relation to each other as the experimental values, but Gurry's figure for aluminum is much lower than Chipman's (stronger deoxidizer). The experimental value for titanium is lower than both Chipman's and Gurry's calculated values but is quite close to the latter. The experimental value for boron is definitely higher than either of Gurry's calculated values but also much lower than Derge's experimental value. Chipman's and Gurry's values for vanadium coincide.

SIGNIFICANCE OF THE ANALYSIS FOR ALUMINUM

One of the difficulties in obtaining data on the deoxidation with aluminum is that the limit of accuracy for analytical methods is reached for the very

low values of aluminum. The values in Table 2 were carefully checked by a skilled analyst and are believed to be accurate within the limits of the method used.* The acid-insoluble portion of the aluminum is generally believed to be present as Al_2O_3 , and in aluminum deoxidized steels, inclusions can be seen which are identifiable as Al_2O_3 and which seem to agree in quantity with the analytical results.

It has been tacitly assumed and widely believed that, when aluminum is added to steel, part of it is oxidized to Al_2O_3 (the deoxidation reaction), and that the solubility of Al_2O_3 being virtually nil, this Al_2O_3 is instantly precipitated. Much of it floats to the surface of the liquid steel, but some of it, because of its small particle size, remains suspended and is trapped when the steel freezes. Such a belief appears untenable in the face of the present data.

The constancy of the value for insoluble aluminum in steel, as shown in Table 2, has been noted before. Sims

* Insoluble aluminum separated by acid digestion, fused in potassium bisulphate, dissolved in dilute H_2SO_4 , and electrolysed on a mercury cathode. The aluminum is precipitated from this solution and determined as Al_2O_3 .

and Dahle² reported somewhat higher values. Halley⁵ analyzed some steels deoxidized with aluminum in large-sized commercial molds and obtained results as follow:

| Acid-soluble Aluminum | Al ₂ O ₃ | Insoluble Aluminum |
|-----------------------|--------------------------------|--------------------|
| 0.001 | 0.001 | 0.0005 |
| 0.009 | 0.008 | 0.004 |
| 0.038 | 0.008 | 0.004 |
| 0.073 | 0.010 | 0.005 |
| 0.169 | 0.008 | 0.004 |

Wentrup and Hieber⁶ gave analyses of 40 experimental low-carbon steels deoxidized with aluminum and with residual aluminum contents that ranged up to 0.83 pct. In 38 of these he obtained contents of acid-insoluble aluminum ranging from 0.001 to 0.012 pct with an average value of 0.005 pct. This is a significant corroboration and is considered to verify, first, that the insoluble aluminum tends to have a constant value and, second, that this value is in the neighborhood of 0.004 to 0.006 pct.

The constancy of this Al₂O₃ content cannot be accounted for on the basis that it was just the residue that failed to float out of the steel while it was still liquid. The recovery of added aluminum seldom is much higher than about 50 pct, and, in the case of a 4 lb per ton addition, the oxidized aluminum would be in the amount of 0.2 pct or thirty times the amount found in the solidified steel. If it is all precipitated, in varying amounts, why should an amount so constant remain suspended?

It cannot be accounted for as the Al₂O₃ that precipitates as a result of the shift in equilibrium constant during cooling of the steel to the freezing temperature, because the amount of oxygen involved is upwards of ten times the amount available from this source on the basis of Chipman's calculated value at 1600°C or thirty times what Gurry's value would allow, as shown in Fig 7.

The only logical explanation seems to be that the Al₂O₃ found in the solid steel was actually in solution in some form in the liquid steel and precipitated during cooling and freezing. Moreover, it was a saturated solution in the liquid steel which accounted for the constancy. All oxide above the saturation value was precipitated instantly and floated out rapidly. The slight difference between the average value for acid-insoluble aluminum in Table 2 and Halley's value could then be due to temperature, because his heats

were probably poured at about 2800°F (1550°C); whereas, the heats of Table 2 were poured in the range of 2900 to 2950°F or a little over 1600°C. The solubility would be expected to be higher at the higher temperature.

It still remains to account for this solubility in the light of physical-chemical concepts.

A TENTATIVE THEORY ON THE DEOXIDATION REACTION AND THE FORMATION OF OXIDE INCLUSIONS

A tentative theory to account for the presence of the Al₂O₃ in solidified steel proposes that the deoxidizing reaction is first of all a homogeneous reaction in which the dissolved deoxidizing element "M" reacts with dissolved FeO in the steel to partition the oxygen and to form a monoxide of the deoxidizer. The reaction is

and the equilibrium constant for the reaction is

$$K_{\text{MO}} = \frac{\% \text{Fe} \times \% \text{MO}}{\% \text{FeO} \times \% \text{M}} \quad [2]$$

The MO formed has a limited solubility which varies with the concentration of M. Any excess of the MO over the solubility limit is quickly precipitated and rejected to the slag. During, or subsequent to, the precipitation, the MO disproportionates to form a higher oxide by such a reaction as

or

The disproportionation reaction may be simultaneous with the precipitation in some cases so that actually no MO exists as a separate phase, in which case it would be indistinguishable from direct precipitation of the higher oxide, or, on the other hand, it may be delayed in other systems, possibly requiring lower temperatures for completion. The presence of two oxides in the external phase, one of which is also in solution, would appear to violate the phase rule. For example, in Eq 3 to 5 above, there are two components and two phases which, at constant pressure, allow only one degree of freedom. This would mean that two solid oxides could exist at only one set of conditions (temperature, pressure, and composition). A way to avoid this objection is indicated by Willis,⁷ who postulates that oxides in

contact with molten metals cannot be regarded as classic stoichiometric compounds. For example, Wüstite, ostensibly FeO, has been found to contain too much oxygen for this composition. It cannot be regarded as a solid solution of Fe₂O₃ in FeO, because in the space lattice of the solid, there are no molecules let alone molecules of Fe₂O₃. It can be regarded only as a nonstoichiometric oxide. It seems possible, therefore, to have an oxide equivalent to MO plus M₂O₃ existing as a nonstoichiometric compound.

The importance of this to the present concept seems evident in the following quotation from Willis.⁷ "Since the composition of a nonstoichiometric compound is dependent on both temperature and the partial pressure of one of the components, any such compound must be regarded as a two-component system, where the classical compound of fixed composition represents only one component. In equilibria, involving variability of composition of a compound, an extra degree of freedom is introduced above those which would be found when the compound is counted as a single component."

Chipman⁸ has given good evidence that oxygen in liquid iron exists as a compound having one atom of oxygen, which for simplicity is assumed to be FeO. Fontana and Chipman⁹ later showed that when iron becomes saturated with FeO, as by cooling or freezing, FeO is precipitated. As the temperature falls, the FeO becomes less stable and partially disproportionates by the reaction

At any rate, some Fe₃O₄ is produced as a separate phase, and some islands of Fe can be observed in the Fe₃O₄. Although no deoxidation reaction is involved, the case is analogous and represents a condition in which the disproportionation to a higher oxide form is not complete even at room temperature.

Zapffe and Sims¹ contended that SiO must play an important part in the silicon deoxidation of steel and gave some visual evidence that SiO might precipitate first and then decompose to SiO₂ plus Si. The disproportion of SiO is apparently very fast, however, and shows only in rapidly chilled specimens. Zapffe¹⁰ later elaborated this thesis with considerable additional evidence. He showed, for example, evidence of the silicon-enriched concentric envelope around the silica inclusion, which

would be the logical resultant of such a reaction.

In the carbon-oxygen reaction in steel, CO is formed and evolved (precipitated) as a gas. This gas always contains an equilibrium content of CO₂ which may be considered to have formed by the reaction

Chen and Chipman¹¹ give excellent reasons to believe that, in the Cr-O equilibrium in liquid iron, the oxygen is partitioned between FeO and CrO in a ratio that varies with Cr content. The only oxide inclusions found in the solidified Fe-Cr alloys, however, were chromite, FeO·Cr₂O₃, for those alloys containing up to 5.5 pct Cr, and chromic oxide, Cr₂O₃, in those of higher Cr content. Many of these chromite or chromic oxide inclusions contained islands of metal in a dendritic pattern. This fits very well into the picture of CrO precipitating and disproportionating as

or

but gives no evidence that CrO ever existed as a separate phase.

Zapffe, in discussing the paper by Chen and Chipman's, argued strongly for the formation of Cr₂O₃ by the disproportionation of CrO, but he made a better case in his own paper.¹⁰

Some evidence for the existence of CrO as a separate phase in chromium alloys was obtained by Elsea, Westerman, and Manning.¹² High-chromium alloys, melted in an argon atmosphere, were found to be very high in inclusions of Cr₂O₃ when beryllia crucibles were used. When alumina crucibles were used, however, the alloys were practically free of oxide inclusions, but the crucibles had high contents of CrO·Al₂O₃ spinel. The CrO had obviously come out of the alloy as such and had combined with the alumina at the high temperature where the CrO is more stable.

Hilty¹⁵ has given very convincing evidence that in the simultaneous oxidation of carbon and chromium, from an alloy of iron, carbon and chromium, the oxides involved in the reaction are CO and CrO and that the reaction is

On the postulate that, in alloys containing up to 5.5 pct Cr, precipitated CrO disproportionates to form chromite according to Eq 9, then

$$K_1 = \frac{[\% \text{Cr}]^2}{[\text{Fe}][\text{CrO}]^4} \quad [10]$$

Since this is a heterogeneous reaction, the K₁ is really a steady state constant, but it can be treated as an equilibrium constant providing the same standard states are used for any given substance in all parts of the system. On the premise that the concentration of iron is nearly constant for such alloys, [CrO] content should be approximately proportional to the square root of [Cr]. For the higher chromium alloys, if CrO breaks down to chromic oxide according to Eq 8, then

$$K_2 = \frac{[\% \text{Cr}]}{[\text{CrO}]^3} \quad [11]$$

and the concentration of [CrO] should vary as the cube root of [Cr].

In Table 3 is listed the limiting oxygen content of alloys, containing up to 20 pct Cr, which are in equilibrium with chromite or chromic oxide at 1595°C and the gas compositions with which they would also be in equilibrium. These values were taken from Table 6 of Chen and Chipman.¹¹ In addition, values for O_{Fe}, O_{Cr}, FeO, and CrO are given which were calculated by the following formulas developed by those authors:

$$\begin{aligned} [\% \text{O}_{\text{Fe}}] &= 0.241 \left(\frac{\text{H}_2\text{O}}{\text{H}_2} \right) \frac{\% \text{Fe}}{100} \\ [\% \text{O}_{\text{Cr}}] &= 3.79 \left(\frac{\text{H}_2\text{O}}{\text{H}_2} \right) \frac{\% \text{Cr}}{100} \end{aligned}$$

The equation for [% O_{Fe}] was developed from data obtained on pure iron, whereas the formula for [% O_{Cr}] was obtained by subtracting the first equation from one for total oxygen.

In Fig 8, the values of CrO are plotted against the square root of Cr contents for alloys containing up to 5.5 pct Cr and against the cube root of Cr content for alloys containing from 5.5 to 20 pct Cr. It will be noted that acceptably straight lines, showing direct proportionality, were obtained.

This gives considerable support to the postulate regarding CrO.

Table 3 also shows that the equilibrium constant for the homogeneous equilibrium

which is

$$K_3 = \frac{[\text{CrO}] \times [\text{Fe}]}{[\text{FeO}] \times [\text{Cr}]} = 14.8 \quad [13]$$

does not vary in the range 1 to 20 pct Cr. It also remains constant when [Cr] or total [O] are below the limiting values or saturation point.

This concept does not appear to violate the heterogeneous equilibrium of the chromium-iron alloys with chromite in one case and with chromic oxide in the other, as shown so well by Fig 10 of Chen and Chipman.¹¹ These higher oxides, or oxides of closely similar oxygen contents, furnish the oxygen pressure that determines the oxygen content of the alloys.

Abundant evidence has been brought forth recently to establish the knowledge that lower valence compounds of aluminum, zirconium, titanium, silicon, and chromium are stable at high temperatures under favorable (reducing) conditions. The production of ductile zirconium and titanium by the hot-wire iodide method depends, in part, on the formation of low-valence iodides which disproportionate to higher valence iodides and metal at high temperatures. Aluminum can be distilled by heating a mixture of the metal and AlF₃. The reaction 2Al + AlF₃ ⇌ 3AlF is reversible with appropriate changes in temperature and the AlF is volatile. The reaction Si + SiO₂ ⇌ SiO is used to produce volatile SiO to coat mirrors. When present in a slag, TiO₂ is an excellent flux, but under reducing conditions, it goes to a lower oxide and produces a viscous slag.

Alumina heated in vacuo at 1800°C with metallic silicon was reduced

to products identified as SiO and (probably) Al₂O.¹³ AlO has been identified definitely in the spectrum of gases at high temperature.¹⁴ When Al₂O₃ is heated in vacuo with metallic Ti or ZrO₂ with metallic Al, these refractory substances are disintegrated by the formation of suboxides

Apparently these reactions are typical and common.

THE ALUMINUM-OXYGEN EQUILIBRIUM

Evidence has been given to the effect that the alumina* found in solidified steels, which have had at least a short interval of time in the liquid state after deoxidation, represents material that was in solution while the steel was molten, and that the oxygen in this alumina far exceeds that permitted by the calculated deoxidation constants. The difference seems to be something more than experimental error.

To obtain further data, specimens having a wide variation in residual aluminum content were selected from those shown in Table 2 and were analyzed for total oxygen by the vacuum fusion analysis method, using a technique which has been shown to have a precision of ± 0.0004 pct O₂. The results are shown in Table 4.

Table 4 . . . Specimens Selected for Determination of Total Oxygen by Vacuum Fusion. The Corrected Value for Acid-insoluble Aluminum is Based on the Belief that the Average Value for this Constituent Shown in Table 2 is More Reliable than Individual Determinations. The Analyses for Oxygen are Typical of Many which Have Been Made on Aluminum Deoxidized Steels

* No Al added.

* This does not, naturally, include those streaks of aluminous inclusions found near the surface of ingots and which usually represent occluded scum.

Most outstanding is the fact that total oxygen decreases with increasing residual aluminum but only to a minimum value of 0.005 pct. For 0.006 pct Al as Al₂O₃, the stoichiometric value for oxygen would be 0.0053 pct which is well within the precision of the analytical methods. Thus, it appears that practically all of the oxygen is present as Al₂O₃ in solid steels containing as much as 0.015 pct residual Al. With contents of 0.007 pct residual Al, there is presumably some oxygen present as FeO.

According to this new concept, the deoxidation reaction is

Any AlO in excess of the solubility for the temperature is precipitated and disproportionates as

This material quickly rises out of liquid steel. The soluble portion of the AlO precipitates during cooling and freezing and forms the familiar inclusions found in aluminum deoxidized steels.

The apparent constancy of Al₂O₃ in the solid steel, which infers a similar constancy of AlO in the liquid steel, would seem to violate the theory expounded on page 821, which stipulates that AlO should vary as some function of the Al content. The typical deoxidation curve (oxygen vs. deoxidizer), however, is roughly an hyperbola and, after a certain content of deoxidizer is reached, the curve becomes nearly horizontal. With such a strong deoxidizer as aluminum, this nearly horizontal portion is quickly reached. Here the bulk of the oxygen is present as Al₂O₃, and although the content is theoretically not constant, the variation is too slight to be detected by present analytical procedures and, for purposes of calculation it may be considered constant without introducing a significant error.

The equilibrium constant can be expressed as

$$\frac{[\text{FeO}] \times [\text{Al}]}{[\text{AlO}] \times [\text{Fe}]} = K, \quad [13]$$

but since the [AlO] and Fe are nearly constant for a wide range of aluminum contents, it may be simplified to

$$[\text{FeO}] \times [\text{Al}] = K. \quad [14]$$

The constant quantity of 0.006 pct acid-insoluble aluminum can be calcu-

lated to 0.0143 pct AlO in the liquid steel. This would liberate 0.003 pct Al, most of which should be available as acid soluble, when it goes to the higher oxide form.

Using the meager data of Table 4, the values for Sample 1279-5 give $[\text{O}_{\text{FeO}}] = [\text{O}_T] - [\text{O}_{\text{AlO}}]$

$$= 0.006 - 0.0053 = 0.0007 \text{ pct} \quad [15]$$

$$[\text{FeO}] = 0.00315 \text{ pct} \quad [16]$$

$$\begin{aligned}^*[\text{Al}_R] &= \text{Al}_S - \text{Al}_L \\ &= 0.007 - 0.003 = 0.004 \text{ pct} \quad [17]\end{aligned}$$

$$\begin{aligned}K &= [\text{FeO}] \times [\text{Al}] = 0.00315 \times 0.004 \\ &= 1.26 \times 10^{-5} \quad [18]\end{aligned}$$

The best test for this constant is to see whether it can predict other conditions. In the case of Sample 1279-3, if the values 0.006 pct for insoluble Al and 0.008 pct for total O₂ are used with this value of K to calculate the residual Al, the figure of 0.004 is obtained compared with the analyzed value of 0.002 pct. For Sample 1279-6, if the values 0.006 pct for insoluble Al and 0.015 pct for soluble Al are used to calculate the oxygen present as FeO, the figure 0.00022 pct is obtained. This gives a total oxygen of 0.00552 pct as compared with the analytical value of 0.005 pct. The coincidence of the calculated and analyzed values is well within the limits of precision of the analytical methods. The quantities of FeO become unmeasurably small for still higher aluminum contents.

Because of the obvious limitations of analytical accuracy in this range, the deoxidation constant for aluminum cannot be regarded as highly accurate. The 1.26 calculated might be as low as 0.5 or as high as 2.5, but it is believed to be in the correct degree of magnitude. Total oxygen, for any given residual aluminum content, calculated from this constant, falls very close to analytical results, in contrast to previously calculated values for the deoxidation constant, as shown above.

THE ZIRCONIUM-OXYGEN EQUILIBRIUM

Data were given earlier (p. 817) to indicate that, in a steel deoxidized with silicon and zirconium, approximately 70 pct of the zirconium was present in acid-insoluble form. This was true over a range of total zirconium from 0.01 to 0.32 pct. If it be assumed that the insoluble zirconium represents oxidized zirconium (the nonmetallic inclusions seemed to be largely zirconium silicate), then it must be presumed that

* R = residual Al in liquid steel
S = acid soluble
L = liberated by disproportionation

some form of zirconium oxide, probably ZrO , has a high solubility in liquid steel and that this solubility varies with the content of residual or unoxidized zirconium. Tentatively, at least, this fits in very well with the presently postulated theory.

NOTES ON THE CHROMIUM-OXYGEN EQUILIBRIUM

When chromium is used as a deoxidizer, some chromium oxide will be precipitated, leaving some CrO in solution. The metal will, of course, be in equilibrium with the precipitated oxide and the values of dissolved CrO (when at $1595^{\circ}C$) can be taken from the curves of Fig 8. From these the following constants are obtained:

For contents up to 5.5 pct Cr

$$K_1 = \frac{(\% Cr)^{1/2}}{CrO} = 38.4$$

$$[CrO] = \frac{(\% Cr)^{1/2}}{38.4} = 0.026 (\% Cr)^{1/2}$$

For contents of 5.5 to 20 pct Cr

$$K_2 = \frac{(\% Cr)^{1/2}}{CrO} = 29.0$$

$$[CrO] = \frac{(\% Cr)^{1/2}}{29} = 0.0345 (\% Cr)^{1/2}$$

By substituting the value for $[CrO]$ in the equation

$$K_3 = \frac{[CrO] \times Fe}{[FeO] \times [Cr]} = 14.8$$

the $[FeO]$ content may be calculated. The total oxygen is then readily obtained.

It will be noted here that no activity coefficients are used and that all components are assumed to have an activity proportional to concentration. This illustrates the postulate of some physical chemists who contend that most materials at very high temperatures have activities proportional to their concentration and that, if the correct chemical species are known and used, activity coefficients, which are really correction factors, are unnecessary.

Very pertinent to the foregoing discussion is the fact that the data for $[O_{Fe}]$ also represent the activity of oxygen in the iron-chromium alloys, or $a_O = [O_{Fe}]$. The activity coefficients reported by Chen and Chipman¹¹ may be obtained as the ratio of $[O_{Fe}]$ to total $[O]$ or $\frac{[O_{Fe}]}{[O_{total}]} = f_O$.

Summary

In experimental work to test the

deoxidizing powers of commonly available elements, manganese, vanadium, and calcium were found to be no stronger than silicon. None of these is able to reduce the FeO content of steel sufficiently to form No. II type sulphides. Magnesium is somewhat doubtful but is disqualified as a deoxidizer from a practical standpoint.

Aluminum, zirconium, titanium, and boron all are capable of producing No. II type sulphides. On a comparison basis, aluminum and zirconium seem to be about equal and are the strongest deoxidizers of the elements tested. Titanium is next, though considerably weaker, while boron is not quite as good as titanium.

Alumina (acid-insoluble aluminum) was found to be quite constant in carbon steel for a wide range of residual aluminum contents. This is explained on the postulate that it was in solution in the molten steel as AlO , which precipitated and disproportionated to $Al_2O_3 + Al$ during freezing.

The theory that deoxidation is primarily a homogeneous reaction involving monoxides of Fe and the deoxidizing element is expounded. Oxides above the solubility limit precipitate and disproportionate to higher valence oxides.

By use of the proper chemical species in deoxidation, equilibrium constants may be obtained which are independent of activity coefficients.

DISCUSSION

J. CHIPMAN*—This paper describes the use of a new kind of indicator for studying the relative deoxidizing powers of several elements used in the deoxidation of steel. This is a very clever device and the results are interesting and possibly useful. The experimental method deserves careful scrutiny in order that there may be no uncertainty about what the indicator indicates. Molten steel, appar-

ently at 2900–2950°F in a basic-lined induction furnace, is deoxidized first with manganese and silicon and then with small increments of other deoxidizers. After each addition a 3-in. ingot is cast in a sand mold. The shape of the sulphide inclusions therein undergoes a sharp change with a critical amount of each of several deoxidizers and it is assumed that this change corresponds in each case to the same degree of deoxidation of the melt.

Two limitations on the use of this indicator must be recognized. The first is that, in order for this indicator to indicate the same degree of deoxidation with different deoxidizing elements, the composition of the indicator must be independent of the kind of deoxidizer used. Our present lack of information on the constitution of sulphide inclusions should caution us not to consider the indicator as an exact criterion of deoxidation but rather as a potentially useful approximation.

The second limitation arises from the fact that the sulphide inclusions are formed during the solidification of the metal, and the indicator can therefore be applied only to the condition of the metal during solidification. This means that its results should be compared not at 1600°C but in the freezing range, which is, of course, the condition of greater practical importance. This is a point which the authors have apparently overlooked and it deserves considerable emphasis. The degree of deoxidation indicated is not that in the furnace but rather that in the ingot during solidification. The amount of deoxidizer which must be added to the melt in the furnace must be large enough to react not only with the oxygen present but also with any additional oxygen which may be absorbed during pouring. If the solubility of the deoxidizer in the melt is very small it may be impossible to add enough of it in the furnace to maintain a high degree of deoxidation in the ingot. The solubilities of both magnesium and calcium in liquid steel are known to be very small and it seems evident that the results reported for these two elements have no bearing whatever upon their deoxidizing power. It is true that ways and means for utilizing the strong deoxidizing powers of these gaseous elements have not been developed, but the only contribution which the authors have made to this problem is another method to be avoided.

The validity of the experimental work on deoxidation with aluminum, like all previous attempts to study this reaction, is heavily dependent upon the accuracy of the analytical methods. When dealing with aluminum contents of the order of

0.006 pct, one must inquire diligently regarding the details of the method as well as possible interferences of such elements as carbon and nitrogen. Moreover, the assumed constancy of insoluble aluminum upon which so much argument is based seems hardly to be supported by the cited work of Wentrup and Hieber. Their acid-insoluble aluminum ranging from 0.001 to 0.012 pct (a twelve-fold range) can scarcely be considered a "significant corroboration" of this supposed constancy.

With regard to the theoretical sections of this paper, perhaps it will be sufficient here to record complete disagreement.

C. E. SIMS (authors' reply)—We concur with Dr. Chipman in pointing out the limitations of the deoxidation indicator used in this study. For example: at best, it is useful to indicate only one degree of deoxidation, that at which Type II sulphides first form. It is also limited to those deoxidizers substantially stronger than silicon; the others are merely lumped in the class of weak deoxidizers.

Its usefulness may be illustrated by the fact that it places vanadium very definitely among the weak deoxidizers, whereas, until recently, it has been widely regarded as a powerful deoxidizer. Statements in reference books and earlier thermodynamic calculations fostered this opinion.

The first limitation set by Chipman does not appear serious. The fact that the change from large globular to fine eutectic sulphides occurs at such low concentrations of deoxidizers, 0.002 pct for Al or Zr, makes it quite unlikely that these elements could materially alter the composition of the sulphides. It is quite obvious, on the other hand, that, at higher concentrations, sulphides of the deoxidizers do form.

In regard to Chipman's second limitation, it is emphasized again that the primary objective was a comparison of deoxidizers. The deoxidation was carried out at a nearly constant temperature of 1600°C. After that, the heats were held a standard time of 45 sec and poured directly into the mold with minimum exposure to air. Obviously, in all experimental work at high temperatures, the specimens must be solidified and cooled before they can be examined or analyzed and some conditions change during that operation. In the present case, the sulphides form during solidification, but it is postulated that the form they take is a direct result of the deoxidation that occurred at the holding temperature of 1600°C. When a different amount of deoxidizer was added, a different result

was obtained. Because of the conditions of handling, it is believed that very little change took place in the content of residual deoxidizer during pouring and solidification. This is attested by the constancy of the alumina content.

The difficulties of using such volatile and insoluble elements as calcium and magnesium as deoxidizers for steel were pointed out in the paper. Perhaps they did not have a fair chance to show their powers, although they were used in the customary manner, and perhaps they are strong deoxidizers as Chipman maintains, but what is the evidence? In another test, calcium vapor was bubbled through a rimming-type steel for a protracted period without showing any evidence of deoxidation. Although suitable under strongly oxidizing conditions, magnesia crucibles have been found unsuited to experimental work with steel under reducing conditions because the magnesia was reduced and volatilized. Alumina under the same conditions was quite satisfactory.

It is readily conceded that the present wet methods of determining Al in steel leave something to be desired. The method used is one generally approved by metallurgical laboratories. Carbon and nitrogen apparently do not interfere because the carbides and nitrides of aluminum are readily soluble in acid. The analyses reported by Wentrop and Hieber, taken by themselves, would have no significance. Although they do have considerable scatter, they lend some support to other, more consistent analyses. Because of the analytical difficulties and very low concentration, a "twelfold" variation is actually not too bad from an analytical standpoint, and, of course, most of the results were much closer to the average value. As pointed out in the paper, even the highest results of 0.012 pct represent only a small fraction of the total aluminum that was oxidized when aluminum was added.

In regard to the theoretical sections of the paper, it was fully anticipated that there would be considerable disagreement, but that alone was not a deterrent. The theory is an attempt to explain observed phenomena not covered by previous theories, but it should not be accepted without critical examination. The alternative seems to be to fall back on assertions that the oxygen content of liquid steel has a low activity because of some vague interatomic attractions and the use of a "fudge factor" called an activity coefficient, when making calculations. The present theory is immature, but, until it is disqualified, it appears to have the advantages of simplicity and workability.

Tracer Study of Sulphur in the Coke Oven

By S. E. EATON, R. W. HYDE, and B. S. OLD

DISCUSSION

(George McMeans presiding)

G. McMEANS*—This paper is a very good demonstration of the use of a new tool for the solution of industrial problems of a physical nature. To have solved this problem without the use of radioactive tracers would have required a far greater amount of investigation and work. The authors have described their work in such detail and in such a manner as to suggest the possibilities of the use of such tracer studies in the solution of many perplexing problems of industry.

R. E. BREWER†—The authors are to

* General Superintendent, Iron and Steel Div., Kaiser Co., Inc., Fontana, Calif.

† Chemical Engineer, Central Experiment Sta., U. S. Bureau of Mines, Pittsburgh, Pa. Papers by members of staff of U. S. Bureau of Mines are not subject to copyright.

be congratulated on this very excellent paper, which describes the results obtained by utilizing radioactive tracers in investigating the complicated reactions in the coking process. The paper has especial merit because the study was made under typical operating conditions in a commercial coke oven. Considering all the difficulties involved, the results obtained are excellent. My brief comments will relate primarily to the method used for determining the sulphur in the gas and to the value of the data obtained in stimulating further research.

In discussing their results, the authors state (p. 17) that "Of the total sulphur charged to the oven in the coal 95 pct was accounted for in the coke and gas. Most of the sulphur unaccounted for is believed to have been lost in the gas, since the gas sampling system removed all

the H₂S but probably only part of the organic sulphur compounds present in the gas. Although sulphur in the acid-insoluble tar residue in the gas scrubbing bottles was determined and added to the total sulphur determination of each sample, it is doubtful whether an aliquot portion of tar for each sample was obtained." The reviewer believes that the authors might have obtained a better sulphur balance had they used an improved procedure for determining sulphur in the gas.

The absorption train should have included a trap to remove the tar and ammoniacal liquor and a wash bottle containing 5 pct sulphuric acid to remove ammonia in the coke-oven gas before it entered the gas scrubbing bottles containing the ammoniacal cadmium chloride solution. Sulphur in the tar and

liquor could then be determined directly; and, at the same time, contamination of the precipitate by tar in the gas scrubbing bottles would be avoided. Ammonia in the gas should be removed to avoid increasing the alkalinity of the ammoniacal cadmium chloride solution, with consequent possible solution of part of the cadmium sulphide precipitate.

The authors have assumed that all of the dry, purified precipitate is cadmium sulphide from which they have calculated elemental sulphur. In addition to cadmium sulphide formed from the hydrogen sulphide, ammoniacal cadmium chloride solution also precipitates mercaptans as cadmium mercaptides and some of the carbon disulphide after partial hydrolysis as cadmium sulphide. Since the percentages of sulphur in cadmium sulphide and in cadmium mercaptide (ethyl mercaptide) are 22.2 and 27.3, respectively, calculation of the elemental sulphur from cadmium sulphide alone would be in error. Granting that the amount of elemental sulphur might thus be reported somewhat high, the higher value has not compensated for the remaining sulphur in other organic sulphur compounds that may have been present and were not precipitated either as cadmium sulphide or as cadmium mercaptide. The gas-sampling system used must therefore have removed "only part of the organic sulphur compounds present in the gas." However, since the total sulphur present in the organic sulphur compounds—such as mercaptans (ethyl and methyl), thiophene and its homologs, carbon disulphide, carbon oxysulphide, thio ethers, and alkyl disulphides—in coke-oven gas is small as compared to the sulphur in hydrogen sulphide, the total error in assuming that all of the sulphur is precipitated as cadmium sulphide would be small. A more elaborate gas-sampling system using more specific reagents in the absorption train to insure complete removal of all of the sulphur in the gas and additional laboratory analyses to determine the sulphur absorbed by each of the various reagents would, no doubt, afford a better sulphur balance. The additional labor and cost of introducing these refinements, however, to determine the 5.2 pct of unaccounted for total sulphur might not be justified in routine operations.

Fig 8 shows the percentage of sulphur content of coke-oven gas originating from the pyritic sulphur of the coal increases markedly between the 4th and 12th hours of the coking period. On the other hand, Fig 9 shows that the sulphur content of the gas originating from the organic and sulphate sulphur of the coal drops steadily after the 4th hour. These observations emphasize the need for coking coals of low pyritic sulphur content and should stimulate new developments in more effective coal-cleaning methods. Organic sulphur in coal cannot be satisfactorily

removed by present methods, but if it is not too large in amount it may be tolerated if the pyritic sulphur is small.

The authors have made a valuable contribution to the knowledge of the coking process. Their paper serves as an excellent guide for determining the principal sources of sulphur in coke. The results of this study should stimulate intensive research in the developments of methods for (1) reducing both inorganic and organic sulphur in the coal charge, (2) converting larger proportions of the coal sulphur into volatile products during coking with resulting lower sulphur in the coke, and (3) treating the coke itself to reduce its sulphur content.

(Attention is called to the following misprints in the text of the paper:

"Ind." in table on p. 4 must mean Allegheny Co., Pa.

"24,198" in line 25, p. 6, should read "24,188."

Sum of values in columns 3 and 4, Table 5, p. 12, for 2d, 5th, and 12th hr do not give the corresponding present values in column 5 of this table. After correction, the sum of all values in column 5 will be 60.5 lb or 24.6 pct of the total sulphur. This slightly higher value for sulphur in the gas, if used, will favor the sulphur balance: Table 6, p. 12; line 1, p. 13; and Table 8, p. 14.).

C. WAGGONER*—The use of a new tool is very enlightening to us who have had mixed feelings toward and recognize the need for collaboration about things like sulphur. I still ask this question. The authors talk about migration and say that it is a reasonable assumption that radioactive pyrites behave identically with the natural pyrites and then in the conclusion the results indicate that there is a migration. I would like to ask is that a migration of sulphur or is it merely a migration of radioactivity?

J. DASHER†—The radioactive sulphur. Sulphur 35 will not make any other sulphur atom radioactive. The element that is radioactive will remain so until it changes into chlorine, so the activity measured in the organic and the calcium sulphide form in the coke shows that the sulphur atoms present in that form in the coke were originally present in the pyrite, and there is no conversion of radioactivity. The atom itself is tagged.

C. WAGGONER—Before we can use a tool we must know a little bit more about it and I was interested in one other part of the paper that dealt with the background of radioactivity. If we are to tag atoms those tagged atoms may cause us trouble later in our product. We can easily calculate at what period of time it would approach the background radioactivity, is that proper?

* General Superintendent, Geneva Steel, Geneva, Utah.
† Mass. Inst. of Technology.

J. DASHER—Yes.

C. WAGGONER—And are we right in assuming that if we got reasonably close to that there would be no danger from action of radioactivity? I am not thinking about action on the person such as you described—the skin of a person would stop this activity—but I am thinking about, say, photographic plates.

J. DASHER—The activity from the sulphur in this experiment would be insufficient to affect a photographic plate.

C. WAGGONER—Will the detail of the experiment be printed?

J. DASHER—The paper was published. The analytical method in detail will be published.

C. WAGGONER—That will be excellent because I am sure it will answer a lot of questions that we who are confronted with problems of this kind will have to discuss with someone intelligently. I think the authors have made a real contribution to the methods of analyzing steel, and I only wish that we were more able to take advantage of it.

R. W. CAMPBELL*—The authors are to be congratulated on the presentation of an excellent paper and the development of a new and unique method in investigating the complicated reactions in the coking process. The results of this first large scale tracer study stress the value of the use of radioactive isotopes in the study of process metallurgy and will probably stimulate further work where similar approach would be necessary to gain the goal desired.

The rapidity of depletion of low sulphur coking coals and the advent of 100 pct mechanized coal mining in certain mining districts of the United States have given the steel industry a very perplexing problem to solve in order to obtain low sulphur metallurgical coke. The pyritic sulphur, with the exception of the very fine sizes, can be successfully removed in a modern coal washing plant, but the organic sulphur remains untouched, and it is this form of sulphur which the scientists should try to reduce in an economical way.

The Republic Steel Corporation was interested in finding out which one of the two major forms of sulphur in coal, namely, pyritic and organic, contributed the greater portion of the sulphur in the coke. Since, however, considerable quantities of sulphur are present in coke oven gas it was thought that if it could be shown definitely that the major part of the sulphur in coke originates from only one of the major forms of sulphur in the coal it would be possible to select types of coal which, although high in total sulphur, still would yield coke of fairly low sulphur content. This problem

* Superintendent Coke Div., Pittsburgh Dist., Jones & Laughlin Steel Corporation.

seemed to be suited for study using modern radioactive tracer technique while employing full-scale coking conditions, and this certainly has been accomplished by the authors.

The initial radioactive sulphur employed had an activity of only 40 micro-curies per g. Due to high dilution factor with inactive sulphur in the coal, the activity was reduced still further and it was found necessary to employ the sulphur present as the pure element in order to obtain sufficient accuracy. Since all samples contained active sulphur of the same age from the original batch, all activity measurements would be directly comparable if they were taken at the same time. As a close approximation, all sulphur samples were counted the same day with frequent checks of the background reading without sample.

The analytical data showed that 70.3 pct of the total sulphur in the coal was retained in the coke, 24.5 pct in the gas and 5.2 pct was unaccounted for. Of the total sulphur in the coal 42 pct was pyritic according to chemical analysis and from the tracer measurements it was found that 40 ± 2 pct of the total sulphur in both the resulting coke and gas evolved had pyritic origin. Thus neither of the two main forms of sulphur in coal, pyritic and organic, is removed preferentially during coking. Employing present coking methods there would be no advantage in choosing coal for its high or low pyritic or organic sulphur content.

Ferrous sulphite and carbon-sulphur complex forms represent all the sulphur in coke under high temperature and reducing conditions, as in the coke oven. After coke is pushed, some of the ferrous sulphite oxidizes to free sulphur and sulphates. However, in the top of the blast furnace, where high temperatures and reducing conditions again prevail, the free sulphur and sulphates revert to the original ferrous sulphite.

The authors conclude that in order to produce low sulphur coke, coals low in initial sulphur must be used and that in view of the large initial evolution of organic sulphur and small amounts of pyritic might be coked for a slightly shorter time to produce coke containing a given percentage of sulphur. Coals high in pyritic sulphur would have to be coked for a slightly longer period of time to obtain the same results.

Their conclusions on the possibility of helping the coke sulphur situation by controlling the coking time, depending on the types of sulphur present in the coal charge, is very interesting and should be studied further. It must be remembered, however, that the physical quality of the coke has always been the determining factor governing the coking time.

Without trying to detract in any way from the excellent work done by the au-

thors in their elaborate and excellent study of sulphur, it is interesting to quote the conclusions of two earlier experimenters in the same field:

Dr. A. R. Powell (1920)¹⁴—"The total sulphur of the coal is the most important factor affecting the sulphur content of the coke and the relative amount of sulphur forms does not affect it materially. Certain other factors, particularly the nature of the coal, vary the amount of sulphur in the coke to a limited extent."

Gilbert Thiessen (1935)¹⁵—"The sulphur in coke is derived from both organic and pyritic sulphur in the coal, approximately 45 pct of the organic sulphur and 60 pct of the pyritic sulphur remain in the coke.

"Because the proportions of the organic and the pyritic sulphur which remain in the coke are of the same magnitude, the sulphur content of the coke is for practical purposes directly proportional to the total sulphur content of the coal. Approximately half of the sulphur in the coal remains in the coke. Because of the loss of volatile matter, the amount of sulphur in the coke is about 80 pct of the percentage of the sulphur in the coal from which the coke was made. Iron compounds other than pyrites in the coal, arising from infiltration or from oxidation of pyrites, increase the retention of sulphur in the coke."

Fig 13 presents two curves from the experimental work of Gilbert Thiessen and shows; "A—Relation of Sulphur Content of Coke to Sulphur Content of Coal" and "B—Sulphur Content of Coke, Expressed on Basis of Original Coal, as Function of Total Sulphur Content of Coal."

Table 9 is a tabulation of some of the experimental work done at our Pittsburgh By-Product Coke Plant.

Fig 14 clearly indicates that 95.76 pct of the total sulphur in the burden is contributed by the coke containing 0.94 pct sulphur.

E. J. GARDNER*—The authors are to be commended for their careful preparation of an interesting and informative paper on the use of radioactive tracers to determine the distribution of the pyritic and organic sulphur in the carbonization of coal for the production of high temperature coke.

The gas evaluation curves, sulphur balance data on the plant scale test run, and the schematic flow of sulphur in a coke oven diagram, wherein the course of the pyritic sulphur is traced in order to determine quantitatively the amount evolved in the gas and the amount remaining in the coke, form an important contribution to our knowledge of the behavior of sulphur in the coking process.

At the Inland Steel Co., we also are concerned at the decrease in the quality of our high volatile—Elkhorn Seam—slack coal as regards ash and sulphur content. When our Wheelwright mine, because of the demand for increased production for the war emergency, went from the customary practice of careful preparation of the coal at the face, followed by hand loading of the coal into the mine cars, to the present practice of machine loading, the ash and sulphur content increased from 4.05 and 0.74 pct in June, 1941, to 9.00 and 0.96 pct respectively in Dec., 1948.

The increase in ash and sulphur in our coal blend produced furnace coke with inferior chemical and physical properties and resulted in a decrease in the quality and the iron tonnage obtained from our blast furnaces.

In order to overcome the adverse effects of mechanical loading on the ash and sulphur content of our high volatile coal, we are installing a coal cleaning plant at our Wheelwright mine. Our mining department assures us that they will deliver washed Wheelwright coal from machine loaded mining with ash and sulphur contents that are similar to the hand loaded product.

Table 10 shows comparative coal and coke analyses for our hand loaded and machine loaded coal.

Table 10 shows that in 1941 our coal mixture had 4.00 pct ash and 0.67 pct sulphur. In 1948, the coal mixture shows 7.40 pct ash and 0.83 pct sulphur. For the same periods, the analyses of our furnace coke went from 5.35 pct ash and 0.58 pct sulphur to 10.20 pct ash and 0.70 pct sulphur.

From the total sulphur analyses of the coal mixture charged and the coke produced, the amount of sulphur remaining in the coke was 63.9 pct for the 1941 and

62.7 pct for the 1948 period; in other words, the percent of the sulphur volatilized in the coking operation was practically the same for the low and high sulphur coal mixtures.

The results reported in the plant scale tracer study have given us a clearer picture than using the conventional methods of chemical analysis, of the rate of evolution and distribution of the pyritic and organic sulphur compounds during the carbonization of coal.

Although it will still be necessary to carbonize coals with low total sulphur content in order to produce low sulphur coke, the experimental data presented by the authors will form the basis for further radioactive tracer studies of the reactions that take place in the course of the transformation of coal to coke.

S. E. EATON, R. W. HYDE, and B. S. OLD (authors' reply)—The authors wish to thank R. W. Cambell and E. J. Gardner for their very interesting comments on the subject of sulphur in the coke oven and the blast furnace, and Ralph E. Brewer of U. S. Bureau of Mines for his very careful review of the paper.

In regard to the 5.2 pct of the total sulphur unaccounted for in coke and gas, Mr. Brewer is correct in saying that more of the sulphur in the coke oven gas could probably have been recovered by an improved scrubbing method. However, we wish to point out that since 95 pct of the sulphur in coke oven gas is present as hydrogen sulphide, the amount of sulphur in the gas which was not recoverable by the system used is rather small. We agree that a slight error may have been introduced by the presence of cadmium mercaptide in the cadmium sulphide precipitate but since sulphur as mercaptans is only on the order 0.3 pct of the

¹⁴ A. R. Powell: *Jnl. Ind. Eng. Chem.* (1920) 12, 1069.

* Superintendent, Blast Furnace and Coke Dept., Inland Steel Co., East Chicago, Ind.

total sulphur in the gas the error should be extremely small. Undoubtedly some of the sulphur in the gas passed through the scrubbing train; to have removed all the sulphur in the gas as well as obtain an aliquot portion of tar would have involved a much more elaborate sampling system. Since we were primarily inter-

ested in the distribution of the forms of sulphur in the coke, a more elaborate system of sampling gas did not seem justified in view of the probable error involved.

Mr. Brewer also noticed a slight discrepancy in Table 5 for the 2nd, 5th, and 12 hr. The values of pyritic, organic, and

total sulphur evolved each hour were calculated to one significant figure to the right of the decimal point, that is, to the nearest tenth of a pound. We would prefer not to change any value in this table as the individual values are more accurate as they now stand.

Some Correlations between Variables Affecting Sulphur in Blast Furnace Iron

By T. E. BROWER and B. M. LARSEN

DISCUSSION

(G. MacMeans presiding)

J. SAUSSAMAN*—One thing I have to say is that when anyone mentions sulphur, we at Fontana, are ready to listen. Although we do not have too much sulphur in our coke, we run into sulphur in our ores, and that is just one more variable in the question of how to control sulphur. Inasmuch as most of the data for this paper were taken from actual operation, I thought it might be interesting to show you some places in our operation which vary from those covered in the paper. The authors talk quite a bit about magnesia in the slag, and the magnesia in the slag at Fontana runs anywhere from 15 to 18 pct, usually being closer to 18 than 15. We get very good sulphur elimination with this slag, although the calcium in the slag is very much on the low side—about 32 pct. The high magnesia content does not appear to affect seriously sulphur elimination.

At the present time the two ores we use carry quite a bit of sulphur, one of them 2 pct sulphur and the other about 0.5 pct sulphur. Of course, the 2 pct sulphur ore cannot be used in the furnace directly due to that amount of sulphur, but it is removed by sintering. That reminds me of the statement that was made in a recent paper that the best way to control sulphur is not to put it in in the first place, so that is the way we do with the ore and have very good results with the sintered product.

The other ore contains about 0.5 pct

sulphur and we control the sulphur merely by a screening operation which reduces the sulphur to about 0.2 pct in the plus $\frac{5}{8}$ in. particles with a large percentage of the sulphur following the minus $\frac{5}{8}$ in. particles to the sintering plant.

In this one ore, running about 0.5 pct sulphur, we have the problem that half of that sulphur is in the form of gypsum or calcium sulphate, and the question then comes up as to how to control sulphur when it is in the form of calcium sulphate. Does it react in the same way in the furnace as the pyritic sulphur? We do not know the answers as we have not been working with it long enough.

L. E. RIDDLE*—I do not think it right to state that some one thing is the reason sulphur in pig iron is high or low. You have to take into account a number of things—variable amounts of sulphur when using the same materials, the kinds of sulphur in the raw materials, temperature changes in the hearth of the furnace, and correlation effect.

I do not agree with Mr. Larsen that varying amounts of alumina has no effect on slag. His data show that in his study of more than 100 samples of slag the alumina did not vary 1 pct. Had he had slags with Al_2O_3 as low as 9 pct and others with 20 pct he would have found that with Al_2O_3 above 18 pct the ratio of CaO and MgO to $SiO_2 + Al_2O_3$ can be lowered greatly with sulphur removal, results equaling those when the CaO and MgO ratio to $SiO_2 + Al_2O_3$ is much higher when the Al_2O_3 is below 15 pct.

Having made pig iron with 19 and 20 pct Al_2O_3 in the slag and ferro-manganese

with 22–23 pct Al_2O_3 and the same products with half these amounts of Al_2O_3 in the slag, we learned the above fact.

B. M. LARSEN (authors' reply)—Mr. Saussaman's comments indicate approximately normal or expected S removal at 15–18 pct MgO in slag with 32 pct CaO. We have experience in one shop with 10–12 MgO and a limited run in another with 15–17 pct MgO; in both cases the ratios were lower by only a moderate amount than at what we feel to be the optimum range of 6–8 pct MgO. All such comparisons between shops must be regarded with caution because of the many factors (manganese and silicon in iron, iron and slag temperature, etc.) which appear to complicate the sulphur removal situation. As regards the division between pyritic and sulphate sulphur, we believe that essentially all the sulphur charged gets trapped in the furnace and all of it ends up in the sulphide form, so it does not matter in what form it is present in the charged materials.

As regards a member's comments on the factors of Mn and temperature, we would only say that until a lot of good temperature data are available on slag and metal casts, we probably must keep an open mind on the inter-relationships between different variables. Higher temperature may have a direct effect of speeding the rate of sulphur migration from iron to slag. On the other hand, to the extent that higher temperatures are associated with higher Mn and Si and more basic slags it is quite probable that here the temperature should be regarded as the secondary rather than the primary variable.

Sulphur Equilibria between Iron Blast Furnace Slags and Metal

By G. G. HATCH and J. CHIPMAN

DISCUSSION

(G. MacMeans presiding)

T. ROSENQVIST*—It is a pleasure to see the excellent way in which the experimental part of this work has been handled. There seems to be little doubt that the distribution data obtained corresponds most closely to thermodynamic equilibrium under the prevailing reducing conditions, namely equilibrium with graphite and one atmosphere CO pressure.

The desulphurization curves in Fig 10 show the same general feature as the curves given by Holbrook and Joseph, but the distribution ratios are from 20 to 40 times greater—undoubtedly due to a closer approach to true equilibrium.

In the theoretical discussion, the authors calculate a theoretical distribution ratio $\frac{(S)}{[S]}$ which they find to be about 50 times greater than the experimental. The deviation is so great that the basis for their calculation needs a more thorough examination.

The authors base their thermodynamic calculation on free energy expressions where diluted solutions of FeS and CaS are used as standard states. (The activity coefficient in diluted solutions is taken to equal unity.) Such a standard state will change when the nature of the solvent is changed. Taking the free energy of the reaction $[\text{FeS}] \rightarrow (\text{FeS})$, Eq 2, which is derived from the distribution of sulphur between an iron and a FeO-melt, it is very unlikely that the free energy of this reaction will be the same for a distribution between pig iron and a calcium silicate slag.

Therefore a more fundamental basis for the thermodynamic calculations seems needed, where all thermodynamic equations are referred to unambiguously defined standard states.

The most natural standard states for CaO and CaS are the pure solid substances at the same temperature. As standard state for sulphur in iron, pure liquid FeS can be used. This rules out Eq 2 $[\text{FeS}] \rightleftharpoons (\text{FeS})$ because $\Delta F^\circ = 0$. The standard equation will then be:

It would be more universal and also

FIG 11—Chemical activity of CaS in blast furnace slag.

(Hypothetical) Curve 1. Approximately ideal solution. Curve 2. Positive deviation from ideal solution.

simpler to refer the escaping tendency of sulphur in liquid iron to the corresponding $\text{H}_2\text{S}/\text{H}_2$ ratio which can readily be determined experimentally. As standard state a gas mixture $\text{H}_2\text{S}/\text{H}_2 = 1/1$ can be used. (This corresponds at the temperature of liquid iron closely to one atmosphere S_2 vapor.) Thus the standard equation for the sulphur reaction can be formulated as follows:

The standard free energy of this reaction has been calculated from the best available data to $\Delta F^\circ_{1773} = -35,000$ cal. This gives for the equilibrium constant at 1500°C

$$K_p = \frac{A_{\text{CaS}} P_{\text{H}_2} P_{\text{CO}}}{A_{\text{CaO}} P_{\text{H}_2\text{S}} A_{\text{C}}} = 2.10^4$$

Now, the solubility of CaS in blast furnace slags has been determined by McCafferey and Oesterle* and corresponds at 1500°C to about 10 pct S (varying somewhat with the composition of the slag.)

If the activity of CaS is assumed linear between 0–10 pct as curve 1, (see Fig 11), then $a_{\text{CaO}} = 0.1 (S)$; (S) being wt. pct sulphur in the slag.

For a diluted solution of sulphur in an iron melt saturated with carbon, the ratio $\text{H}_2\text{S}/\text{H}_2$ is, according to Kitchener, Bockris and Liberman,† about 0.01 [S], [S] being wt. pct sulphur in iron. Substituting these values in the expression for K_p we find

$$\frac{(S)}{[S]} = 2.10^3 \cdot a_{\text{CaO}}$$

The value 2.10^3 is only 4 times greater than the experimental coefficient found

by Hatch and Chipman, but the value is very sensitive to a small error in ΔF° .

A better agreement with the experimental distribution coefficient can be obtained if one assumes the activity of CaS to run like curve 2 (Fig 11). This will give a lower theoretical $\frac{(S)}{[S]}$ value, a value which varies with (S) exactly as Hatch and Chipman learned. Such a shape of the activity curve, which corresponds to a positive deviation from Raoult's law, is actually to be expected from the fact that liquid silicate and sulphide phases usually show incomplete miscibility.

A closer agreement between experimental and theoretical data can not be expected before we have more complete data for the individual activities of CaS and CaO in the slag. The activities a_{CaS} and a_{CaO} referred to the solid phases as standard states, are exact defined quantities contrary to the somewhat undefined expression "free lime," and they are independent of any theory for the constitution of liquid slag.

J. CHIPMAN (authors' reply)—The authors wish to thank Mr. Rosenqvist for his very interesting and useful thermodynamic addition. Curve 2 of his figure offers the needed basis for explaining the increase in the ratio $(S)/[S]$ with increasing sulphur content. Attention is called to an error in the printed paper: Fig 2 and 3 are reversed.

M. TENENBAUM*—In the figures showing the relationship between excess base and sulphur distribution (Fig 6, 7 and 9) the slope of the curve tapers off in the negative basicity range. Somewhat the same thing is observed with open hearth slags. In that case, the fact that some sulphur distribution between slag and metal is obtained with negative basicity is interpreted as indicating some dissociation of the lime silicate compounds whose existence in oxidizing basic slags has been used to explain various observed phenomena with regard to other slag-metal reactions. In the case of the blast furnace slags, the reduced slope of the sulphur distribution curve with decreasing excess base is attributed to the amphoteric effect of alumina. Has the possibility of other explanations been investigated?

* Inst. for the Study of Metals, Univ. of Chicago.

B. M. LARSEN*—In view of this effect of alumina that we failed to find so far in most plant practices, if I interpret that triangular diagram correctly, it seems to me that the lines indicated very little effect of alumina and there was not any effect on sulphur at all.

I am not accustomed to using the triangular diagram, but you will notice these lines fall almost parallel to those corners (*Indicating slide*). That would indicate the alumina has a quite small effect which would agree with what our experience has been in most plant data.

There was one other thing—this departure from the distribution laws would be a very nice thing if it really worked out in practice because we are getting into higher sulphur content in the slag all the time. I am a little skeptical about

* Research Lab., U. S. Steel Corporation.

it. I feel more work should be done, probably more work with higher sulphur contents in the metal phase to minimize analytical errors. In other words, it looks as though this point is so important as to deserve more exhaustive equilibrium studies to make more sure of this effect because it would be desirable to be able to increase the sulphur in the slag.

J. CHIPMAN—We agree with you that more work needs to be done with higher precision on the sulphur analysis. These sulphur analyses were made with extreme care and the method was checked repeatedly against standards. The sulphur analysis was done by the combustion method in a manner which is perhaps better than one would normally encounter and results were always duplicable within ± 0.001 pct. Had we known that these sulphurs were going to

come so low I think we would have started out in the first place to use radio isotope methods for improving the precision of the analyses. We expected to get sulphur distribution ratios more or less in the neighborhood of what is found in the blast furnace. Even with 5 pct sulphur in the slag we were still able to get unexpectedly low sulphur contents in the metal. There is no doubt about the result that we have shown—that if you double the sulphur content of the slag you do not double the sulphur content of the metal in equilibrium. The ratio (S)/[S] is not a constant.

With regard to the effect of alumina, the results show clearly that it behaves as an acidic constituent in the basic slags. In the more acid slags this characteristic seems less pronounced. No detailed explanation of this observation is required.

Relation between Chromium and Carbon in Chromium Steel Refining

By D. C. HILTY

DISCUSSION

(B. G. Emmett presiding)

C. E. SIMS*—This is a most interesting and important paper. It is important from two standpoints. First, it has aspects of being highly accurate and therefore extremely useful to the operating man in showing how far he can go in oxidizing carbon from a steel bath while retaining chromium and the effect of temperature on this limit. Fig 5 is undoubtedly the highlight of the paper, and in checking it against available data, it seems capable of predicting actual results.

The other important aspect is the apparently significant fact that reactions within a steel bath, such as between carbon and an oxide, are homogeneous reactions which do not require equilibrium with an external phase. In this case, it seems obvious that the reaction and the equilibrium established were between dissolved carbon (or carbide) and dissolved CrO. The classic reaction which requires equilibrium with solid Cr_2O_3 did not fit the data. It was recognition of this principle that made Fig 5 possible.

G. R. FITTERER*—It might be in assuming the CrO is dissolved in the metal that you are actually approaching the correct factor for activity. If that is true and if the percentages that were used represent an equilibrium constant, this would mean, in effect, that the minimum temperature at which chromium would be reduced by an equivalent percentage of carbon would be about 2400°F from your equation. I believe that is in line with my experience particularly if you deal only with low percentages.

J. CHIPMAN†—The author in discussing the equilibrium of the reaction offers two choices of explanation. One postulates an effect of chromium on the activity coefficient of carbon; it would require perhaps more data than are available to us at the present time to test this thoroughly. The other postulate which he offers is a reaction with CrO. This explanation is consistent with physical and chemical principles provided that a solid phase CrO is present, and that is

essentially what he is postulating. If that oxide were present one would expect and, I think, almost require the kind of results that he obtained. The weakness of that postulate lies in the lack of confirmatory evidence regarding the presence of solid CrO as such. This should offer an interesting subject for further study.

It seems a pity that the theoretical arguments revolving around CrO should have obscured for a moment the very real excellence of this paper.

E. CARTER*—I think there is a problem that presents itself in practical application where the metal temperature is from 3200 to 3300 and the temperature desired in pouring is considerably less.

B. M. LARSEN†—I get the impression from some of the work that was done earlier that there is probably a localized zone of high temperature at the slag metal interface which effects the removal of the carbon. Without that I wonder if the effect is possible to have a localized superheat and an equilibrium there favorable to low carbon content and

* Univ. of Pittsburgh, Pa.

† Professor of Metallurgy, Mass. Inst. of Technology.

* Vulcan Steel Foundry.
† U. S. Steel Corporation.

still not have the whole bath heated up to that equivalent temperature.

D. REEDER*(replying for author)—I do not doubt there is a localized area there, but still the agitation of the bath, particularly at these temperatures, and the effect of applying the oxygen, (blowing the oxygen in there) will give a stirring effect; and also the temperature is so great the molten metal is very liquid and would tend to circulate more.

B. M. LARSEN—In practice you have a heavy liquid below. That heavy liquid may not get stirred very deeply.

D. REEDER—That is true. This is under very high oxidizing conditions and I believe that would have an effect on moving the metal itself.

B. G. EMMETT—I might say along those lines that our experience has been in the injection of oxygen in an arc furnace you get a violent action which would, I believe, tend to stir the metal. I would also like to comment along the lines of this paper. It has been my ex-

perience—belief at any rate—that there has been positively too much chromium steel made with no effort to boil. Consequently, when you machine the castings you find them full of holes. If you give the metal a good boil it tends to liberate hydrogen and make a good clean piece of steel rather than one that is full of gas.

D. C. HILTY (author's reply)—It is gratifying that the results presented in the paper seem to be consistent with Dr. Fitterer's experience. Mr. Larsen has brought up an interesting point for speculation. I am inclined to agree with Mr. Reeder and Mr. Emmett, however, that the rather considerable bath action that results from oxygen injection goes a long way toward equalizing temperature throughout a steel bath except, possibly, in a very localized zone immediately adjacent to the point of oxygen input.

With regard to the CrO postulate and the interpretations placed upon it by Mr. Sims and Dr. Fitterer, I believe my position has been adequately stated by Professor Chipman. As pointed out in the paper, the metallic phase was assumed to be in contact with a nonmetallic phase saturated with CrO at steelmaking tem-

peratures. In this connection it is notable that slag samples taken from chromium steel heats at the end of the oxygen blow have been observed to contain particles of metallic chromium as well as chromic oxide and chromite. One possible explanation for these observations is that at high temperatures the slags may have contained CrO which decomposed on cooling in a manner analogous to the decomposition of FeO.

The primary objective of this investigation was to establish an empirical relation that would be of practical value to the operator in establishing a practice for melting chromium steels from charges containing chromium. The chromium-carbon-temperature relation shown in Fig 5 of the paper has been checked in the field in both basic and acid arc furnaces and has been found to hold quite well under both conditions. In a number of instances practices have been deliberately devised on the basis of the curves of Fig 5, and in all cases the heats behaved in the furnace as predicted. It would appear, therefore, that regardless of the theoretical explanation of the results presented in the paper, the primary objective has been attained.

The Effect of Hydrogen on the Ductility of Cast Steels

By CLARENCE E. SIMS, GEORGE A. MOORE, and DONALD W. WILLIAMS

DISCUSSION

(R. C. Madden presiding)

G. A. LILLIEQVIST*—I wish to compliment the authors on the excellent manner in which they have presented their data. The improvement of ductility obtained on test bars after aging at room temperature or at low temperatures of around 400°F has been a well-known fact for many years. The authors have found an explanation for this phenomenon and have presented in their paper conclusive proof that hydrogen plays an important part in controlling ductility values.

While we have never attempted to analyze for hydrogen, a great deal of our

time has been devoted to the study of aging treatments to improve the ductility of steels and we have found results similar to those presented in this paper. It was our finding that in practically 100 pct of the steels investigated there was a definite improvement when 1-in. bars were aged at 400°F for 16 hr, 550°F for 1 hr or at room temperature for 4 months. We also noted that the heavier sections were more affected than light sections and that more time was required in the aging treatment to obtain the maximum ductility.

In our investigation we also noted when an acid electric furnace heat was made as rapidly as possible, that is, to obtain a vigorous boil to reduce the carbon and then tapping as soon as possible, good results were obtained. Very little improvement was obtained in aged

bars over unaged bars. They were both very good.

I again wish to state that the authors have done an excellent job in presenting interesting information regarding the causes of low ductility values in unaged bars which should be of considerable benefit to the steel casting industry.

C. E. SIMS (authors' reply)—The authors appreciate the comments of Dr. Lillieqvist which give confirmation from practice of the data presented. The work of many investigators, including Dr. Lillieqvist, has tended to establish beyond doubt the effect of hydrogen on the ductility of steel, but this has been largely of a qualitative nature. The present work was designed to test and substantiate these observations and put them on a quantitative basis.

* Research Director, American Steel Foundries, East Chicago, Ind.

The Origin of Silicate Inclusions in Basic Electric-arc-furnace Steel of Higher Carbon

Contents

By AXEL HULTGREN

DISCUSSION

(R. C. Madden presiding)

G. R. FITTERER*—In discussing this paper I would like to state simply, that Professor Hultgren's objection to Stokes' law is interesting but not necessarily a correct interpretation. I would like to point out that Stokes' law states that the velocity of a particle, either when precipitated or rising in a fluid, is dependent chiefly upon three factors. One of these is the viscosity of the fluid which in this case is liquid steel. Another is a difference in density between the liquid steel and the nonmetallic inclusion and the third is the square of the radius of the inclusion particle itself. Now, if the particle has a radius in one case of ten times another, the one with the larger radius will be eliminated at one hundred times the velocity. This law states, in effect, that rain drops cannot become as large as watermelons and it is very fortunate that they cannot.

I would also like to point out that since it is a limiting law, it indicates that it might control either the agglomeration of the silicate particles or their dispersion. In other words, a particle may coagulate with others until the limiting size is reached. Any growth beyond this will cause the large particle to break up into smaller ones other conditions being the same. On the other hand, if in the action of pouring the heat considerable turbulence is present in pouring into the mold or even tapping in the ladle the limiting velocity as demanded by this law might be exceeded and therefore cause the break-down of the inclusions into the form that we saw here. Now, whether or not the small particles that are broken

off from the large inclusions as shown, redissolve in the steel is a point which is disputable and has not been proved by this paper.

B. M. LARSEN*—We have a few samples taken from open-hearth furnaces. I do not know whether they illuminate this question, but we took samples from the tapping stream and also out of the ladle. They came out very logically, looking at it from Hultgren's viewpoint. The tapping stream samples from open-tap heats with no block in the furnace had no inclusions except extremely tiny ones. In the ladle the inclusions jumped up to a volume percentage about the same as Hultgren found though of considerably smaller average size. The larger ones were gone in the platform samples.

A. HULTGREN (author's reply)—I wish to thank Dr. Fitterer for kindly taking the trouble to present my paper. To his comments regarding Stokes' law and its application to the present problem my reply is that I am not aware of having objected to this law, in thought or writing. If inclusions, by growth or coagulation, reach a certain size they will rise at a considerable velocity and collect at the top surface of the liquid steel. The results of experiments with steel held in the ladle for different periods, as shown in Tables 5, 10 and 13, agree well with Stokes' law.

The breaking down of large slag inclusions—or rain drops—into small ones as caused by turbulence is not demanded or governed by Stokes' law which applies to conditions of nonturbulence.

Dr. Fitterer apparently interprets Fig 10-14 as evidence of large inclusions

breaking down owing to turbulence in pouring. I think, on the other hand, that those figures support the idea of reaction products forming temporarily around inclusions which are not in equilibrium with the metal. My arguments are:

1. The inclusions had no doubt been deformed from turbulence during pouring but their round or rounded shape indicates that the turbulence had largely subsided when they were caught by the freezing steel.

2. If the satellites were formed by fragmentation of the large inclusions in connection with deformation they would not be likely to remain in a surrounding zone of uniform thickness after the latter assumed its rounded shape. Fig 15, on the other hand, shows small inclusions irregularly dispersed in relation to a large one, possibly as a result of fragmentation.

3. The lack of equilibrium at the time of formation of the inclusions is evidenced by the change in appearance of the inclusions while the steel is held in the ladle (Tables 5 and 14), the change observed indicating that the metallic oxide contents are gradually decreasing.

The absence of satellite zones around the inclusions in the samples taken from the ladle are evidence of their short-lived existence. The dissolution of small particles during the simultaneous growth of larger ones in the same matrix is a common occurrence in metallic systems. The low oxygen content of the metal would also favor dissolution. As Dr. Fitterer says, however, this is a disputable point.

The results reported by Mr. Larsen from his study of open-hearth steel supply valuable additional evidence. In conclusion, I ought, perhaps, to emphasize the limitation indicated by the title of the paper: the conclusions drawn are not necessarily all applicable to low-carbon steels.

Sintering Characteristics of Minus Sixty-five and Twenty Mesh Magnetite

By A. STANLEY and J. C. MEAD

DISCUSSION

(E. H. Rose presiding)

E. H. ROSE*—You have wrapped up

* Tennessee Coal, Iron and Railroad Co., Birmingham, Ala.

a great deal of new and interesting information in one quite compact package, and I wonder if it might not help the

audience a bit if you would just recapitulate your main conclusions—not all of them, but the outstanding ones about the size, the reactions, and so forth.

J. C. MEAD (authors' reply)—In our research work, the following factors were found to have a very pronounced effect on the minus sixty-five mesh magnetite.

The use of 20 to 30 pct of sized return fines in the prepared feed, when using a hearth layer over the grate area, was very beneficial. Before the sized returns were investigated, and the amount controlled, the results of the tests varied widely due to the fluctuating amount of dust in the "returns."

The control and stabilization of the moisture percentage in the magnetite and coal culm permitted more efficient mixing of these materials which raised the production rate and decreased the amount of coal culm required.

Close moisture control in the prepared feed is essential when sintering at a vacuum of 40 to 50 inches water gauge. Either too high or too low a moisture control will permit the bed to "pull holes," short-circuiting the air and decreasing the production rate.

Accurate control on the amount of sinter fuel in the prepared feed increases the quality and quantity of sinter produced. An excess amount of coal caused too high a fusion temperature which slags and makes a very brittle sinter. Too little coal resulted in too low a fusion temperature which made a weak sinter containing some unsintered material.

While the research work in the test pan showed that minus twenty mesh magnetite can be sintered without much control, in actual plant practice, very close control is needed on the magnetite, coal, and prepared feed. The plant will maintain a high production rate if the moisture in the prepared feed stays between 5.5 to 6.0 pct. Any variation above or below this range lowers the plant production rate.

A variation of $\frac{2}{10}$ pct of anthracite coal in the prepared feed will change the production rate.

Any fluctuations of "dust" from the return fines and from the dust collectors can cause wide variations in the moisture of the prepared feed. If the "dust" is used at a uniform rate, it simplifies moisture control and does not affect production.

The use of return fines having a maximum particle size of minus $\frac{3}{8}$ in. in the prepared feed and the use of a thick hearth layer over the grate area have been tried on the 250-sq ft pans and have increased the production rate. However, the use of smaller return fines requires closer moisture control than before because the bed does not hold together during the sintering quite as well as it did when using the coarse return fines in the prepared feed.

In all cases in research and in operation the closer the control maintained over the

magnetite, coal, return fines, dust, and moisture, the higher were the quality and quantity of sinter produced.

E. H. ROSE—The presentation that Mr. Mead has made here today is one of acute interest to practically all iron ore producers, particularly in view of the fact that we are going to be faced with some very finely divided material when we proceed further with low grade iron ores.

G. J. HOLT*—I missed the first part of the paper, but I heard Mr. Mead talk about pellets. I did not get the significance of the pellets.

J. C. MEAD—This pellet we found was due to fine magnetite building up around return fines, and in our test we added water into our returns in the latter part of the mixing to eliminate them. During the first part of our tests we put the water right in with the magnetite, mixing it with a concrete mixer, and we found that in going over the lifters it was rolled up into a ball. Contrary to our original idea that pellets would help us, we found that after the sintering we could take these particles and crush them with our fingers; they break up eventually; they also formed zones of weakness where in being dropped or given a tumbling test they broke down the quality of our sinter.

F. D. DE VANEY†—I just wanted to make this comment on the magnetite we are going to pelletize this year. It is about 1 pct on a hundred mesh and about 85 pct minus 200 mesh. We have recently carried on some tests using Dwight Lloyd machines and we found that for this fine material we can get a fair capacity and make a nice sinter if we roll our concentrates into balls that are from $\frac{1}{8}$ in. up to approximately $\frac{1}{2}$ in. in diam. We found with such material, contrary to pelletizing, that the added coal had to be placed on the outside of the pellets. In other words, we rolled these balls up in a drum and then we introduced this coal about a foot or two from the discharge end of the drum and put a layer of coal around the pellets; then we put them on the sintering pan and in that way we made a rather nice sintering on the Dwight Lloyd machine. Do you plan on making your pellets in a rotary drum?

MEMBER—We have not had a lot of experience, just 6 months or so on the rolling pellet, and I do not want to get into too much of a discussion on that; but we proposed using the same methods and the size of the balls is directly determined by the percentage of moisture in the balls. If you keep that moisture down the balls will get no bigger.

A. C. RICHARDSON‡—As I listened to this paper, I found it a little hard to

follow some of the conclusions reached from the data which are worthy of serious study. We have had some experience, in the laboratory, in sintering various types of ores and find that there is very little information of value in literature on this subject. I hesitate to talk about sintering in the presence of Mr. Holt, Mr. DeVaney, and Mr. Johnson who have had a lot of experience with this subject, but a lot of the sintering practice, as far as I can see, is fairly empirical; perhaps it always will be. I think, however, that the work reported by Mr. Mead, wherein he has tried to evaluate the sintering variables and then interpret them in the light of what might be encountered in practice is very valuable. I would like to suggest that more papers along this line would be helpful contributions. Mr. Mead and his company are to be complimented on publishing this information.

E. H. ROSE—Recently the American Iron and Steel Institute had a meeting on sintering in Pittsburgh which I happen to have had the pleasure of attending and there were two representatives there from, I think, practically all of the steel companies throughout the country. There were two men from Bethlehem and two from Jones and Laughlin, a couple from Carnegie, Illinois, and a couple from our place down in Birmingham. Altogether there were some thirty men there in teams of two, one a research man and the other an operating man. There was a round table discussion to see what we could formulate in the way of a program in that organization to find out what we should do to approach within shooting distance of the very thing that Mr. Mead has brought out. It is quite clear that sintering, particularly in the fine sense, is a precision operation, or should be, and yet at that meeting we paneled all of the experts and asked them a lot of questions. We all resolved to do something more about that, and a program is getting under way which I hope will result in much more information on the whole subject. Now, the astonishing thing is that none of us at that meeting could even state what is good sinter. Of course, we are all seeking a sinter that will double the production of the blast furnace and all that sort of thing. No one could define it there. Perhaps someone can define it at this meeting. If so we certainly want him to tell us about it.

F. M. HAMILTON*—This paper on sintering variables is quite interesting to us and no doubt the rest of the industry. The sintering process is being more closely scrutinized and studied since more ores require agglomeration than heretofore, and it appears as though the trend will be accelerated in the near future.

We have expended considerable time and effort on sinter research in the past

‡ Battelle Memorial Institute.

* Jones and Laughlin Steel Corporation, Negaunee, Mich.

few years and much of our work has been along the same line as that of National Lead. Results are in agreement with those obtained by National Lead, although the approach to the individual problems was somewhat different in some cases, and different types of material were used.

In the case of the study of moisture control of the mix, our method was to make up different types of sinter mixes at various moisture contents and then determine the amount of airflow it was possible to obtain under fixed conditions through the mix without sintering. In this manner curves were obtained which showed optimum moisture contents for maximum airflow. Then mixes were made up with moisture contents on either side of the optimum amount and subjected to sintering tests. The time, in minutes, required to sinter a test batch of 35 lb was then measured by means of a continuous strip chart record of the exhaust gas temperature. It was found that the optimum moisture content varied with the material being used. For example, New York State magnetite from Benson mines gave the best airflow values at $7\frac{1}{2}$ pct moisture while fine Minnesota hematite gave the best airflow values at 10 pct moisture. Furthermore, the best moisture content for sintering was found to be just slightly lower than the optimum indicated by airflow tests.

In connection with pellets, I note that difficulties were encountered in sintering when pellets were unintentionally formed in the mixer. Our experience has been similar in this respect but we purposely made pellets in a pelletizing drum for sintering purposes. After many trials along these lines we conclude it is quite difficult to successfully sinter pellets made from fine materials. One of the reasons for the trouble appears to be the magnitude of the difference between the optimum moisture content for sintering and the minimum moisture content at which pellets can be formed.

Our work with the surface tension properties of water in the mix agrees with that of National Lead. Wetting agents are very detrimental to sintering; however, little success has been obtained by the use of oils, lime, or limestone with our raw materials.

As a result of experiments in the plant by our New York operators, fine fractions of coal were found to be detrimental to good operation. Best results in this plant are obtained on a No. 5 Buckwheat coal.

The authors of the paper emphasize the importance of the proper use of returns in sintering fine materials. Our laboratory work indicates that large size returns are a waste of good blast furnace feed and their use as returns in the mix is of little or no value in promoting bed porosity. We expect to be in a position to carry out production runs along these lines in the near future.

The present paper is both interesting and informative on a subject of great importance to the steel industry today. It indicates recognition of the growing importance of closer metallurgical control and better plant equipment for improved sinter operations.

T. E. LLOYD*—Concerning pellets, I think that both of you are right about pellets. When you attempt to sinter a pellet that is too large, very often the coal inside of it does not burn. More often it is roasted to a coke. In such cases, obviously, it is better to have this fuel on the outside of the pellets. If the pellet is small, air gets to the coal, it burns rapidly and you have a sinter.

You have probably noted that there is a remarkable difference in pellets. A charge in which the individual small pellets have been formed by rolling until they are free of air and are solid, (a good term is "dense") will sinter faster and more uniformly than a charge of identical proportions of moisture, fuel, and others, which has not been so carefully pelletized. I believe that in many of our arguments here regarding the sintering of pellets we must first take into consideration the physical qualities of the pellets. How good is your pelletizer or mixer? To add moisture uniformly is almost an impossibility, but how close does the pelletizer approach this goal? What is the specific gravity of your individual pellet?

A few years ago, the New Jersey Zinc Co. believed that a sintering mix could be benefited if it were squeezed by running through rolls before mixing. I do not know how far they followed this up but the idea is a step in the proper direction for two reasons. First, it tends to unify the moisture content. Second, it squeezes air out of the mix which in turn serves to densify the agglomeration of particles in the individual pellets composing the mix.

H. W. JOHNSON†—It is my understanding that the commercial plant is operating on a minus twenty mesh material now.

J. C. MEAD—That is right.

H. W. JOHNSON—With a bedding about 1 in., what is the screen size of your finished product and your weight per cubic foot of the product.

J. C. MEAD—There have not been any bulk density tests taken on the plus one inch sinter. There have been bulk density tests run on the return fines and they have been the following: 101 lb per cf on minus 1 in. plus eight mesh screen size, 99.4 lb per cf on minus $\frac{1}{2}$ in. plus $\frac{3}{8}$ in. screen size. The bulk density of sinter will vary widely unless some limits on screen sizes is followed which will

exclude the "fines."

The screen size of the finished product is all plus 1 in. There have not been any screen analyses made, but by a visual check most of the sinter is plus 6 in. size with a maximum lump size of 2-ft pieces

H. W. JOHNSON—I think it would be a valuable addition to the discussion if that point were actually made—the weight per cubic foot—if there is a possibility of getting it. I think the importance of the weight of that material is of great significance. We have operated our furnaces on some test runs with high percentages of sinter with no improvement in operation. I think much of the reason for that is that we have failed to recognize the importance of the quality of the sinter used and one measure of this quality is the weight per cubic foot.

E. H. ROSE—I think that is quite true, Mr. Johnson; this also came out in Pittsburgh recently in a great many of our arguments about sintering. We can never get together because we cannot even define our subject. What defines quality? what is good sintering? In the investigation I mentioned a moment ago we are hopeful we will be able to set up some definitions. After all, just to say a sinter is hard or not hard or that it is bad or not good, very bad or very good, still does not say anything you can define and reproduce. It does not permit you to run a test with sinter as one specific definition and see what the blast furnace does and with another specific qualified quantity of sinter, what the blast furnace does on that.

Mr. Mead, did you make any porosity measurements?

J. C. MEAD—No, we did not.

T. E. LLOYD—First we know that iron ore at around 900 to 1000°C reduces two or three times faster than sinter of the same size. Secondly, it goes without saying that the structural or physical properties of iron ore fines in a furnace are impractical. Finally, it is known, but not often enough remembered, that sinter becomes increasingly more difficult to reduce as the carbon content, within practical ranges, increases. To me, the ideal sinter is a sinter coming from a charge so thoroughly and uniformly mixed that the practical range of fuel, say between 3 and 6 pct, can be held at its absolute minimum. Without the uniformity of thorough mixing, this range cannot be held. Either a trifle extra fuel is required to produce sinter or inevitably there will be portions of unsintered and channelled product.

When an ore is fine enough it can be pelletized. These pellets when roasted at around 900 to 1000°C are usually quite tough and contain about 40 pct voids. Not forgetting the difficulty of sulphur, and other elimination, if this could be

* Newark, N. J.
† Inland Steel Co.

done on a sintering machine I should think the resulting product would be even more ideal.

E. H. ROSE—Mr. Mead's mention of lime in his experiments only goes to remind me that in sinter, as in so many other affairs of this world, what is one man's meat is another's poison.

F. D. DE VANEY—I am a little bit reluctant to say anything about pelletizing. We are in the process of getting a full-size plant in operation, and one is reluctant to talk about something still to be done. The plant we have up in Aurora is a test plant in a way. In pelletizing or sintering the concentrates, we were interested in the most efficient and cheapest way. We rolled our concentrates up into balls and we learned a lot about that operation too. We rolled the material up in a drum about 8 ft in diam at a rate of 30 tons an hour, and the balls, when they came out, were hard. They would not stand shipping but they would stand movement around the plant. We fed these into what we call a tandem type furnace and then they were fired. We add our heat through a combustion chamber. The furnace is of the regenerative type, so our top gases come off at about 225°F and our pellets come out at the bottom at from 250 and 275°F. These pellets are hard when fired. I hope next year we will be able to prepare a paper and tell you just how the process works.

L. J. ERCK*—It surprised me a little to hear Mr. Mead say that the pellets which were made would not form a hard pellet on the grate inasmuch as they were a 100 pct pellet charged on a sintering grate. That point in my mind is just a little hazy now as to why the material produced in cake form would definitely sinter and yet the pellets would not. The

material we are working with at the present is a straight hematite. We have found on several occasions that the fuel has to be very thoroughly mixed, and I mean thoroughly. The pellets themselves, if not thoroughly mixed, will vary, and if that is so you will find that one pellet will burn while the next pellet will be soft. Likewise, we found that each individual pellet almost has to be a thorough and complete mixture of the ore and fuel, for if it is not you will find that one part of the pellet will be soft and the other part hard. In respect to adding lime, that problem was brought up inasmuch as the concentrate on which we are working does not present enough of the minus 325 mesh size to form favorable feed to the balling drum. There must be a certain percentage which I believe we can be safe in saying is about 50 pct—at least 50 pct. I have seen a few tests at 40 pct but 50 is certainly more satisfactory.

We thought if we could add lime of minus 325 mesh proportion in the proper percentage, we would be doing quite a trick; we would not only be making up the deficiency of the minus 325 mesh but we would also be making something equivalent to a more or less self-functioning material. The material was prepared and placed in the pelletizing furnace and we ended up with a slag mass of about 900 lb that had to be lifted with a crane, and that ended that experiment.

A. C. RICHARDSON—What was the temperature?

L. J. ERCK—That is another point I might bring up. These materials vary. We just finished running a pelletizing test down at the station under which we had no control as to the moisture content. It was a filter cake with a very high moisture and in putting it through the balling drum all the material immediately formed balls. The new material added to the returns usually built up the said

balls until they became of age. This was not the case. All the feed immediately formed balls from $\frac{1}{16}$ in. up to about $\frac{1}{4}$ in. so in placing that in the furnace we had to control the heat, not carrying it as close to the top as we usually do.

L. A. ROE—In our attempts to sinter pellets we used a batch sintering machine which was operated at a temperature of about 2475°F. Mr. Erck is speaking of firing pellets in a shaft furnace, and probably uses temperatures of 2000° or less. I wish to call attention to the fact that temperatures utilized to sinter pellets are considerably higher than temperatures used to fire pellets in a shaft furnace.

J. C. MEAD—What was the size of the feed you used in making the pellets, Mr. Erck?

L. J. ERCK—It has to be of proportion so that you do not diminish the quantity of minus 325 which is so essential for forming the pellets in the ball drum. You must be sure you have the proportionate amount of fines. Of course, the amount that you add in hematite is still relatively small.

E. H. ROSE—Is anyone familiar with the pelletizing operation at Santa Cruz on the cement?

G. J. HOLT—While trying to produce lump ore we used cement as a binder and almost everything from straw up and down. We were trying to produce lump ore. We ended up by deciding we did not know enough about it and gave up the entire project. Are you using a binder in your work?

E. H. ROSE—Yes. At the moment we are rather intrigued with the use of the paper mill waste. There are lots of paper mills in our vicinity, and we do have to heat treat it afterwards.

The Influence of Temperature on the Affinity of Sulphur for Copper, Manganese and Iron

By E. M. COX, M. C. BACHELDER, N. H. NACHTRIEB, and A. S. SKAPSKI

DISCUSSION

(D. T. Rogers presiding)

D. T. ROGERS*—The conclusions drawn in this paper have important practical significance to the steelmaker and the metallurgist if, in practice, it is demonstrated that metallic copper in the charge will pick up sulphur from the furnace atmosphere and thus increase the

sulphur content of the bath. The problem of residual copper arising out of increasing copper in the scrap available to the industry is, in itself, a matter of concern to the steel maker. If, in addition to the often detrimental effects of high residual copper upon the physical properties of some important steel grades, there is to be a complication of the sulphur problem, then we have a set of conditions that bodes no good for the open hearth melter and the open hearth metallurgist.

M. B. BEVER*—Investigations of gas-metal equilibria continue to be of interest, especially as new possibilities for improving experimental techniques emerge. Higher purity of reacting substances, better refractories, improved methods of temperature control and an increased awareness of the pitfalls of high-temperature equilibrium work are

* General Metallurgist, Jones & Laughlin Steel Corporation.

* Assoc. Prof. of Metallurgy, Mass. Inst. of Technology.

some of the factors that should contribute toward better data on gas-metal reactions.

The authors have furnished adequate and interesting information on many aspects of their experimental procedure. A more detailed discussion of several factors, however, is desirable. The loss of hydrogen from the system by diffusion, thermal diffusion within the gas phase and the thermal decomposition of hydrogen sulphide may be named. Have the authors examined the composition of the solids after each experiment, and were both the true stoichiometric sulphide and the pure metal found to be present?

It is well known that hydrogen diffuses readily through silica at high temperatures and the same is probably true of other gases and refractories, although to varying extents. The authors' procedure of checking various furnace materials against each other is to some extent a safeguard against errors of this kind but the loss of hydrogen through silica should be acknowledged as an inevitable certainty. This loss can probably be tolerated since equilibrium between the gas mixtures and the condensed phases is likely to be maintained.

The use of an impeller for keeping the gas atmosphere in motion tends to eliminate the possibility of thermal diffusion, given a sufficiently high gas velocity, but this may in turn interfere with temperature equilibrium. The thermal decomposition of hydrogen sulphide is another potential difficulty on which further comment by the authors would be desirable.

Concerning the numerical evaluation of the results of this investigation the heats of formation evidently are based on an extrapolation over a temperature interval which is altogether too wide. It also seems very doubtful whether the scattering in the plot of the logarithms of the pressure against reciprocal temperatures is any less serious than the scattering of the free energy-temperature data which the authors have rejected as a means for evaluating entropies.

The authors concede that the interpretation of their results for the steel-making process can be only tentative as far as the solid ingot is concerned. However, their interpretation of some fundamental features of the behavior of sulphur, copper and manganese in liquid steel is also open to question. They state that because of the relatively high affinity of copper for sulphur the sulphur content of the bath increases with the copper content of the scrap and that consequently the desulphurization process is hampered. This argument is equivalent to the statement that the presence of a deoxidizer in the bath raises its oxygen content and interferes with deoxidation. On the other hand it would seem to be consistent with the authors' point of view to expect that sulphur may be used to remove copper from molten steel. To

avoid such conclusions it must be recognized that this investigation deals with pure substances and its results can be applied to the physical chemistry of steel-making only by the rigorous methods of the thermodynamics of solutions.

R. E. MINTO* and H. B. EMERICK*—This discussion is aimed at the authors' principal conclusion, to wit: "... that metallic copper which is present in the scrap is to be expected to pick up sulphur from the open hearth furnace gases and thus raise the sulphur content of the bath."

An opportunity was afforded to test the validity of this conclusion in actual practice when during a recent period Jones & Laughlin Steel Corporation made 50 heats of 0.40 pct copper low alloy high tensile steel wherein the major portion of the copper requirement (all but minor final additions to adjust analysis) was obtained from high copper scrap charged with the regular scrap at the start of the heat. This scrap averaged 5 pct copper content, the copper being in the form of a heavy gild metal cladding and not as a copper-iron alloy.

A study was made to determine the effect of this added copper in the charge on melt-in sulphur and ladle sulphur chemistry. To do this, the routine sulphur and copper analyses on these heats were tabulated and compared with 50 heats made in the same period (and heat for heat chronologically as close to copper charged heats as possible) but with the practice of obtaining the copper requirement by the addition of pure copper late in the refining stage of the heat. This procedure assured reasonable constancy of lime charge and total sulphur content of the raw materials. The two practices are differentiated by calling the first group "copper charged" heats and the second group "copper addition" heats.

Preliminary copper tests are taken about 3½ hr before tap. Sulphur preliminaries are taken about 1½ hr before tap. When copper is supplied by pure copper it is added comparatively late in the heat—from ½ hr to 1¼ hr before tap. The heat at this time has been under slag cover for considerable time and subsequent absorption of sulphur from the furnace atmosphere is negligible. During the test period sulphur content of fuel oil ranged from 0.35 to 0.89 pct, averaging about 0.75 pct sulphur.

Pertinent data may be summarized as follows:

| Practice | Copper Charged | Copper Addition |
|------------------------------------|----------------|-----------------|
| No. heats..... | 50 | 50 |
| Pct preliminary copper—Range..... | 0.29/0.64 | 0.06/0.14 |
| Avg..... | 0.38 | 0.09 |
| Pct ladle copper—Avg..... | 0.41 | 0.38 |
| Pct preliminary sulphur—Range..... | 0.030/0.055 | 0.021/0.050 |
| Avg..... | 0.0373 | 0.0363 |
| Pct ladle sulphur—Range..... | 0.023/0.038 | 0.023/0.034 |
| Avg..... | 0.0271 | 0.0271 |

* Metallurgical Dept. Jones & Laughlin Steel Corporation, Pittsburgh, Pa.

These data indicate that an appreciable pickup of sulphur is not experienced when about 1000 lb of copper is charged as high copper scrap in 175 ton basic open hearth heats melting down in about 4 hr in a furnace burning 0.75 pct sulphur fuel oil. No evidence is found to support the authors' contention that metallic copper present in the scrap may be expected to pick up sulphur from the heating gases, thus increasing the sulphur content of the bath.

C. E. SIMS*—I will not discuss the experimental work, not having gone into that portion of it closely, but let us assume that the figures are correct for the sake of argument and that copper sulphide is more stable than iron sulphide or even more stable than manganese sulphide at the steelmaking temperatures. It does not seem to me, however, that such a conclusion gives the authors the right to assume that copper, when diluted down to a fraction of a per cent, as is usually the case, could still exert an important effect on the affinity of that iron copper alloy for sulphur, or its ability to pick up sulphur from the gases. Now, if metallic copper is present as pieces of copper in the scrap, during the melting of the steel it probably would pick up a larger proportion of sulphur than the steel scrap and, of course, an important contamination of sulphur does occur during the melting. Even so, when it is present in such small quantities it does not seem that it could have an important effect on the total sulphur content. However, if it is true that in the finished steel the sulphides contain a large portion of copper sulphide then I think there is a significance that has not been touched upon by the authors. We know that copper steels give considerable trouble during the hot working of plate in the form of surface checking and edge cracking. In other words, in examining steel that has been hot worked and which shows this surface cracking we find that there has been a deep penetration of oxides along grain boundaries. Now, this occurs only during the hot working, and if a copper sulphide does constitute an important portion of the sulphides it may form a liquid eutectic at these hot working temperatures that would influence the penetration of oxide along the grain boundaries and cause this phenomenon of surface and edge cracking. This probably could be checked by finding the relative trouble from a high sulphur steel and a steel very low in sulphur but with

* Battelle Memorial Institute.

about the same copper content.

M. TENENBAUM*—I would like to confuse the role of copper and sulphur in the melting of plain carbon steels a little bit if I can. We make intentionally a good tonnage of steels containing over 1 pct of copper. Quite often we charge nearly all that amount of copper with the original solid charge and we have never run into any difficulty with any increased melt or final sulphur in this grade. Now, to confuse the situation, we often get complaints from our melters (and I am sure they have not read Dr. Skapski's paper) about the difficulty of removing sulphur from copper bearing heats, that is, heats containing 0.15 pct or higher copper in the liquid bath. They claim to observe this rather consistently and insist this condition actually exists. On reviewing our metallurgical reports in an attempt to get statistical evidence to support their observations, we have never been able to bring out any data that would indicate any increased difficulty in eliminating sulphur in the presence of copper.

N. H. NACHTRIEB (authors' reply)—The principal objection of Mr. Sims (supported by the evidence contributed by Messrs. Emerick and Minto) might be rephrased in this form: Is the thermodynamic activity of copper dissolved in liquid steel sufficiently high to remove sulphur from the heating gases and to fix it in the form of copper sulphide soluble in the steel? Our experiments give no answer to this question, inasmuch as they dealt with pure copper and iron with their respective sulphides, and not with copper at the level of concentration in which it prevails in actual steels. For the latter case the relevant chemical reactions may be written as:

* Inland Steel Co.

The corresponding free energy relationships are:

$$\Delta F^\circ_{\text{Cu}_2\text{S}} - \Delta F^\circ_{\text{Cu}_2\text{S}} = RT \ln \frac{(a_{\text{Cu}_2\text{S}})^2}{(a_{\text{Cu}})^4 (p_{\text{S}_2})}$$

$$\text{and } \Delta F^\circ_{\text{FeS}} - \Delta F^\circ_{\text{FeS}} = RT \ln \frac{(a_{\text{FeS}})^2}{(a_{\text{Fe}})^2 (p_{\text{S}_2})}$$

Whether copper is capable of competing with iron for sulphur under steelmaking conditions will depend upon whether $[\Delta F^\circ_{\text{Cu}_2\text{S}}] > [\Delta F^\circ_{\text{FeS}}]$. In turn, this depends not merely upon $\Delta F^\circ_{\text{Cu}_2\text{S}}$ and $\Delta F^\circ_{\text{FeS}}$, but also upon the activity of the copper dissolved in the steel, the activity of the copper sulphide (in the steel or in the slag), and upon the activity of the iron sulphide. We may consider the activity of the iron to be unity for all practical purposes. Since activity data are lacking, we cannot predict with any confidence that a fraction of 1 pct of copper in steel will result in an increase in the sulphur content of the steel as a result of reaction with the heating gases. The experimental evidence of Mr. Tenenbaum and that presented by Messrs. Minto and Emerick suggest that the activity of copper in steel must be *insufficient* to cause appreciable sulphur pick-up or to materially hinder the desulphurization process.

I should like to answer Mr. Bever's comments as follows:

Gas circulation, aided by the impeller, was estimated to be about 1 cm³ per sec. This, we feel, is high enough to overcome the Soret Effect of thermal diffusion. At the same time, it is probably low enough to permit the establishment of the equilibrium:

For the highest temperature run with Cu₂S (1519°K) the experimentally determined (H₂S)/(H₂) ratio has the value 5.15×10^{-3} . The pressure of sulphur vapor at this temperature is only 2.26×10^{-6} atm. (from Kelley's data for the thermal decomposition of hydrogen sulphide). This corresponds to only 0.044 pct decomposition of the hydrogen sulphide in the hot zone, and represents an error which is well within the errors in the analytical determination of hydrogen sulphide.

Mr. Bever is undoubtedly correct in stating that hydrogen diffuses through silica and other refractories at high temperatures. However, this introduces no error, since the measured ratio (H₂S)/(H₂) is maintained by the metal-hydrogen sulphide equilibrium:

Loss of hydrogen by diffusion through the furnace tube leads to a corresponding diminution in the hydrogen sulphide pressure.

Finally, Mr. Bever's comments comparing desulphurization and deoxidation may be examined. Elements serve as deoxidizers only if their oxides form a second phase whose solubility in the metal is low. Should their oxides be quite readily soluble in the metal, the oxygen content of the metal *would be increased*. Similarly, elements whose sulphides are very sparingly soluble in the metal should be effective in removing sulphur from the metal. To the extent that oxides (or sulphides) are soluble in the liquid metal the processes of deoxidation (or desulphurization) would be hindered; such elements might conceivably perform a disservice if their activities (and the solubilities of their oxides or sulphides) in the metal were sufficiently high.

The Role of Thermochemical Factors in Basic Open Hearth Production Rate

By T. E. BROWER and B. M. LARSEN

DISCUSSION

(H. C. Swett presiding)

L. REINARTZ*—In larger open hearth furnaces we have had somewhat different experience from Mr. Larsen. In the first

* Middletown, Ohio.

place, we find a very considerable increase in speed of the heat if you lower the limestone charge, and furthermore, we have found a tremendous improvement in tons per hour by using heavier scrap iron in the charge. We have recently made some experiments in different ways to charge furnaces which have shown

much greater regularity of slag run-off with about the same high percentage of pig iron being used. We have made heats containing up to as high as 70 or 75 pct of hot metal.

With this practice we have made some low carbon heats in very fast time. Some steel plants in the East have done very

good work when charging light scrap iron because they are able to charge continually. In most plants where you must use light scrap iron, charging time increases very materially, and, as a result, the length of the heat time is very much increased.

T. T. WATSON*—We have had considerable experience in all cold metal charging practice and examination of a large number of heats definitely indicated that the charging time is an extremely important factor affecting heat time. An increase in charging time will increase heat time. As the optimum charging time is approached the rate of flow of the raw materials (steel scrap and pig iron) is equally as important as the charging time.

M. TENENBAUM†—About six or seven years ago at Inland it was possible to relate our heat time with our limestone charge. About 1944 we mechanized our coal mines and we got a little poorer analysis hot metal as a result. We then found that we had to use quite a bit of our heat time in working sulphur. Accordingly, our limestone charges were increased. When we finally increased the stone charge uniformly throughout the shop, it was found that despite the in-

creased limestone charge our heat time was not affected. When our practice was standardized to the point where we did pretty well on sulphur, we then dropped the limestone charge through the shop. Again we went back to the old condition where it did not make any difference. Apparently the time saved in pulling lime was lost in working sulphur. It is just a sort of warning that where you may save a few Btu's during melting you sometimes may lose more than you have gained. The loss can appear either as poor product quality or as increased heat time used to meet quality requirements.

B. M. LARSEN (authors' reply)—The comments here on the effect of heavy scrap, charging time, etc. illustrate the need for a more rational analysis of furnace variables in general. In melting down light or heavy scrap, we have (1) the "sharpness" of the furnace, (flame intensity, direction, etc.), (2) the rate of charging and the aggregate time with doors open, and (3) the amount of oxygen absorbed by each ton of scrap during melting. These factors are all involved in furnace speed and also are somewhat interrelated. For example, the more "sharp working" the furnace is, the faster will light scrap have to be fed in to avoid delay due to periods with charge down pretty flat and fuel reduced waiting for more charge. The advantage of heavy scrap will be greater with slow charging

and also with charging conditions such that the furnace doors remain open an inordinate percentage of the charging time.

We cannot be sure even that light scrap always means more oxygen absorption, though that seems very probable in the average case. The point we tried to make in the paper was that more oxygen absorption from the gases means a lower net heat requirement by the bath; therefore, if whatever light scrap being used can be prepared and charged to the furnace about as fast as it can be melted down, with a minimum of open door periods, then we are *likely* to get faster production rate on light scrap charges. On the other hand, with the complex of factors above mentioned, it is easy to see the possibility of just the opposite effect, as mentioned by Mr. Reinartz. Also, dense piles of oily turnings or well compacted bales of sheet scrap might give a low amount of oxygen absorption, so that the detailed physical character of the scrap charge is probably involved.

Regarding Mr. Tenenbaum's comments, our experience has been that extra limestone does not always increase time of heat appreciably and this would be true especially where extra lime was needed anyhow for sulphur elimination; if it was not put in with the charge it would have to be added later so that the extra work in refining would offset any advantage from shorter melting periods.

The Interaction of Liquid Steel with Ladle Refractories

By C. B. POST and G. V. LUERSSEN

DISCUSSION

(H. C. Swett presiding)

J. STEVENS*—The authors state that the contamination in the metal was due mostly to the ladle refractories. Did the contamination vary with different brands of refractories or different qualities in the ladle?

C. B. POST (authors' reply)—That would be expected. In our shop we have used a grade of firebrick which is fairly standard. We do use high refractory nozzles to combat this erosion and high refractory sleeves, but there is such a problem when you get a skull in a ladle you just cannot use these high refractory bricks; you rip out the whole ladle getting

the skull cleaned up. The acid bricks form a glass, and you can pull the skull out when you do get them. I believe you might find variations among the different refractories depending on how much silicon is in the brick. This determines how much silica is going into the interface between the steel and the brick. Our brick is about 35 pct alumina and 65 pct silica. With a brick of 35 pct alumina in the slag patches new calculations would have to be made.

R. PARDEE*—Where can you draw the line in determining the refractories as being a silica refractory?

C. B. POST—More silica than about 50 pct. I think perhaps that is generally

the criterion. The brick we use is a good high grade fire brick.

T. S. WASHBURN*—With reference to the higher silicon that is recommended as a result of this investigation, is it contemplated that the specified range would be raised to 0.40–0.60 pct silicon, or possibly 0.50–1.00 pct silicon? These higher silicon ranges would affect the physical properties of the steel and consequently there might be some complications with respect to educating the consumers to accept this revision of the conventional analysis.

C. B. POST—It will take considerable work. Take AMS 6260 as an example. Ordinarily this specification calls for 60 or 75 manganese. Silicon has some

* Murray Refractories, Murray, Utah.

* Mexico Refractories Co.

* Inland Steel Co.

hardenability in itself, and I believe if you aim for 40 to 60 for both the manganese and silicon you will have the same hardenability. At least, we have had no difficulty in meeting all the tests of the AMS 6260 specifications on that score. It might be if you had a steel too lean in hardenability for the job under the best of conditions you might get into a little trouble. I agree with you that it is going to take some work and by the people who are more qualified to talk on it than I. As far as I know, I do not think we will run into any difficulties in what work we have done.

A. A. BRADD*—The authors present very interesting and valuable information about the effect of the Mn/Si ratio on the nonmetallic inclusion content of the steels investigated. However, another factor controlling the formation of the type of nonmetallic inclusion discussed by the authors is the composition of the ladle refractories with which the steel comes in contact before entering the mold. The authors' investigations were done with 65 pct SiO_2 —30 pct Al_2O_3 —5 pct Fe_2O_3 firebrick. Rait and Pinder

* Ass't Supt. Treatment Dept., The Midvale Co.

in a paper on "The Origin and Constitution of Certain Non-Metallic Inclusions in Steel," published by the British Iron and Steel Institute in June, 1946, found that manganese aluminosilicate inclusions could be reduced to a minimum if the firebrick refractory with which the molten steel came in contact had at least 38 pct Al_2O_3 . Their work was done with steels containing about 0.30 C, 2.80 Ni and 0.65 Cr, and Mn/Si ratio ranging from 1.68 to 3.87.

The harmful effect of higher Mn/Si ratios on cleanliness ratings might not be so pronounced if more aluminous refractories were used.

The Ionic Nature of Metallurgical Slags. Simple Oxide Systems

By J. CHIPMAN and LO-CHING CHANG

DISCUSSION

(H. C. Swett presiding)

C. B. POST*—Just what are you showing that has not been shown by fixing the attention on molecular species and choosing the molecular species to give you a perfect solution?

J. CHIPMAN (authors' reply)—In general a fairly satisfactory thermodynamic treatment of slag-metal equilibria can be worked out on the basis of assumed molecular species in the slag. This has been the method used by Shenck and more recently by White, Winkler and I

also used it in studying dephosphorization. Darken and Gurry found that it did not fit satisfactorily in the case of their data on iron oxides. The ionic formulas used here conform to the data much better and probably correspond somewhat more closely with the actual structure of the slags.

C. B. POST—It does seem to be similar to you?

J. CHIPMAN—It is alternative, and may lead to a more complete understanding.

C. B. POST—Have you had a chance to talk to glass technologists on this? Have they been using this type of set-up for glass solutions?

J. CHIPMAN—Yes, and the ionic formulas have given them a little better understanding of what liquid glass is like.

C. B. POST—Nelson Taylor always said we were going about slag reactions from the wrong viewpoint when using molecular species. Evidently the glass technologists use ionic species exclusively when dealing with liquid glass reactions.

J. CHIPMAN—I agree that it seems more rational and more accurate to use ionic rather than molecular formulas. We should be cautious, however, and not suppose that we really understand the structure of a slag just because we are able to fit its reactions by ionic equations.

Electrolytic Zinc at Risdon, Tasmania. Major Changes Since 1936

By S. W. ROSS

DISCUSSION

(C. C. Long presiding)

A. A. CENTER*—This paper reminds me of the beginning of the work of the Electrolytic Zinc Company of Australasia.

Early work for this Company, as some of you may know, was done at the Bully Hill Plant in California. After working there for some time Herbert Gepp, now Sir Herbert, came to the Anaconda Co. plants in Montana where I met him. He spent some months there, in fact almost a

year if I remember rightly. That was when we were breaking in the new electrolytic zinc plant at Great Falls, Montana. From there he went back to Australia and started in on the plant there. I believe they had an original plant of about 20 tons per day of cathode zinc. We heard from them for some time, until they were able to go along on their own, and they have done very well ever since as you have heard.

Their practice, (the flow sheet, the leaching practice), has been quite different as reported in the paper and apparently they are still following that

practice to some extent.

While the earliest work on selective flotation was done down in Australia, the big companies there, strange to say, were far behind the American companies in taking it up; and it is only in comparatively recent years they have gone to the alkaline circuit and dropped out thereby more of their iron and lead. The zinc plant now is up to a capacity of 100,000 tons a year and I believe that may be notched up to about 105,000.

T. H. WELDON*—I would like to ask

* Consolidated Mining and Smelting Co.

Mr. Gordon of the Risdon staff, whether, in the handling of these high sulphide calcines, there has been a build up of manganese in the solutions and if so how is it controlled?

A. R. GORDON*—Manganese has not built up tremendously. We have manganese in solution at present to the extent of about 18 g per liter. Removal in the cells by oxidation and losses in various incompletely washed residues and precipitates maintain a state of equilibrium. However the manganese content of feed solution has varied over the years from about 6 to over 20 g per liter. We have never had to take any special steps to control the manganese build up but if the amount increased unduly we would probably institute the discard of electrolyte virtually stripped of its zinc content.

L. P. DAVIDSON†—How much depletion do you have between your purified solution and your electrolyte when your manganese is that high? It will go in about 20 or 25 g per liter. What does your cell acid run?

S. W. ROSS (author's reply)—The removal of manganese in the cells varies chiefly according to the state of the anodes. New anodes will remove several grams per liter of manganese whereas old anodes, say over 12 months old, will remove less than $\frac{1}{2}$ g per liter. On the average I would say we remove about 1 g per liter during passage through the cells.

C. C. LONG‡—Would some of the electrolytic zinc experts care to talk a bit about the removal of germanium and tin by means of soluble silica?

W. G. WOOLF§—Is the precipitation of germanium and tin by means of the soluble silica a chemical reaction or an absorption phenomenon?

S. W. ROSS—I do not think that anybody in Risdon has a very clear idea whether the removal is chemical or by absorption. I think the idea was that it might be absorption, but there is nothing definite.

* Risdon Works, Tasmania.

† American Zinc Co., Monsanto, Ill.

‡ St. Joseph Lead Co. of Pa., Monaca, Pa.

§ Bunker Hill Co., Kellogg, Idaho.

H. R. HANLEY*—I understand that the electrolytic zinc plant at Risdon, Tasmania, makes 3-day cathodes at current efficiencies above 90 pct. In this country the stripping interval is limited to one day. Do you think that superior purification is responsible for the longer cathode deposition between strippings.

S. W. ROSS—Of course in thinking about the period of stripping you must remember the difference in current density too. We use a cathode current density of upwards of 30 amp per sq ft, whereas some of your plants in this country use appreciably higher cathode densities—I think as high as about 50 amp per sq ft. At the same time we have always believed that our ability to run long stripping periods has depended mainly on three factors, (1) adequate purification, (2) a suitable combination of addition agents, and (3) maintenance of reasonably low cell temperatures.

Purification is of paramount importance, and perhaps the most vital step is that in which limestone is added. It is not difficult to drop current efficiency by many percent by improper conditions of purification in spite of the fact that the iron is completely removed. Then it took us a long time to find what was apparently the best combination of addition agents. Under our particular conditions we have never improved upon the particular combination of glue and betanaphthol referred to in the metallurgical data of the paper. Any substantial departure from these amounts adversely affects current efficiency. Finally the maintenance of reasonably low temperatures is of great importance. We have often had parts of the cell room up to over 40°C with a distinctly adverse effect on efficiency.

I would say that solution purity is probably the major factor in permitting long stripping periods but other factors are important.

H. R. HANLEY—Do you think the soluble silica in the zinc solution at Risdon has any effect on the crystal structure of the cathode?

S. W. ROSS—I am not very sure about

* Rolla School of Mines, Rolla, Mo.

this. The use of soluble silica as an addition agent in zinc electrolysis is not uncommon practice and its presence is undoubtedly beneficial under the conditions in which it is used. At Risdon about $\frac{1}{10}$ g of silica per liter survives the purification steps and enters the cells. It is quite probable that it has some influence on electrolysis and as Dr. Hanley has suggested it may affect the crystal structure. The way in which addition agents affect current efficiency and the structure of the deposit is a subject which has yet to yield many of its secrets. Much of the work done in the past has been somewhat on the hit and miss principle. We have carried out some research work on the structure of the zinc and its relationship to addition agents but I do not remember any attempt to link the effect of soluble silica with structure.

A. R. GORDON—Concerning the use of fine calcine in place of limestone for iron purification, I did not notice any reference to this in a quick look through the paper, but at Risdon we have often used fine calcine quite successfully and thereby reduced the requirements of sulphuric acid to maintain the sulphate content of the circuit.

S. W. ROSS—I note that our chairman referred to the removal of germanium and tin by means of soluble silica. I would like to draw attention to the point that no mention is made of tin in the paper in this connection. Silica appears to play an important role in the control of germanium but not of tin.

I thought that some remarks might have been provoked by the section of the paper headed "Roasting Policy." Risdon practice appears to differ widely from that employed by other plants in this regard and sometimes our roasting is looked upon as poor. However, the high sulphur oxidation per square foot of hearth area, achieved virtually in the absence of fuel addition, reduces both capital costs of the roasting plant as a whole and operating cost per unit of sulphur oxidized. On the other hand we have incurred the capital and operating costs of a flotation plant. The assessing of the debits and credits of this policy makes an interesting study.

Cadmium Recovery Practice at the Donora Zinc Works

By G. T. SMITH and R. C. MOYER

DISCUSSION

(C. C. Long presiding)

L. P. DAVIDSON*—In the analysis

* American Zinc Co., Monsanto, Ill.

of the cadmium sponge how is the sample prepared?

M. M. NEALE*—The analysis of the

* Manager, Donora Zinc Works, Donora, Pa.

cadmium sponge?

L. P. DAVIDSON—You gave a very high percentage of metallic cadmium, 2 pct zinc, 2 pct lead and say 93 pct

cadmium, or thereabouts. Just exactly how do you prepare a sample so that on a dry basis you get that analysis? Is that a dried sample?

M. M. NEALE—Yes, that is a dried sample, but I cannot answer your question as to just how it is prepared. Our chemists do that and I do not follow that through.

L. P. DAVIDSON—With the cadmium sponge from our plant we find that the chemist will give an analysis of about

70 to 75 pct, and then if you analyze it completely there is about 10 pct that you do not find; if you put it in a combustion train and actually collect the water you will find there is around 10 pct water in what is ostensibly a dry sample. We found that by washing it with alcohol one gets a sample on a dry basis so that although a part of the cadmium may be oxidized on drying, it will figure to 100 pct. Without washing by alcohol we have not been able to get it,—that is why I asked the question.

M. M. NEALE—I cannot answer your question fully on that.

A. W. SCHLECHTEN*—I merely ask for information and I fear that in doing so I may reveal my own ignorance but the question is whether the addition of zinc dust alone effectively removes germanium from the solutions.

M. M. NEALE—I cannot answer that.

* Missouri School of Mines, Rolla, Mo.

The Recovery of Cadmium from Cadmium-copper Precipitate, Electrolytic Zinc Co. of Australasia, Risdon, Tasmania

By G. H. ANDERSON

DISCUSSION

(C. C. Long presiding)

H. R. HANLEY*—I have been asked to discuss briefly the development of rotating cathodes for the electrolytic deposition of cadmium.

The earliest recorded use of rotating cathodes was by Hoepfner at Frufurt, Germany about sixty years ago. He electrolyzed zinc chloride solution using diaphragms to separate electrodes.

In the early experimental work of the Bully Hill Copper Mining and Smelting Co., Shasta County, Calif., rotating aluminum cathodes 4 ft in diam were used in the electrolysis of an acid zinc sulphate solution. Finished cathodes weighing up to 400 lb were produced. Because of mechanical difficulties, this type of cathode was abandoned for zinc, but was later used for cadmium because of the relative smoothness of deposit in comparison with stationary plates with comparable current densities. Cadmium sponge which forms on the cathode at moderate current densities (without special treatment) is entirely eliminated by a slow rotation.

The rate of rotation of the cathode has an effect on the mechanical nature of the deposit. A high rate of rotation concentrates the adhering electrolyte on the shaft; a moderate rate appears to concentrate on the cathode a short distance out from the shaft tending to corrode the deposit in the form of a ring. At a very slow rotation (2 to 3 rpm) the adhering electrolyte gravitates nearly vertically, thus avoiding the cutting ring referred to above.

The true explanation for the smoother deposits obtained on rotating cathodes

may not be given definitely as the numerous factors involved are not thoroughly understood. Smooth deposits are obtained when the orderly growth of the metal crystals in the cathode lattice are disorganized. Thus the crystals form and grow for a very short interval when they are arrested and a new crystal forms. The continued growth of the original crystals provides large crystals and a rough deposit. Also if the acidity of the electrolyte is low, hydrogen gas bubbles adhere to the deposit. As the cathode is rotated the gas surface is brought into the atmosphere where they burst; thus the deposit is made on a surface relatively gas-free.

An aluminum hub distance piece was riveted to each aluminum disk 4 ft in diam, slipped on a 4½ in. steel shaft and pressed tight to prevent acid electrolyte seeping through to the shaft.

The 9-cathode assembly was supported on insulated bearings. Electrical contact to the shaft was made through what was equivalent to a copper pulley. Sufficiently high conductivity brushes were placed on the face of the pulley to lead the current to the cathode bus bar. The assembly was driven by a link belt contacting a sprocket insulated from the shaft.

The lead anodes were semicircular and supported on porcelain insulators placed on the bottom of the cell. Two anodes were provided for each cathode to permit an 8-in. space between them without increasing the ohmic resistance. This ample spacing permitted easy stripping of deposit with the assembly in place.

Cathode cadmium was melted under 650 W cylinder oil. After casting, the primary slabs were remelted under molten caustic soda and cast into pencils 1½ in. in diam.

Rotating cathodes for deposition of

cadmium are used at Risdon, Tasmania, and at Magdeburg, Germany.

W. G. WOOLF*—This paper is very interesting to me because in our work at the Electrolytic Zinc Plant of the Sullivan Mining Co. we had an exactly similar problem—that is, a method of producing cadmium from our purification residue, the recovery of the contained copper as a copper precipitate which could be sent to a copper smelter and the production of merchantable cadmium. It is interesting to me, not knowing of the work of the Risdon people, how closely we approximate them in their main metallurgy, diverging at several interesting steps which I would like to discuss for just a moment.

For example, at Risdon they oxidize their purification residue. In our practice we take the current residue as it is produced in the purification department of the zinc plant and process it in the cadmium plant. The only oxidation that it obtains is the oxidation in the presses, the dumping of the presses and the collection and transportation of the residue to the cadmium plant.

We find that the leaching of that residue does not necessarily require the oxidation step that the Risdon people evidently find necessary.

The discussion of oxidation comes in again in the matter of the treatment of the precipitated cadmium sponge with zinc dust which again at Risdon is oxidized but which we do not attempt to oxidize except as it oxidizes itself in the storage. There is a partial oxidation which cannot be avoided, as Mr. Davidson pointed out, but we make no attempt to attain a complete oxidation and we dissolve the cadmium sponge in the sul-

* Electrolytic Zinc Plant, Sullivan Min. Co., Kellogg, Idaho.

* Missouri School of Mines and Metallurgy, Rolla, Mo.

phuric acid electrolyte of the electrolysis without any further oxidation.

Coming to the question of the rotating cathode, I have discussed this a few days ago with Mr. Gordon who visited our plant prior to this meeting and asked him why at Risdon they had the rotating cathode. He mentioned one reason perhaps was that they started with it and they continue with it because it apparently gives them satisfactory results.

The second point was that in the long-time deposition as the cathode rotates, if there are any sprouts they are easily knocked off so they obtain a smooth deposit. As a result, they are not bothered with sprouting which is one of the difficulties of cadmium electrolysis. In our procedure we have stationary cathodes. Our cathodes are stripped every 12 hr which gives us a relatively thin cathode, but the thin cathode does not bother us very much in the melting procedure.

The difference in the melting at our plant and the Risdon plant is that we melt in an iron pot with electric furnace under caustic soda. There is relatively little oxidation. The amount of dross that we obtain is comparatively small and we find no need or requirement for the thick deposits such as Risdon obtains.

A. A. CENTER*—This matter of weathering the cadmium-bearing residue is rather interesting. When we did our early work at the Anaconda Co. on cadmium about thirty years ago, we found that the cadmium copper precipitate, which we had thrown out on the ground and left there while we worked out main electrolytic zinc plant difficulties, as a weathered product leached much more easily and we got a higher leaching recovery than we got with the current production. Mr. Woolf pointed out on the other hand that they do not find it necessary. It is somewhat a matter of product at each plant, and the prior operations leading to this product in each plant.

With reference to rotating cathodes, some of you may remember, but it may be news to others, that the electrolytic zinc plant built in Park City, Utah, about thirty years ago had rotating cathodes for electro-deposition of zinc. As I recall when I was there the plant was making about 7 tons a day of zinc with rotating cathodes. The capacity of the plant, I believe, was about 20 tons of zinc per day. This plant operated a few years but shut down when the price of zinc dropped off after the first World War and was finally dismantled.

A. R. GORDON†—Regarding the question of oxidation of cadmium precipitate we have done experimental work to determine whether we could leach the precipitate directly as it comes from the zinc plant and found that it was not as

satisfactory as allowing it to oxidize first. As to why it should be so I do not know. We tried leaching it in acid with an addition of manganese mud to give oxidation in the leach, but even that was not satisfactory. Have you any explanation, Mr. Woolf, why there should be that difference in leaching?

W. G. WOOLF—The thing I neglected to point out in my discussion was the fact we return electrolyte from our cell room which carries about 270 g per liter as compared to lower acidity of your zinc electrolyte and I think perhaps that is the reason for it.

A. R. GORDON—Very likely that is the reason but we had heard about your practice before and tried out the straight leaching but in our conditions it was not satisfactory. There is another question I want to ask Mr. Woolf, what do you do with the trees that you scrape off your cathode cadmium in the cells?

W. G. WOOLF—As I pointed out we make only a 12-hr deposit and the deposit is quite free from trees and is dense and smooth.

A. R. GORDON—You have nothing to knock off to drop to the bottom of the cells?

W. G. WOOLF—No.

A. A. CENTER—I just want to say that the matter of the strong acid is not the whole answer, because, as I pointed out, our early experience at Great Falls was exactly the same as at Risdon, that the weathered material leached much more readily and yielded a higher recovery than the fresh product. Later we were able to leach fresh product with little drop in recovery using acid which was not much higher than before.

T. H. WELDON*—I do not know whether this will further confuse the issue or clarify it, but at Trail we more or less follow the same practice that Mr. Woolf mentioned was in vogue at Kellogg. We take our purification residue directly from our Shriver presses, pug it up and deliver it by pump to leach tanks with return acid. The leach pulp is circulated through the centrifugal pump and we think that a certain amount of aeration is introduced here which speeds up the leaching action. To finish the leach, we make sure that there is a slight excess of the cake. In that way, the copper is not taken into solution and yet a good recovery of cadmium is obtained. We then filter the leach to obtain a clear cadmium solution, and we use a very fine zinc dust in deficiency to precipitate high grade cadmium sponge. This particular sponge is delivered to the cadmium plant where, in the course of the operation, it is in storage for at least one week, and we think that some

oxidation there is necessary.

Someone brought up a question of thallium. We have some thallium present in our ore which reports in our purification residue and that is taken care of in our purification of the cadmium electrolyte. If the purification is properly controlled, thallium is taken out in the residue. If it is not properly controlled some thallium will get over into our cells and at the time of cleaning the anodes in the cell, we will get a sludge in those cells that might contain up to 2 pct thallium. But as I say, normally that can be taken care of in the purification step.

Also, we are making a 24-hr deposit and we think the character of the deposit is dependent on the purification. If our purification is good we get good solid deposits with very little treeing, and the small amount of trees we do get are rolled up with the cathode and melted under a caustic slag. We make about a 98½ to 99 pct melting recovery.

A. R. GORDON—Talking about thallium, in what form is the thallium removed?

T. H. WELDON—If you remove any chances of reducing power in your finished leach and you purify the solution by a permanganate purification you will oxidize that thallium and precipitate it, probably as the hydroxide.

A. R. GORDON—Do you recover that at all?

T. H. WELDON—Not at present.

A. R. GORDON—What bad effect has thallium on the electrolysis if it is not removed?

T. H. WELDON—Principally in treeing.

A. R. GORDON—I mention that because our cadmium plant electrolyte has some thallium.

T. H. WELDON—A certain amount is deposited in the cadmium as well.

A. R. GORDON—Was treeing the bad effect?

T. H. WELDON—I think so.

H. R. HANLEY—Difficulties were found in cadmium electrolysis due to the accumulation of thallium in the electrolyte. This substance causes rough deposits and increases oxidation of the cadmium during melting. It was removed by adding sodium dichromate to the neutral cadmium solution, which forms an insoluble chromate of thallium impurity.

K. MORGAN*—Our practice at Avonmouth differs somewhat from that which has been outlined in the papers we have heard this afternoon.

* Consultant, San Francisco, Calif.
† Risdon Works, Tasmania.

* Consolidated Mining and Smelting Co., Trail, B. C.

* Imperial Smelting Corporation, Avonmouth, England.

We are smelters and are consequently afraid of all electrolytic processes. We follow somewhat the practice outlined by Mr. Neale. We take our sludges and Cottrell dusts from our acid plant purification system and extract these with acid. We take the neutral solution and precipitate arsenic by controlled additions of zinc dust. During this process we volatilize about half of it, leaving 50 pct in a residue containing an equal proportion of cadmium, which is subsequently treated.

We then take our solution and slightly acidify it. Incidentally we like to leave a little arsenic in at this stage, about 0.01 g per liter. We do not use zinc dust for our main precipitating stage but use zinc rods made from high purity zinc. These are agitated in trommels, which are rotary drums, the surface of which is formed of a wire mesh screen. We place the zinc rods inside the trommels and rotate them in the solution. We find this method gives us a very dense hard sponge which settles to the bottom of the tanks. It is periodically withdrawn and filter-pressed and we find we can then melt it directly under caustic soda giving us a good yield of metallic cadmium.

The next stage depends somewhat on the purity of the metal. We use spectrographic methods and frequently find it is pure enough at that stage to cast directly into sticks or whatever is required. Sometimes the impurity content is too high and in that case we distil the metal in the furnaces somewhat similar to those outlined by Mr. Neale. If thallium is present, as it frequently is, we remove this by a melting treatment under zinc chloride. We built up a dross which contains up to 2 to 3 pct thallium. We recover this by subsequent treatment.

C. C. LONG—Mr. Morgan, what is the normal cadmium content of the solution from which the cadmium is cemented by these rotating zinc rods?

K. MORGAN—The solution runs about 100 g per liter zinc and 20 g per liter cadmium.

C. C. LONG—And the tail solution contains how much cadmium?

K. MORGAN—Our tail solution from the trommel agitators contains about 1 to 2 g per liter cadmium. We strip that cadmium by zinc dust treatment before returning the zinc liquor as a wetting down medium to our sintering plant.

L. P. DAVIDSON—What is the grade

of the zinc with your zinc rods, and have you had any trouble with the cadmium forming on the rod and giving you essentially a cadmium coated rod that did not precipitate any more cadmium? I have seen that happen.

K. MORGAN—We make our rods of high purity zinc and find that by controlling the acidity and by keeping a very little arsenic in solution we overcome the trouble.

L. P. DAVIDSON—You want the arsenic to prevent the plating of the cadmium on the rods?

K. MORGAN—Yes. At first when we developed the method we tended to form dense coats on the rods which were very difficult to deal with. We found this could be overcome by leaving a little arsenic still in the solution. Nowadays we find quite often we can strip the arsenic entirely and still get no trouble; but as a general practice, we still like to leave a little arsenic in the solution.

H. R. HANLEY—In the production of sponge cadmium from cathode or slab zinc, it is necessary that the solution move slowly around the zinc.

Turbulent solution causes the cadmium to cement on the zinc surface and prevents further precipitation.

G. H. ANDERSON (author's reply)—Regarding the necessity for the oxidation of the cadmium copper precipitate before leaching, our first work nearly 30 years ago was on an accumulation of precipitate which had weathered in a heap for a considerable time.

This material leached easily and a high cadmium extraction was obtained but rather more copper dissolved than was desired. When unoxidized precipitate was treated it was found that the cadmium extraction was poor and insufficient copper was dissolved to insure the satisfactory handling of the cadmium precipitate in the latter stage of the process.

After various tests it was found that an oxidation time of 48 hr in open bins was the most satisfactory for Risdon precipitate.

There is no doubt that the composition of the precipitate affects its rate of solution. If small amounts of arsenic and probably other elements such as cobalt, are present, the solubility is increased and this is the most likely reason for the differing behavior of the various cadmium-copper precipitates. Risdon precipitate

contains very little arsenic and cobalt.

This applies also to the high grade cadmium precipitate obtained later in the process.

At Risdon it has been considered good practice to control the oxidation of the wet high grade cadmium precipitate by applying a very low temperature to the material spread on a hearth so that a uniform product is obtained for subsequent leaching.

Our interest in the question of the oxidation of cadmium-copper precipitate was revived a few years ago when two of our staff returned from a visit to U.S.A. with the information that it was common practice to leach the precipitate without prior oxidation. Tests were conducted but it was found impracticable to obtain a high extraction of cadmium with a low finishing acidity in a reasonable time.

Referring to the revolving cathodes, it was found during the development of the process in 1922 that under the same solution conditions rotating cathodes could operate at a current density of 15 amp per sq ft whereas with stationary cathodes, a current density of only 7.5 amp per sq ft was possible over the same time of electrolysis.

Records show that in the early days of the plant, with apparently excellently pure solutions, it was possible to obtain regularly a current efficiency of 93 pct for a 96 hr stripping period with a current density of 15 amp per sq ft.

It is possible that the poorer results obtained in recent years are related to the presence of thallium.

During the early days of the plant, the whole of our raw material came from Broken Hill in New South Wales, Australia. This contained practically no thallium but now up to one third of our raw material is drawn from Rosebery, Tasmania, and this has introduced considerable quantities of thallium. As much as 20–30 mg thallium per liter is found in the cell feed solution but not more than 0.001 pct has been determined in the cadmium metal.

Also it was once the custom to purify the solution with KMnO_4 , but this was discontinued because of the very slow filtering rate of the pulp and in its place was substituted the practice of discarding cell spent solution to rid the circuit of impurities.

Apparently the KMnO_4 purification is more necessary now than prior to the use of raw material from Rosebery.

Cadmium Recovery Practice in Lead Smelting

By P. C. FEDDERSEN and HAROLD E. LEE

DISCUSSION

(C. C. Long presiding)

T. J. WOODSIDE*—In the paper it

* Amer. Smelting and Refining Co., El Paso, Texas.

was stated that many of the A. S. and R. plants probably used a process patented by Roscoe Teats in 1930. I might describe

briefly that process as used at El Paso which I believe is typical of the four or five A. S. and R. plants at which it is used. Blast furnace baghouse dust carrying anywhere from 10 to 20 pct cadmium is mixed with approximately 20 pct slack coal and 25 pct fine limerock, charged into a Godfrey roaster, roasted at a temperature of 1500°F, temperature being measured through the arch of the

roaster near the uptake, and the cadmium oxide fume running anywhere from 50 to 65 pct cadmium, the grade of the fume depending on the amount of cadmium in the feed.

A. R. GORDON*—Regarding the practice at Port Pirie mentioned in this paper, I think that cadmium is no longer recovered as carbonate. It is not treated

* Risdon Works, Tasmania.

at Risdon as it was previously. It is some years since I saw the plant at Port Pirie and then cadmium was recovered as carbonate. Also I have not seen any published material describing their present treatment, but I believe it includes precipitation of the metal from solution by means of zinc, a method similar in some respects to that described by Mr. Morgan.

The Effect of High Copper Content on the Operation of a Lead Blast Furnace, and Treatment of the Copper and Lead Produced

By A. A. COLLINS

DISCUSSION

(P. C. Feddersen presiding)

H. R. BIANCO*—I should like to ask Mr. Collins if that statement he made about the addition of drosses to the blast furnace slowing down the blast furnace is a result of his own experience or a result of the experience of some older metallurgists; and perhaps I should ask him to define the type of drosses that he means.

A. A. COLLINS (author's reply)—That has been my own personal experience with dross. On various occasions at Chihuahua we attempted to incorporate the dross in our regular blast furnace charge and to shut down the dross reverberatory to try to save some money. As expected, we had very poor results. I think that Ed Fleming will well remember on one occasion, that was back about 1933, when we attempted the first experiment along this line, and as a result of the sulphur addition to the blast furnace to matte out the copper we ended up with hanging furnaces and mushy slags and abandoned the dross experiment, once again turning to the use of the reverberatory for handling dross.

H. R. BIANCO—Is that dross you refer to from the drossing kettle?

A. A. COLLINS—Yes, the dross that I am referring to came from drossing kettles. Furthermore, to back up my previous assertion, I had occasion in 1943, while up at Leadville, to once again experience the routing of dross through the blast furnace with its sulphur addition, since they had no dross reverberatory, and to observe that once the dross was removed, the furnace was speeded up almost 100 tons a day. All of these are personal experiences and I

think that Mr. Feddersen also has had a little experience along this line—in fact, I believe all of us have had some experience.

H. R. BIANCO—I know at Trail they recirculate considerable dross through the blast furnaces and we also recirculate dross at Herculanum and I am not aware that it has done much towards slowing down the blast furnace.

A. A. COLLINS—We have always had very poor results. In the first place you have got to add a sulphur addition to pick up that copper and once you do that, that sulphur is apt to combine with some of the zinc and you are going to form a little mush; before you know it you have furnace hangs and a poor working furnace. Now of course that depends on the amount of zinc you have on charge. But in 1943, Leadville had roughly about 7 pct zinc in their slag and it worked very poorly. Previously when they had 4 or 5 pct zinc in their slag it did not matter.

B. L. SACKETT*—At Tooele we had a great deal of experience with copper. We have always been able to keep a lead well, however, in spite of the fact we have run as much as 5 pct copper and only 15 pct lead on the charge. But regarding the handling of dross, our dross reverberatory furnace is only 7 or 8 years old. Before that we recirculated the dross through the furnace and thought we were doing a pretty nice job. Of course these things are all more or less relative—in other words you establish a certain condition much better than one of a few years ago and possibly as good as any other of which you know and you think you have pretty good results.

When we first took the dross off of the blast furnace and put it through the dross

reverberatory furnace we immediately found out that we had gained something very real in furnace speed. Since that time there have been occasions when, because of the dross reverberatory being down, we have had to use dross again through the blast furnace and that has checked our original experience in slowing down the furnace very definitely.

So we feel that a dross reverberatory is a very valuable asset at the Tooele Plant.

A. A. CENTER*—Mr. Sackett's being here reminds me of trying to run with a minimum of lead concentrates the maximum of dross producing electrolytic zinc plant residue. He came up from International Smelting Co. to help us get started on that.

We took an old copper blast furnace at Great Falls, Montana, and made a lead furnace out of it by putting a lead well on the other long side which of course is a very unorthodox lead blast furnace. Our aim was to treat the residue from the electrolytic zinc plant, as I said, with a minimum of lead concentrates. That meant a maximum amount of dross. At that time selective flotation was not general practice, so our zinc concentrates ran relatively high in copper and other dross-producing elements; and of course these were largely in the zinc plant residue. I think we might call it muscle metallurgy, but we had an interesting, successful experience there and we ran for over a year thanks to Mr. Sackett's helping us get started. I have the details, but time does not permit. We did well enough so that the A. S. and R. Co. at East Helena kept boosting up the offer to us for the electrolytic zinc plant residue and there was not enough lead concentrate to supply two lead smelters there in Montana, so the matter finally finished up by the A. S. and R. Co. taking all of the residue under long term contracts.

The Use of Oxygen-enriched Air in the Metallurgical Operations of Cominco at Trail, B. C.

By R. R. McNAUGHTON, T. H. WELDON, J. H. HARGRAVE, and L. V. WHITON

DISCUSSION

(P. C. Feddersen presiding)

P. C. FEDDERSEN*—Mr. Weldon, how far do you think you can go on that? That is, how much oxygen could you use, what percentage?

T. H. WELDON (authors' reply)—That is the very interesting part of this investigation. The boys have just been theorizing a bit and it might be possible eventually to use pure oxygen in the zinc roasting in which case you could make 100 pct SO₂. Of course, you would have to redesign your furnace completely and have to supply a great amount of cooling to control temperatures. In some of the newer acid production methods where they use a cyclic process, 100 pct SO₂ would be very valuable. That would be an ultimate goal.

A. Y. BETHUNE†—What sort of zinc extraction do you get using the oxygen-enriched air in place of straight air in the roasting process? Does it change the leaching characteristics of the calcine in any way?

T. H. WELDON—No, I do not believe it does; actually with good roast using air only you will get, I think, as good a calcine as with oxygen-enriched.

A. Y. BETHUNE—Then in your opinion the application of oxygen enriched air or even straight oxygen would not have an adverse effect on the leaching properties of the calcine?

T. H. WELDON—No. We have run tests in our experimental roaster using as high as 50 pct O₂ and 50 pct air, and calcine produced is very similar to normal plant calcine.

* Bunker Hill Smelter, Kellogg, Idaho.
† Sullivan Mining Co., Electrolytic Zinc Plant Kellogg, Idaho.

C. C. LONG*—Mr. Weldon, you told us how use of oxygen in suspension roasting increases the capacity. At Joseph-town we have the opposite problem. When operating on typical low zinc, high iron concentrates we find suspension roasters quite flexible as regards capacity. When operating on high grade concentrates relatively low in iron, operations proceed smoothly at 150 tons a day. However, if the feed rate is cut down to the order of 130 or 125 tons combustion is apt to cease. It occurred to me that perhaps use of oxygen-enriched air might enhance the flexibility when oxidizing such concentrates.

T. H. WELDON—That is a very good question. Actually I think the condition there is that an iron free zinc concentrate is lower in thermal value than a high iron concentrate. Also the ignition temperature is higher. In other words Sullivan concentrate with around 12 pct iron has a fuel value of 2200 Btu's. Some of these sphalerite concentrates will have a much lower Btu value, in the order of 1800 Btu, therefore heat is not available there to maintain ignition temperature, if radiation losses are constant, or if excess air or moisture is present. I quite agree with you that a low iron concentrate is a little harder to handle and the value of oxygen-enrichment would be greater with that type of concentrate.

I did not mention that we also roast iron concentrates for the production of SO₂ for our acid plants. This iron concentrate is a pyrrhotite. In the case of the iron concentrate a larger percentage of the oxygen is tied up as metallic oxides and the theoretically possible SO₂ is only around 10 pct. Since theoretically possible SO₂ concentration is about 10 pct, if you require high gas strength, oxygen-

enrichment is of much greater value there.

W. F. JOHNSON*—I would like to mention in connection with Mr. Long's question, that I did some work 10 years ago in oxygen-enrichment and found that the ignition temperature was considerably lowered with a slight increase in oxygen content so that it probably would require a much lower temperature to get ignition, and the furnace would not go out so readily.

L. P. DAVIDSON†—In answer to Dr. Long's question about suspension roasting of low iron concentrate, we had a concentrate which we roasted successfully that had less than 2 pct iron. The only way we could roast that and get good tonnages was to updraft our furnace. We sent those data to Trail, but I think we were considered heretics.

Frankly, I like a suspension roaster that is updrafted. You can, if you want to, put some air in on the bottom hearth to finish off those last few traces of sulphide sulphur, and your updraft will permit you to do it. We were limited on the tonnage we could treat, we had no waste heat boiler and had to take our gases to a chamber acid plant. We had to keep the temperature up to get sufficient concentration in our glover tower by updrafting the furnace. Taking the gas off from the top of the combustion chamber instead of down on the seventh hearth enabled us to increase our tonnage, decrease the sulphide sulphur in the calcine and we had a much better working furnace.

Our dust loss, that is the collection in the cyclone, was no greater than when the furnace was downdrafted.

Concentration of the SO₂ Content of Dwight-Lloyd Sintering Machine Gas by Circulation

By W. S. REID

DISCUSSION

(P. C. Feddersen presiding)

R. R. McNAUGHTON*—The Smelt-

* Consolidated Mining and Smelting Co. of Canada, Ltd., Trail, B. C.

ing Co. and Mr. Reid and his men at Selby are to be congratulated on the job they have done on sinter gas recircula-

tion. I think it is not going to be very long before most companies that have a sulphur dioxide emission problem will realize that they must collect and fix that sulphur some way.

T. E. LLOYD*—Between the windboxes, did you have dead plates?

W. S. REID (author's reply)—Not a dead plate as such. Ordinarily we think of a dead plate as a solid cast iron plate some 20 or 22 in. wide. Between our windboxes in the recirculation units there is a light plate, flat shaped but tapering off at either end; just an umbrella, we call it. It does prevent passage of excess air which otherwise would pass through the ribs of the pallet.

T. E. LLOYD—Just between the pallets?

W. S. REID—Wide enough to extend between two ribs of the pallet.

T. E. LLOYD—I was interested in the fact that you cool the gas there and then abandon it. The Tennessee Copper Co. at Copperhill, Tenn., are cooling a terrific amount of gas. Would you proba-

* Engineers Inc., Newark, N. J.

bly succeed better if you took the considerable amount of moisture out and recirculate the gas? What did you notice in the difference when you were running it?

W. S. REID—There are advantages in cooling and also in taking the moisture out, but our problem was entirely a practical problem. By getting the ducts cold, especially due to the periodic operation of Dwight-Lloyd Sintering Machine wherein you must close it down periodically to clean the windboxes, any moisture you get into that flue system just corrodes it greatly. It went out on us in a short time. We then tried stainless steel flues, and if the moisture is in there they go out just the same. We eventually wound up by using a lead flue from our second-over machine which is used periodically only. Lead itself stands up all right, but the expansion and contraction broke the lead flue so we were constantly welding the flue to keep it from leaking SO_2 into the building. We have eventually wound up by using wrought iron, as our tests show that wrought iron, insulated to keep the pipes warm all the time, presents no serious corrosion problem. Cooling causes

condensation of moisture and the flue goes out in a hurry.

T. E. LLOYD—You spoke of segregation, do you mean you attempted to put the charge on the pallets in such a way that you did not even have a segregation on the pallets?

W. S. REID—No, it is exactly the reverse of that. We want the segregation there, that is, a uniform segregation of the coarse material on the grates to form a grate dressing. Major segregation of coarse and fine from the feed hopper itself is bad. If the feed can be kept flowing uniformly out of the feed hopper, then by close regulation of the talus pile, there will be a uniform rolling of the coarse particles to the grate with no sluffing, and no slides; then a uniform bed throughout the machine will be obtained and that ties right in with the concentration of gas.

T. E. LLOYD—You found it necessary to have fresh air come in from around the muffle?

W. S. REID—Immediately in front of the ignition muffle until the bed is well under way on ignition and burning well.

Autogenous Roasting of Low-grade Zinc Concentrate in Multiple-hearth Furnaces at Risdon, Tasmania

By J. A. B. FORSTER

DISCUSSION

(P. C. Feddersen and T. D. Jones
presiding)

W. G. WOOLF*—The paper has a wealth of data that take careful, detailed study. As has been indicated the highlights can be only touched in the paper. The design and the arrangement of the rabble teeth as well as some of the other details of operation show a very careful study and a scientific approach to the problem which in most plants using hearth roasters are matters of trial and error with empirical conclusions and, perhaps too often, just arbitrary supervisory preferences which may be erroneous. Here the problem has been approached from a scientific angle which I think well merits careful study. The ability to treat the tonnages they get through these furnaces I think is made easier by reason of the high sulphide sulphur in the resulting calcines which the balance of the plant—the leaching and so on—can cope with.

As indicated by Mr. Weldon in his dis-

cussion earlier this morning, in most zinc plants an attempt is made to have as low a sulphide sulphur content in the roaster calcine as possible. But in the operation of the Risdon plants, they are able to cope with sulphide sulphur content up to 5 pct which is far beyond the amount of sulphide sulphur that can be handled elsewhere. I think the autogenous roasting is made easier because driving out the last percentages of sulphide sulphur brings on the necessity for extraneous heat, and that is further exemplified because even at Risdon the author shows the desirability of using some oil to better the operation, particularly for uniformity of roasting results and to obtain more regularity of furnace operation.

A. A. CENTER*—Regarding the hard crusts in the beds of the furnace and autogenous roasting, the paper speaks of the former being due, at least to a considerable extent, to lead sulphide in the crusts. I wonder if the author has considered the hard crusts as being due in large part to zinc sulphate. While I was developing large zinc operations we

ran into hard crusts which had to be dug up. I took several lumps which were so hard they showed the marks of the rabble teeth very plainly and kept them in my office for some weeks. A visitor came along one day, and as he was having similar troubles, I told him what we were doing about ours. I started to pick up one of these lumps and to my amazement the thing crumbled in my hands whereas originally it had been so hard it wore the rabbles down very rapidly in the furnace. I sent the sample to the laboratory and found that it analyzed very high in water-soluble zinc and sulphate-sulphur. The crumbling of the lumps was evidently due to the anhydrous zinc sulphate gradually taking on moisture from the air and forming crystalline zinc sulphate seven parts water. The increase in volume would, of course, result in disintegration of the lumps.

As to getting a high tonnage in the autogenous roast, that is partly because of finishing at about 5 pct sulphide sulphur. It is a real job to get down to, say, $\frac{1}{2}$ pct sulphide sulphur, which is what is usually desired, and still put through a good tonnage.

* Bunker Hill and Sullivan Co., Kellogg, Idaho.

* Consultant, San Francisco, Calif.

Autogenous, multiple-hearth roasting of zinc concentrates usually yields calcine analyzing not much under 5 pct sulphide sulphur. For example, a lithopone plant which had been used to treating only zinc wastes bought some calcine, immediately ran into troubles, and called me in. On finding where they were buying the zinc calcine, I knew they were getting calcine produced from zinc concentrates in an autogenous, multiple-hearth roaster operation, and that the calcine would probably run around $4\frac{1}{2}$ pct sulphide sulphur. This proved to be the case in spite of several disclaimers.

It is to be noted that the above discussion was sent in at the request of the AIME staff, and is based only on the abstract of the paper as heard at the San Francisco meeting.

J. A. B. FORSTER (author's reply)—Mr. Woolf is quite correct in thinking that the means used at Risdon for recovering unroasted sulphide from calcine make it easier to obtain very high roasting rates. Advantage has been taken of this at times to make up for shortage of roasting capacity by tolerating an uneconomically high sulphide sulphur in calcine.

The Risdon provision is unique in being a flotation unit which returns to the roasters a concentrate that can be roasted autogenously. It is not unusual in other roasting plants to screen the calcine, crush the oversize and re-roast it, either alone with the assistance of extraneous fuel or mixed with new concentrate. In such cases the calcine assay quoted is usually that of the screen undersize. It is not easy to compare the performance of a roaster treating low grade concentrate

and delivering unscreened calcine with one working on high grade concentrate and screening the product, but the sulphide in Risdon calcine is mainly in the coarse fraction.

By sacrificing some roasting capacity to give the material longer time in the furnace, the sulphide left in the coarse fraction can be reduced considerably, but in this case so little heat is evolved in the lower hearths that extraneous fuel is needed to maintain roasting temperature. This has been a common practice.

Additional roasting time can be given in the lower hearths by modification of rabble teeth; and since more roasting is then done in these hearths, the amount of extraneous fuel needed is less. The author hopes to demonstrate at a later date that, by carrying modification of the rabbling system to the logical conclusion, a very thorough roast can be obtained at a high hearth rate, and strictly autogenously.

Dr. Center's observations are correct, insofar as they went. There is a great difference in conditions if the space between hearths and teeth is filled with material partly roasted or with sand. In the first case, if the immobile beds are not hand-stirred every two or three days they become so hard that heavy bars and hammers are needed to chisel them. In the hottest zone where the material still contains much sulphide there is little or no sulphate formation, the binding of the bed being due to the condensation of galena vapor from the mobile bed, galena having a vapor pressure of 2 mm at 850°C and 4 mm at 920°C. Galena also condenses on the teeth which are cooler than the mobile bed, and the resulting drag on the hard hearth cake can stop a

furnace or break rabble arms. Of course a galena-free concentrate would behave quite differently in these hearths.

It is in the lower hearths, where the material is much more completely roasted and temperatures are well below that of its decomposition that zinc sulphate forms in the immobile beds. Sulphation is accompanied by expansion of volume and there develops an upward pressure against the teeth which is just as damaging as the drag in the hotter hearths.

When the immobile bed space is filled with sand the conditions are somewhat different. In the hotter hearths galena vapor still penetrates the bed causing some consolidation, and galena crusts are formed on the teeth; but provided the latter are replaced by clean ones every two or three weeks no drag develops until the bed is fully consolidated—a process which takes over three months if excessive temperatures are avoided. Owing to changes of temperature in hearths, columns and rabbles, and to growths on teeth, some sand is lost from the bed surface and is replaced by a crust similar to ordinary hearth cake, but as long as the crust is relatively thin and there is some unconsolidated sand below, no trouble occurs.

In the lower hearths the crust which forms in the same way is quickly sulphated, but as it is very thin no noticeable drag develops. The crust thickens slowly, and it is probable that under slight pressure some sand is gradually squeezed out laterally, but the beds remain in good condition for at least nine months, except around drop-holes and close to the walls where necessary cleaning results in loss of sand; consequently these beds are renewed twice a year.

Development of the Modern Zinc Retort in the United States

By H. R. PAGE and A. E. LEE, JR.

DISCUSSION

(L. P. Davidson presiding)

A. E. LEE, JR. (author)—In addition to the paper we should like to make a few remarks. First, the seriousness of bending of the clay retort cannot be overemphasized. Not only did bending limit the length of the vessel, but it permitted corrosive fluid slags to concentrate in the belly of the retort and thus increased the possibility of boring. Bending also practically prohibited the use of cleanout machines and increased the danger of excessive fume losses by allowing furnace gases to escape around the top of the retort mouth.

It will be noted that the Blackwell pottery practice places considerable emphasis on careful drying of retorts. Perhaps it is another smelter superstition, but traditionally the aging of retorts beyond a reasonable drying period has been considered important to long life. We are unable to give a good explanation of why aging should improve retorts. During the past fall in an attempt to prove a theory that the combined water in the clay decreased during aging, about 50 samples of wet retort collars were placed in a dry room when it was closed. Loss of weight, combined water and free moisture were measured each week over the 100 day drying period. The affinity

of the dried retort for moisture makes difficult the accurate measurement of free water; however, there was a clearly defined free moisture change from about 12.5 pct when freshly made to about 2 pct at the end of 18 days, then a gradual loss to about 0.25 pct at 70 days and an apparent equilibrium near this figure through the 100th day. There was no appreciable change in the combined water. The change in weight of the average sample was, however, rather unusual, there being consistently a loss of weight throughout the entire 100 days. From the 63rd day on this leveled off to about 0.03 pct per week. These were small samples and certainly should have dried

somewhat faster than the larger retort. Possibly the drying process continued although at a very low rate during the last 30 to 40 days and this caused the weight change, but our method of determining free moisture was not accurate enough to record it. In any event we have concluded that our test did not show any evidence of change in structure through loss of combined water.

An important characteristic and defect of the silica retort is its inability to withstand sudden temperature change. This is very important in starting up a furnace block. Until recently we had started a new block by filling it with green dried retorts, lighting the drops at a minimum gas setting and gradually bringing the new brickwork and green retorts up to a charging temperature over several days. This is, of course, a delicate operation and it is most difficult to hold the gas flames so low at the start as not to touch any of the retorts, especially those in the second row. We averaged a loss of at least half the original retorts during the first 3 or 4 charge cycles. A major cause of retort failure was checking about 2 ft from the mouth where the tip of the flame had touched the retort during the period of low gas firing. Recently the idea was conceived to close up the front of the furnace with butts and bring up to about the heat of a retort preheat kiln; then put in hot retorts. This method has been used on the last 3 blocks started with excellent success. The extra labor required has been more than offset by savings in retorts and by achieving normal recoveries several shifts earlier. An opportunity is afforded to measure accurately the life of the original 800 retorts and this was done on the first block started in this manner. The average life of the 800 original retorts was 34.23 cycles compared with 26.43 for all retorts in all our furnaces during the same period.

ARTHUR D. TERRELL*—That paper just given is exceedingly interesting. You only have to look at me to know that I can go back in history further than my Blackwell friends. As regards the first retort presses used in this country, they were I believe installed by the New Jersey Zinc Co., one of them at Bethlehem, Pa., and the other at Joplin, Mo., the old Empire Zinc Co. I became identified with the zinc industry in 1899 and went to Iola, Kansas in 1900 with a Mr. George E. Nicholson who sold his plant to the New Jersey Zinc Co. and I remained with it for 22 years.

These presses were installed about 1898. They were abandoned as far as those plants were concerned, and one of them was shipped to the Prime Western Spelter Co., Iola, Kansas, plant about 1903.

As regards the oval retort, they are used not only for increase in strength due

to the type of cross-section, but the heat penetration is better.

My recollection is that in a number of horizontal retort plants in the early days, a pottery consisted of two floors: one, where the retorts were made and were set on that floor for a few days until they got dry enough to be handled; then they were elevated by a one-retort-capacity hand elevator and put on the second floor, remaining there until they were taken out for use in the furnaces.

A small percentage of the zinc that goes into the walls of a fire clay retort, forms spinel.

With regard to the carborundum retort, I was with the New Jersey Zinc Co. when they made the first ones at Palmerston, Pa., and followed the results fairly closely. They were tried at some of their other plants, but never were permanently adopted as far as my knowledge goes.

The National Zinc Co., Inc., Bartlesville, Okla. made a test run on silicon carbide retorts several years ago, but did not continue their use. There have been some very unfortunate experiences and very expensive ones with the trial of carbide retorts. One of the difficulties, I believe Mr. Lee has not touched upon is the question of keeping down the blistering on the outside, particularly where you use natural gas as a firing fuel. That not only tends to weaken the retorts but makes it very difficult to get them out of the furnace after they have been in service for many months.

As far as making the retort is concerned, the indicated pressure we use for making the butt of a retort is between 2000 and 2500 psi, and the pushing out pressure is about 1200 psi. Of course, I do not think those refer to the pressure Mr. Lee has in mind. Now it is true that it seems advisable to dry clay retorts for a minimum of 30 days, unless accelerated drying is used. However, I will mention one experience we had with one of the New Jersey Zinc Co. plants at Collinsville, Okla. It had just been started the year before I became connected with it, and it grew faster than the pottery capacity did, and we got down to a 10-day life of retorts in the pottery. I confess I was very much disturbed thinking that we might have to dead fire some blocks in order to catch up on our retorts. But we ran that plant for a little while on retorts that were dried only about 10 days until we could get more rapid production of retorts which we did by putting in a new pump and a Simmons valve. Our hydraulic press capacity was then about 250 retorts in an 8-hr day instead of about 100 retorts.

As regards starting up a furnace with silica flour retorts, our experience has been just about what Mr. Lee's company's experience has been, and we had some very unfortunate results in high loss of retorts. The next time we start up a block of furnaces we are going to do about the same as Blackwell has done.

A. E. LEE—One thing I forgot to mention is a printing error in the first sentence of this paper. That is the date when commercial scale use of horizontal retorting began in the United States; that should be 1860 instead of 1890. It is interesting to note that Matthiessen and Hegeler at LaSalle, Ill. have been operating since 1860.

K. MORGAN*—It is a little difficult for me to comment on Mr. Lee's paper because our practice today at Avonmouth and also, I think, throughout Europe generally, differs in almost every respect from that outlined by Mr. Lee.

For instance it appears to be the general practice in the States to use either the silicon carbide type of retort or the silica flour type. We do not use either. We use an all clay mix. Then again on the question of de-airing, we have tried de-airing, but do not find it gives us any advantage. On our standard mix we use Belgian clays. During the war, for obvious reasons, we could not get Belgian clays and we had to use English clays. These have not the plasticity of Belgian clay and with them we do find we get some advantage from de-airing, but on Belgian clays there is no advantage at all.

There are a number of other difficulties which I am afraid would take up too much of your time, but I should like to make a few points:

The first is on this question of life. Figures for life can be very deceptive. You need to know the amount of zinc that is produced, since if you do not drive your retorts, you can get almost what life you like. It is only when you are pushed for output and have to strike a balance between output and life that life figures become significant. I should like to know from Mr. Lee how much zinc he makes per day from each retort. Our retorts are fairly big. We make about 77 lb of zinc a day from each retort. At the moment we get about a 27-day life and while we are always trying to improve it we have not been able to do so without being prepared to drop output.

The next point on which I should like to have Mr. Lee's comment and also that of the previous speaker is on the question of holing. We have to use ores containing anything up to 14 pct iron. The reason why most of our retorts fail is due to holing and when this occurs we find it is generally associated with laminations in the retort. We think that if we could stop the formation of laminations during extrusion we could greatly reduce our retort failures.

A. E. LEE—In answer to your first question about the life of the retort in terms of zinc produced, I agree this is a more accurate criterion than days. We do not figure it in terms of zinc but in terms of retorts per ton of sinter or zinc-

* Imperial Smelting Corporation, Avonmouth, England.

bearing material charged. In recent years we have gotten about 0.6 retort per ton of sinter.

I believe that the clays you have in Europe are somewhat more refractory than the ones we have available here in the States and that they withstand a higher temperature without bending. That perhaps accounts for your success with the straight clay retort.

Insofar as slagging is concerned, we have had some bad experiences with ores running as high as 12 to 15 pct iron. With ores of this character we have found retorts with the bottom half filled with a very hard iron slag after a period of several shifts.

As you point out, boring or holing occurs with furnace charges containing appreciable amounts of iron. This effect can multiply retort losses when the fluid slag drips down on retorts below. We attempt to control this by close firing so that during the latter part of the furnace cycle the charge is not so barren that the heat absorbed can be used to make the slag active.

Regarding laminations, we do not have much of that. We think perhaps this is one of the advantages of our de-airing pug mill.

L. P. DAVIDSON*—Mr. Morgan, in your slagging troubles are they all attributable to iron alone or do they become worse with a larger amount of lead?

K. MORGAN—No, I do not think we ever attributed trouble to lead. In every case we find the corrosive slag is an iron silicate.

L. P. DAVIDSON—It is not due to the formation of a very fluid lead silicate?

K. MORGAN—Not in our experience.

A. D. TERRELL—I might say we have at times gotten over 85 lb of zinc per retort. Most of the smelters are using the 48-hr cycle now and you do not reach as high top temperature to work off furnaces as you do on a 24-hr cycle, and that makes a difference in life of retorts.

C. R. KUZELL†—It has been very refreshing to hear this paper in a field of metallurgy that most of us in other fields

of metallurgy were always led to believe was rather stagnant. From what I am able to gather, having heard from some fellows of the modern-day cost of building electrolytic plants, it looks as if we are still going to be confronted with dealing with retort plants for some time.

Since we on the selling end are interested only in the question of zinc production to the point of producing zinc concentrates and selling them to these retort and other plants, of course the matter of retort life is of interest. We are often irritated by those settlement sheets showing the high penalties for iron and other fluxing impurities which cause a failure of these retorts about which we have been hearing. Consequently I have three questions which are prompted by ignorance, curiosity, and selfishness—by ignorance because I have never seen a zinc retort, by curiosity because I am naturally curious, and by selfishness because of the irritation that arises from seeing these high deducts.

I would like to ask three questions:

(1) What is the porosity of these retorts? (2) What is the relative loss of zinc through the walls of the retort? (3) Why have they never made retorts of basic refractories? As the basis for answering the question I would like to specifically recommend the hypothetical use of chemically bonded periclase subsequently burned and then used as a retort.

A. E. LEE—I do not know of any figure for retort porosity as such. However, we do have figures on the amount of zinc absorbed in the retort walls. As previously stated this was 7-9 pct of the retort weight with clay retorts. At Blackwell we recently assayed used silica retorts with a furnace life of about 26 cycles and found only 0.9 pct zinc. It has also been estimated that 2 pct of the zinc in the charge was lost through the walls of clay retorts and this is borne out by the deposits in the regenerators of some of the old producer type of furnaces. But I do not know any figure to give you on the carbide or silica retorts.

In regard to use of other refractories, I would say off hand that they might have the same failing as the early cast carbide retorts—they cannot stand the heat shocks. I would like to know what Mr. Terrell might think on that subject.

A. D. TERRELL—I feel what Mr. Lee has said would be the difficulty. They would not stand the thermal shock.

C. R. KUZELL—I would like to point out that four decades ago the copper industry in bessemerizing copper matte for the production of blister copper departed from clay and silica linings and adopted basic linings of magnesite. In some of the more recent years some of the plants have used periclase, which is a purer magnesite—purer than formerly used in magnesite brick. That has been used in the form of rammed linings and also in the production of the bricks where bricks continue to be used. The converting process is also cyclical and subject to thermal shock but nevertheless the use of the basic material has been highly successful. It would seem to me that if those who get penalized for excess iron in selling zinc concentrates would use a basic refractory like magnesite which would not be corroded by the iron and other fluxing constituents of the concentrates maybe we would be better off and get rid of some of those deducts.

A. E. LEE—There has been some experience with that type of lining. In 1900 Benjamin Sadler patented a non-corrosive retort lining. The lining consisted of magnesite, chromite or carborundum which was ground to pass a 20-mesh screen. A regular dried retort was coated on the inside with sodium silicate. Then the ground lining was added and the retort rotated until a uniform $\frac{1}{8}$ in. lining was obtained. The lining was burned into place when the retort was preheated for furnacing. This lining resisted iron slags but as in the case of the cast carbide units it cracked easily and let the slag attack the retort.

Queneau also worked out a means of making retorts consisting of layers of different materials. The inner layer was of a material resistant to attacks by the charge, the outer layer of a material resisting the action of the firing fuel, and the inner layer to form the body of the retort and give it strength. This vessel was unsuccessful because of the tendency of the layers to contract and expand at different rates, causing separation and cracking.

Controlled Drying of Retorts

By R. R. FURLONG and D. H. WERTZ

DISCUSSION

(L. P. Davidson presiding)

A. E. LEE*—I would like to ask Mr. Neale if he has determined the moisture content of his dried retort. Also, has he

* Blackwell Zinc Co., Blackwell, Okla.

ever experienced difficulty with bending in the dry room where the green wet retorts contain 17 pct moisture and are placed 3 in. apart?

M. M. NEALE (replying for authors)—I cannot answer your first question as we

have had no experience with that. Setting the retorts 3 in. apart, we had no trouble with bending. We thought we would, anticipated we would, but did not.

L. P. DAVIDSON*—You mention,

* American Zinc Co. of Illinois, Monsanto, Ill.

Mr. Neale, in your opening remarks that some of your colleagues in the zinc industry were somewhat skeptical about the use of it. I can say from second-hand knowledge that about 15 years ago the Hohenlohe people in upper Silesia had

some sort of patented scheme basically such as you have done here and as the demand for zinc in 1937 came along they had a number of furnaces down—down for a long time, and did not have an adequate supply of retort to start with. They

used in principle the same process that you did and they were using the clay retort Mr. Morgan described. They had very successful drying, cut down their retort inventory tremendously, and they were very well satisfied with it.

Development of Muffle Furnaces for the Production of Zinc Oxide and Zinc at East Chicago, Indiana

By GUNNARD E. JOHNSON

DISCUSSION

(L. P. Davidson presiding)

E. D. HYMAN*—How much sorting of scrap is done?

G. E. JOHNSON (author's reply)—We do practically no sorting. We charge "run of mine" scrap to the furnace. The unmeltables, mostly iron, are in such demand today that there is no difficulty in disposing of them. It may soon be desirable to sort out from the unmeltables as much of the brass as possible.

J. J. BRUGMAN†—We have somewhat similar problems in the secondary aluminum business. What is your method of removing the unmelted material from the furnaces? Why have you such an apparently small space in which to charge your materials? Do you find that you have to seal that opening, or can you have it open and continuously charge at one end and pull out the other?

G. E. JOHNSON—Our means of melting scrap is efficient only to the extent that we use the waste heat from the vaporizing chamber to do the job. It is a batch process. We open the charge door and place the scrap on the hearth by hand shoveling. The door is then closed during the melting down period. After the melting is complete, the opposite door is opened and the unmeltables are raked out. The doors are approximately $3\frac{1}{2} \times 4\frac{1}{2}$ ft and are not sealed during the process only closed. They are nominally tight. Some metal is oxidized in the process. We have visualized a means of conveying the materials through this melting unit with the metals that are melted trickling out during its travel.

T. H. WELDON‡—Mr. Johnson, in line with the last question, is it necessary to seal the furnace between the melting down and the vaporizing unit, or have you got an inverted syphon in the bottom of the chamber?

G. E. JOHNSON—That was one of the first things we encountered. We had to have a sealed opening, and it is a

molten metal seal.

You have indirectly asked me another question, which was: "Do you have to seal up the melting unit?" I would say we should exclude as much air as possible, although we are not too efficient in doing that. We allow the melting unit doors to be open when we charge and when we remove unmeltables. You can readily see that that would lead to the idea of having a controlled atmosphere in the melting unit, and I think this would do a more efficient job of melting the scrap.

T. H. WELDON—How often do you charge the furnace?

G. E. JOHNSON—We charge the melting unit, and rake out the unmeltables, about every hour.

H. R. HANLEY*—Are any provisions made for controlling the rate of oxidation for the production of various size particles for certain characteristics of the zinc oxide product?

G. E. JOHNSON—Yes, there are many. You are getting pretty much into the fine points of zinc oxide manufacture. Some of us still think we have something to learn about that. In general, this muffle furnace as I have described it to you produces a rounded particle of zinc oxide which is generally formed by a rapid oxidation of the zinc vapor, followed by rapid cooling. We have gone to the other extreme in some of our experiments. We have changed the furnace to produce a type of zinc oxide, such as we thought was peculiar to American process zinc oxide, by controlling the temperature at the point of oxidation and maintaining that temperature for a much longer period of time than we do when we make the rounded shape.

There are other relationships that this furnace readily provides. One of the important factors is the ratio of air to zinc vapors. We can vary that by varying the air supply to the baghouse, or vary the rate at which we are vaporizing the zinc by the simple expedient of regulating the temperature over the carborundum arch. We have a number of variables that

permit us to produce all of the grades of French process zinc oxide from lead-free up through the highest grades of seal oxides. There are many controls that we can apply to the operation. What I have said is but a brief condensation.

K. MORGAN*—Can Mr. Johnson give us some idea of the fuel consumption of the furnace? How much oil does he use per ton of zinc distilled? I am also interested to know what sort of heat transmission he gets through the arch? What is the thickness of the tiles used to construct the arch? Some time ago we built a small furnace for a different purpose, using a carborundum arch, and we found that the reflectivity of the molten zinc surface was so great we had to use a very high arch temperature. We found we made an improvement by having a layer of carbon on the surface of the zinc. Has Mr. Johnson had any experience on these points? Does he make any sort of insolubles which he leaves in the furnace which he cannot tap out?

G. E. JOHNSON—I believe your first question was the fuel consumption. If I recall, somewhere in this paper there is a test that I quote. I believe we used 800 gal in a given period of time. Offhand I cannot translate that into tons of metal. I might also state that we have this understanding; that the carborundum arch, as the temperature becomes higher, becomes more efficient in heat transmission. As a matter of fact, I believe it is at about 2600°F or higher that the highest efficiency of heat transmission becomes available. We have calculations that I cannot quote from memory which indicate that the carborundum arch does a really very fine job for this type of furnace. Another point that we had considered was the fact that this furnace could be readily constructed so as to furnish an ideal source of heat for waste heat boilers. If a carborundum arch was used over the melting unit, we would have no zinc vapors in the gases at all—just clean combustion gases from which we would have removed some of the heat.

L. P. DAVIDSON†—The insolubles?

* Imperial Smelting Corporation, Avonmouth, England.

† American Zinc Co. of Illinois, Monsanto, Ill.

* San Francisco, Calif.

† Idaho Smelting, Seattle, Wash.

‡ Consolidated Mining and Smelting Co., Trail, B. C.

* Missouri School of Mines and Metallurgy, Rolla, Mo.

G. E. JOHNSON—Insolubles to me means anything that we could not tap out of the furnace. Is that correct? Let us start with the new furnace first to be technically correct. As we charge scrap into any furnace of this type there is, of course, an absorption of metal by the brickwork. That is very small in these furnaces. In fact, our recoveries of zinc over all are better than 98, probably 99 pct, accounted for. As far as I know, except for that furnace absorption and small amount of zinc we use in the molten-metal-seals, it all taps out of the furnace. You may be thinking of another thing on which I have not touched and that is the amount of dross formation in the melting of that scrap in the melting unit. There is a mush which sometimes might get into the vaporizing unit and form the insoluble you were thinking about. We have solved that. I mentioned a trough leading from the melting unit to the vaporizing unit. That trough, just before it enters the sealed opening, widens out to a large bath just outside of the vaporizing unit. If any dross forms, it collects on the surface of the metal at that point, and before it enters the

vaporizing unit. We skim it off there in an opening provided in the furnace, and thereby prevent the very large part of the dross from ever getting into the furnace.

L. P. DAVIDSON—That is, in that canal between the melting section and the vaporizing section?

G. E. JOHNSON—Yes.

E. D. HYMAN—My question concerns scrap—also scrap of the type you get from steel company's galvanizing plants. Do you treat such scrap as that commonly called sal-skims?

G. E. JOHNSON—No, we do not, since sal-skims are oxidized, and this furnace is designed primarily for distillation from metallic, zinc-bearing materials. I thought at first you were going to ask me, do we treat galvanizer's dross? We have treated much of that, as previously indicated. In treating galvanizer's dross we have had to tap out a residue metal from the vaporizing unit toward the end of the run. In fact, we have carried the distillation so far that the irony-residue had to be removed by strong arm meth-

ods, "muscular metallurgy." We finally came to the conclusion that galvanizer's dross should be treated in a furnace designed for that purpose. This is an interesting subject and I should like to know some of the answers myself.

A. D. TERRELL*—Is there any appreciable amount of blue powder formed in condensing the zinc into metallic zinc?

G. E. JOHNSON—Our figures indicate that less than one half of one percent of the zinc produced over a prolonged period of operation on zinc is formed as blue powder. That rather pleases us when you look at the figures which I have quoted on retorting where blue powder is very much more of a problem than it is on these furnaces. I think the reason is quite self-evident to us; we heat the condenser—we have facilities for heating the condenser before ever allowing the zinc vapors to enter. One detail I did not mention—we have a little outlet at the top of the condenser with a ball on it to relieve any excess pressure.

El Paso Slag Treatment Plant

By T. J. WOODSIDE

DISCUSSION

(L. P. Davidson presiding)

A. E. LEE*—One question of the flue leading to the tube coolers. What gas velocity is maintained to prevent settling of the finely divided fume?

T. J. WOODSIDE (author's reply)—30 fps. Of course some fume settles out, but is immediately carried away by the screw conveyors.

H. R. BIANCO†—How effective are the soot blowers? Do you have to use any hand lancing?

T. J. WOODSIDE—Only one point, which is right at the top of the economizer

and which the soot blowers do not reach, we occasionally hand lance. But everywhere else the soot blowers have been very effective and no hand lancing has been done.

L. P. DAVIDSON*—Do you have considerable variation in the lead content of the fume collected if the lead is higher, and is there greater tendency for the fume to stick on the boiler tubes?

T. J. WOODSIDE—There is very little variation in the lead content. From 5 to 7 pct is the widest range variation we have had and we have noticed no difference in the behavior of the fume.

C. R. KUZELL†—Mr. Woodside has been quite generous with data pertaining

to metal and fuel economics. I think he stated that the coal consumption of the furnace was $2\frac{1}{10}$ lb for a pound of zinc recovered. I take it that that is the gross coal input to the furnace. I wonder what the net fuel consumption in terms of coal might be after crediting the fuel equivalent of the waste heat steam recovered?

T. J. WOODSIDE—The fuel value of the waste heat steam is approximately 42 pct of the heat input to the furnace. A very large part of the heat, of course, goes out in jacket water—44 pct.

A. D. TERRELL*—I would like to know how much lead is in the delead material.

T. J. WOODSIDE—It is a little less than 2 pct now.

The Morenci Smelter of Phelps Dodge Corporation at Morenci, Arizona

By L. L. McDANIEL

DISCUSSION

(A. A. Smith, Jr. presiding)

A. A. SMITH*—This is a very complete description of one of the country's major copper producing units, and I know that it is of great interest to the copper metallurgists.

P. T. BENSON†—The matter of build-up of magnetite in a reverberatory furnace is probably of primary concern to any copper metallurgist, and I am much interested in Mr. McDaniel's remarks about using silica flux separately from the regular charge to combine with the converter slag iron rapidly and prevent deposition of magnetite.

In the description of the converter flux makeup mixing of barren quartzite with the pit run ore reduced the alumina content and the reason given for that is again to help reduce the formation of magnetite. Have you conducted experiments enough to be able to tell us just where the breaking point in the alumina content of the converter flux is with regard to the formation of magnetite?

L. L. McDANIEL (author's reply)—Probably it is not so much a matter of quantity of alumina as it is the ratio between silica and alumina, although maybe both count. We try to keep a ratio of about 5 or 6 silica to alumina. Our pit ore will run about $3\frac{1}{2}$ to ratio.

* American Smelting and Refining Co., Barber, N. J.

† American Smelting and Refining Co., Tacoma, Wash.

We change that by adding barren quartzite until we get about the ratio we want. Then we find that if we use that flux alone it is apt to be rather violent. So we add revert material to bring the silica content down to about 65. We can hold around 63 or 65 pct silica with a silica:aluminum ratio of at least 5 to 1 and get fairly good operation.

ALLAN NORRO*—I have been traveling around visiting different smelters and I also used to go to Garfield. They get about 50,000 tons of copper per converter lining and there has not been any trouble with magnetite in the bottom of the reverb. I would like to know why you do not blow magnetite linings in your converters.

L. L. McDANIEL—I think that is a matter of local practice or preference. Garfield has had very wonderful converter life which they get by magnetizing. We have not actually tried magnetizing at Morenci. But probably for the same reason that some other smelters have not, we think it might not be economical to take the time out to blow linings on a converter.

ALLAN NORRO—It just takes 5 hr once a week and this 5 hr is still production. The production will lose about 2 hr a week, and it does not take down your capacity.

L. L. McDANIEL—I repeat we have not yet done any magnetizing at Morenci.

* Boliden Mining Co., Sweden.

PAUL T. BENSON—We do practice magnetizing at Tacoma but do not get quite the life on converter lining that Garfield does. If we get 25,000 tons we consider that satisfactory. Sometimes we get 30,000 or better. We do not consider that much time is lost in magnetizing because you are blowing matte while making the magnetite lining. Our practice is, after it is completed, to go right ahead and put more matte in and begin blowing slag.

A. C. LOONAM*—I am interested in the fact that you installed multiclones instead of a cottrell. Has this been satisfactory?

L. L. McDANIEL—Our experience with multiclones on converter gases has been quite satisfactory. We have not tried the multiclones on extremely fine particle size, so I cannot give you any information on that; but on converter gases they have been satisfactory.

PAUL T. BENSON—Mr. McDaniel might add something about the multiclone performance at Douglas. I observed that a few years ago and it seemed to be very successful.

L. L. McDANIEL—We installed multiclones on converter gases at Douglas smelter of Phelps Dodge Corporation with about the same results we have had at Morenci. Very satisfactory.

* Deutsch and Loonam, New York City.

Distillation of Zinc from Copper Base Alloys

By FRANK POLAND

DISCUSSION

(A. A. Smith Jr. presiding)

S. ROLLE*—As one who has been privileged to read Mr. Poland's paper before its publication, I wish to express high praise for it and the record which it gives of the work done by the Research and Development Department of Revere Copper and Brass Inc. in developing a

satisfactory furnace for the recovery of metallic zinc from secondary metals by distillation. I have also had the opportunity of studying the operation of the furnace when running on scrap brass at the Detroit plant of Revere, and I can therefore say from knowledge gained first-hand that the unit is efficient and economical when used in conjunction with distillation. However, when I read what Mr. Poland has to say in reference to the possibility of using the furnace for

melting copper cathodes for the production of oxygen-free and tough-pitch copper shapes, I am constrained to be somewhat skeptical. No doubt the furnace can readily be modified so as to make it possible to melt cathodes, but that is only a part of what is required to produce refinery shapes.

Because of its construction the atmosphere in the furnace is highly reducing and even without protective gases such as nitrogen the copper cathodes which are

* The Scomet Engineering Co., New York City.

substantially oxygen-free will not become oxidized—that is, the copper will remain oxygen-free. If then the molten oxygen-free copper is discharged from the furnace in a closed launder and then to a pouring device which is also closed, in other words follow the Scomet process for the production of oxygen-free copper (OFHC), there is no reason why good quality oxygen-free copper cannot be made by substituting the Wilkins-Poland furnace for a Summey or Scomet furnace for the primary melting. But when we come to the production of tough-pitch copper, the matter is not quite so simple. The experience gained at the Ontario Refining Co. plant in Copper Cliff, Ont., Canada, reveals that when they allowed the copper to remain oxygen-free in the arc melting furnace and then convey it to the molds in an open launder in order to pick up the requisite amount of oxygen, it was extremely difficult, if not impossible, to control the oxygen content and to make sound tough-pitch copper castings. Even in the launder there was clear evidence that the copper was gassy by the constant discharge of copper rain; the resulting castings were of poor quality and lacked uniformity. After considerable experimentation the operators at Copper Cliff hit upon the idea of venting the arc furnace so as to permit the molten copper to pick up oxygen in the furnace. From then on there was little or no difficulty in producing tough-pitch copper of excellent quality.

It is my belief that in order to produce good quality tough-pitch copper if the Wilkins-Poland furnace is used for melting the cathodes, it will be necessary to oxidize the bath by venting the furnace so as to introduce air. What will happen to a resistor furnace of this type when operating in an oxidizing atmosphere we do not know because it has not been tried; but I should judge it would not be very satisfactory. And if the furnace is not vented and the copper emerges oxygen-free, then the same difficulties will be encountered as when Copper Cliff attempted to produce tough-pitch using the arc furnace.

Mr. L. W. Bahney, Manager of The Scomet Engineering Co., has informed me that he was unable to produce good quality tough-pitch copper wirebars at Carteret, N. J., when he attempted to introduce the proper amount of oxygen in the launder by exposing the moving stream of oxygen-free copper to the air.

In other words, he confirmed the results obtained at Copper Cliff even though the melting was done in an induction furnace instead of an arc furnace.

FRANK F. POLAND (author's reply)—I have the impression that Mr. Rolle is inferring that because air had to be vented to Copper Cliff's arc furnace it will be necessary to do the same for all other furnaces. It is my understanding that the metal as it comes from the furnace at Copper Cliff varies from about 0.005 to 0.01 pct oxygen. Can anyone present tell me if I am correct in this?

J. S. SMART*— $0.01 \pm$ is the figure that is generally used.

FRANK F. POLAND—I believe there is more than one way to obtain the same end result and Mr. Rolle does not hesitate to say that he believes the resistor furnace could, in conjunction with the proper pouring equipment, produce good sound oxygen free castings. However, he has some doubt as to the successful casting of good commercial tough pitch refinery shapes. We must not lose sight of the fact that the furnaceman has for a long time, and still is, applying his skill in the production of electrolytic copper castings and that the end result we are seeking is to get molten copper in such condition that when it solidifies in any given mold a level or slightly crown set will result. There is no doubt that fundamentally this is accomplished by the release of gas during solidification. However, there has been a lot of discussion as to how the gas got into the metal and what kind of gas it is but the fact that it is a controlled amount liberated during solidification has not been questioned.

At Copper Cliff I believe it is necessary to vent air to the furnace because it is operated with an arc and I feel quite certain they would get into a lot of difficulty with the operation of the furnace itself if this were not done.

Air is 79 pct nitrogen and in my opinion it is questionable if the amount of oxygen introduced in the arc furnace at Copper Cliff is enough in itself to assure uniform flat set. The set there I feel quite sure is controlled by their furnaceman today, as it always has been, that is between the furnace taphole and the

molds.

At Perth Amboy, N. J. some years ago we set up a gas plant where desulphurized and dehydrated producer gas was made. This gas was used to pole several 250 ton reverberatory furnace charges to an oxygen free condition. These charges after having been blown to low set by standard procedure were covered with enough charcoal to supply all the carbon needed for reduction plus an excess to cover completely the bath after completion of the deoxidation step. This furnace was equipped with two casting wheels, one casting wire bars and the other vertical cast cakes. The purpose of that experiment was to find out if copper could be made oxygen-free in large quantities. It was done successfully. The oxygen-free metal was cast into wire bars and vertical cast cakes. The set required the minimum of control by the furnaceman and the oxygen in the wire bars and cakes was approximately the same as regularly produced. This experience shows that properly prepared oxygen-free copper can absorb oxygen between the furnace and molds in an amount sufficient to produce commercial electrolytic set wire bars and cakes.

Some years ago at one of the large eastern refineries the casting equipment was such that it was necessary to pole regularly their large reverberatory furnaces down to 0.005 to 0.01 pct oxygen and during this period hundreds of thousands of good commercial set wire bars and cakes were produced. The oxygen content was 0.035 to 0.045 pct in the castings.

During the development of the continuous casting process a small resistor furnace was used to melt approximately 1000 lb of cathode copper per hour while being flushed with nitrogen. This furnace was equipped with a door so that a standard 15-lb ladle sample could be cast from the molten bath. All of these samples were sound and had a commercially good set.

The three examples that I have given and, I believe, the Copper Cliff practice prove that good commercial electrolytic copper can be cast from oxygen free metal that has been flushed with either air (nitrogen plus oxygen), commercial nitrogen or carbon monoxide plus nitrogen provided proper equipment is installed between the taphole and molds for control of the oxygen absorption from the atmosphere.

On the Structure of Gold-silver-copper Alloys

By J. G. McMULLIN and J. T. NORTON

DISCUSSION

(E. R. Jette and J. R. Long presiding)

E. R. JETTE*—The way this ternary was developed there are two directly determined points on each of the isothermals except the 700° isothermal, where I believe there is only one. How were the end points determined, and what was the basis for it? Whose work formed the basis for the silver copper line?

M. B. BEVER†—At most temperatures the authors determined three points of the isothermal line. For example it can be seen from Fig 3 and 4 how three points for the 600°C contour line

were obtained. The authors took two additional points for each temperature from the copper-silver binary diagram contained in Hansen's volume on constitution diagrams. It is correct that the 700°C contour line is based only on one point in the ternary field which was found by a slight extrapolation of Fig 4.

R. I. JAFFEE*—Are the tie lines representing phases in equilibrium parallel to the silver-copper boundary?

M. B. BEVER—Are you asking that as a matter of principle?

R. I. JAFFEE—I assumed that would follow from principle. I wonder if that is in accordance with the authors' ideas too.

M. B. BEVER—I do not believe the authors obtained any information on the tie lines in the two-phase field. Of course, in the limiting case of very low gold contents the tie-lines approach to the silver-copper boundary, but generally in the two-phase field I do not think that the tie-lines have to be parallel to the boundary.

E. R. JETTE—I am quite sure they do not have to be parallel. You cannot tell from this work in which direction they go.

E. A. GULBRANSEN*—Were any pycnometric measurements made to check the lattice parameters of the alloys?

M. B. BEVER—I did not hear any-

* Univ. of California, Los Alamos, New Mexico.
† Mass. Inst. of Technology.

* Battelle Memorial Institute.

* Westinghouse Research Laboratories, East Pittsburgh, Pa.

thing about such measurements and I think I would have if the authors had done such work.

E. R. JETTE—The cameras that were used for this work come in three ranges. Do you know whether they use the most precise range or the more convenient middle range?

M. B. BEVER—As I remember it, the authors used a Phragmen No. 3 camera.

E. R. JETTE—That covered the outer range which is the most precise, and it makes me wonder why the results are only considered good to 2/1000 Å. It is capable of doing better than that. Perhaps that is all they needed?

M. B. BEVER—I think that is so. If

you recall Fig 2, the essential quantity to be determined was the temperature above which the parameter is constant. That temperature corresponds to the intersection between the inclined and the vertical parts of the left curve in Fig 2. The precision with which this intersection could be determined was not limited by the precision of the lattice constant measurements.

J. G. McMULLIN and J. T. NORTON (authors' reply)—As Dr. Bever stated in his reply to Dr. Jaffee's question, we did not determine the tie-lines between the two phases co-existing phase in the two-phased alloys. Masing and Kloiber¹ show the lines for the 400°C isothermal section. These tie lines run roughly parallel to the Ag-Cu boundary when the compositions

are plotted in atomic percent. We know of no reason why the tie lines must lie in this direction except when they approach the Ag-Cu boundary.

In reply to Dr. Jette's question on the cameras, we used an unsymmetrical focussing type camera covering the range of θ values from 45 to 83°. We did not utilize the greatest degree of precision possible with these cameras because our specimens were relatively coarse filings instead of the very fine powders usually required for precision work. We feel that the degree of precision we did obtain was entirely adequate for this project and that the added time necessary to obtain another significant figure in the lattice constant was not justified.

Platinum-tungsten Alloys

By R. I. JAFFEE and H. P. NEILSON

DISCUSSION

(E. R. Jette and J. R. Long presiding)

C. S. SIVIL*—The authors are to be congratulated on their excellent work and on the clarity of their paper.

In our opinion the method of preparation of the platinum was perhaps not the best that could have been chosen. The precipitation of platinum by zinc results in a powder that contains not only a comparatively high percentage of zinc, but also a fairly high content of occluded gases. While the final ignition at 750°C would remove some of these gases, there may remain a considerable oxygen content, unless this ignition were carried out in hydrogen. The use of this "black" powder invariably results in swelling during sintering. A platinum powder that is freer from this objectionable swelling is that obtained by the ignition of ammonium chloro-platinate, but even such a powder will give a compact which may swell somewhat, not only when the compact is sintered but also when the compact is worked to wire. In some of our early experiments with powder metallurgy at Baker and Co. we would often make a platinum wire which, on annealing, would swell from a diameter of 0.015 in. to a diameter of 0.017–0.018 in. It is our opinion that this swelling results from (1) the cold welding of the surface of the compact due to the pressure of compacting, and (2) the sintering of this surface to a layer impervious to gas before the temperature of the inside of the compact was high enough to permit diffusion so

that the elimination of entrapped gas could not proceed. Some support is given to this view by the observation that the swelling was reduced by reducing the compacting pressure or the cross-section of the compact.

Turning our attention to the micrographs, the writer is inclined to agree with Price, Smithells and Williams that the structures of Fig 9 and 10 are due to sintering in the presence of a liquid phase, despite the argument of the authors. Is it not conceivable that the presintering of these alloys resulted in slugs that consisted mainly of a platinum-rich matrix which, when the slugs were sintered electrically, became liquid before sufficient tungsten had dissolved to raise the melting point above the sintering temperature? Prolongation of the sintering would answer this question. The writer's view would be that the high intersolubility of platinum and tungsten led to the structures observed for the alloys containing 6 pct and less platinum and 38 pct and more platinum; in the tungsten-rich, by rapid diffusion of the molten platinum into the tungsten and, in the platinum-rich, by rapid diffusion of the tungsten into the molten platinum. Perhaps Messrs. Jaffee and Nielsen kept record of the heating curves of their sintering of these alloys and such curves may give an answer to this question.

R. I. JAFFEE (authors' reply)—Mr. Sivil's comments on the swelling of high platinum content alloys are very well taken. In our work in high platinum alloys, swelling during sintering could not

be overcome. Consequently, we are glad to have his suggestion on the use of ammonium chloroplatinate ignited in hydrogen to reduce swelling. Concerning the presence of zinc in the platinum powder used, we believe that any present would have volatilized during the high temperature sintering operation. At one time we had occasion to try to make tungsten base alloys containing 10 pct Cr. By the time the bar was sintered, all of the chromium had volatilized. In view of this we believe that zinc would have volatilized also. Our point concerning the so-called "heavy metal structure" still should hold. In the theory of this structure it is assumed that the matrix present in the final product is molten at the sintering temperature, and represents the equilibrium condition. If such were the case it is highly improbable that the bar would support its own weight, which it would have to do during electrical sintering.

S. J. SINDEBAND*—Were any fusion point measurements made on bars which had been completely sintered prior to making this determination? Perhaps that would cast some light on the point just raised regarding the possible presence of liquid phases. I wonder, when the fusion point is measured in the course of the sintering operation, whether the equilibrium is always obtained prior to the initial appearance of fusion in the hole.

R. I. JAFFEE—Perhaps I did not make the point clear, but there were two steps involved. The first step was to prepare

* Baker and Co., Inc., Newark, N. J.

* American Electro Metal Corporation, Yonkers, N. Y.

the alloy, which involved taking it up to a known sintering temperature. As a second step the specimen was necked down and was taken up to the fusion point. We hoped to attain equilibrium by the first step, the sintering operation, and did not expect any further diffusion during the fusion point determination.

S. J. SINDEBAND—Perhaps the confusion comes from the text proper, because there is a statement there that the presence of the hole did not interfere with proper sintering.

R. I. JAFFEE—That is right, but the hole was put into the specimen before the sintering operation and before the fusion point determination.

H. P. NIELSEN (authors' reply)—The diffusion takes place very rapidly at the very high temperatures. While we have no complete evidence that perfect diffusion had taken place nevertheless within a matter of minutes the diffusion would have taken place so that it would be practically perfect.

E. R. JETTE*—The melting point or the solidus points seem to be very sensitive to small amounts of impurities, and perhaps the only adequate answer is to report some spectroscopic analysis of your ingots before sintering and after melting to see if there was anything that could affect the melting points.

R. I. JAFFEE—The experiments with tungstens of different nonmetallic contents indicated the extreme sensitivity of the solidus temperature impurities. It has been some time since we did this work, and I do not think the specimens are available to examine spectroscopically. It would be a good idea, however.

E. R. JETTE—We do not often get papers where the working temperatures start over 1700°C.

E. A. GULBRANSEN†—Would you

* Univ. of California, Los Alamos, New Mexico.

† Westinghouse Research Laboratories, East Pittsburgh, Pa.

elaborate on the methods used for measuring the temperature? In particular, how is the absolute temperature determined from the brightness temperature?

R. I. JAFFEE—The temperature measured was that at the bottom of a hole in the specimen, which was assumed to be radiating under black body conditions. This temperature was taken to be the true temperature. When I referred to brightness, I was referring to the relative brightness at the bottom of the hole compared to that at the surface of the bar. Perhaps I do not get the entire connotation of your question. Do you care to add anything further, Dr. Nielsen?

H. P. NIELSEN—Only that I understand that the hole should be five times as deep as the diameter or better in order to come close to black body conditions, and we made sure we had at least that depth.

E. R. JETTE—Is there any way of getting an accurate calibration of temperature under these conditions?

R. I. JAFFEE—The method used to measure temperature is admittedly not the most ideal one. A very good method employs the use of a cylindrical specimen with a small hole in it. Under such conditions a practically perfect black body is obtained. If there were no radical temperature gradients through the walls of the cylinder the conditions would be right for very reliable observations of temperature. Use of such a specimen was not feasible in the present work.

E. A. GULBRANSEN—Is it possible to interpret the etching pits as residual porosity of the material?

R. I. JAFFEE—I cannot answer that question absolutely. It is possible that they might be. However, they did not appear in the polished specimen before etching, and, also, were rather shallow.

E. A. GULBRANSEN—Did the density of the material come up to what you would normally expect of compositions of this type?

R. I. JAFFEE—We did not check density.

E. A. GULBRANSEN—How do you interpret your hardness measurements? You have a tremendous increase here, 160 to about 900. To what do you attribute this change?

R. I. JAFFEE—Straight solid solution hardening of the tungsten solid solution by platinum. A similar sort of thing, although not nearly so marked, occurs at the platinum end of the system. Tungsten is one of the most potent of the hardeners of platinum. Although I agree with you that this is a remarkable increase in hardness for a substitutional solid solution, we do not see any other mechanism for the hardening. The maximum point in the hardness curve coincided with the solubility limit.

E. A. GULBRANSEN—Are there any changes in the lattice parameters?

R. I. JAFFEE—Yes, lattice parameters were measured. Some figures are given in the paper. Thus, for pure tungsten we obtained a lattice constant of 3.1583, which checks quite well with the accepted value. A 4 pct platinum content in the tungsten causes the lattice constant to decrease to 3.1572, which amounts to a very small shift.

L. D. JAFFE*—In connection with Mr. Gulbransen's comment, is there any possibility of a precipitation on cooling from the sintering temperatures or with the specimens quenched in some fashion?

R. I. JAFFEE—Cooling from the sintering temperature was quite fast, because after the transformer is shut off, the specimen cools to below a red heat in a few seconds. Therefore the opportunity for precipitation is rather limited.

H. R. STEPHAN†—Is there a possibility that you get a high strength matrix to hold your specimen together and still have a liquid phase present.

R. I. JAFFEE—The micrographs show fairly clearly the matrix was the platinum-rich solid solution. I think that rules out that possibility.

Use of Electrical Resistance Measurements to Determine the Solidus of the Lead-tin System

By R. HULTGREN and S. A. LEVER

DISCUSSION

(E. R. Jette and J. R. Long presiding)

M. B. BEVER*—The method re-

* Massachusetts Institute of Technology.

ported in this interesting paper promises to be of fairly wide applicability. It may be expected that the solidus and liquidus lines in other low-melting alloy systems can also be determined by resistance measurements. As these alloys are especi-

ally slow to reach equilibrium, a static method will improve the accuracy with which these parts of their phase diagrams can be determined.

It should be noted that the sensitivity of the method for the determination of

the solidus is not the same at all compositions. The straight line representing the solid phase and the curve representing the two-phase region intersect in a decreasingly definite manner, as the temperature range of solidification increases.

A question must be raised concerning the eutectic temperature in the lead-tin system. The authors state that melting begins at 183°C, but in Fig 5 they somewhat arbitrarily place the eutectic at 185°C and in Fig 6 at 183.3°C. It may well be asked whether the resistometric method is not capable of high precision also in locating the eutectic temperature.

If the resistances of the liquid alloys reported in this paper are plotted against composition at a single temperature such as 320°C the value for the alloy containing 19 pct tin appears to be abnormally low or possibly that for the 24 pct tin alloy is unduly high. Although the authors did not intend to determine absolute values of the resistance, they perhaps have an explanation for this unexpected behavior of the resistance as a function of composition. It is of interest in this connection that Bornemann and Müller* and Matuyama† found that the resistance of liquid lead-tin alloys decreases quite regularly as their tin content

is increased.

A recently published observation may be added to the data from the literature presented in Fig 7. Borelius, Larris and Ohlsson* used resistance measurements to determine the solvus in lead-rich lead-tin alloys. They found that an alloy containing 18 pct tin on heating becomes a single phase at 182.5°C, and is still solid at 183.8°C. These data agree well with the results presented in Fig 7 by Professor Hultgren and Mr. Lever.

E. R. POTTER†—It is nice to run across papers where the authors present their data as they record them rather than making their graphs agree with their conclusions. Now in respect to this one alloy—the 19 pct tin—which happens to have a rather low value at some temperature in the liquid state, we do not know whether Dr. Hultgren used the same tube for all his alloys or whether he used various tubes during the experiment. If he had used different tubes, there would be some experimental error due to the cross-sectional area variations from tube to tube. It might be that Dr. Hultgren would have a rather simple answer to this point but I cannot answer the question.

E. R. JETTE—This is one of the oldest systems in physical metallurgy.

B. GONSER*—I might point out that the tin used is not a particularly pure tin, although it is mentioned as such. It is commercial grade. Tin of higher purity can be obtained both in commercial brands guaranteed 99.9 pct pure, and in special grades. I would recommend that similar work be done with tin of higher purity such as the 99.99 pct electrolytic tin produced by Vulcan Detinning Co. or others.

E. R. JETTE—If we are looking for the easiest possible system to try out the electrical resistance method, I would say this would be it. This is not to detract from the work but there is a certain precision attainable in handling this particular system and it would be difficult to reach in a system that melted 500° higher. Also, it is obvious that using the electric resistance method means you must be able to put the alloy in such a physical form that you can measure a resistance. This is not always easy and I suspect that the authors of the previous paper on the platinum-tungsten system might have had a great deal more difficulty in doing the job by resistance methods.

The Effect of Orientation Difference on Grain Boundary Energies

By C. G. DUNN and F. LIONETTI

(E. E. Schumacher and A. Wachter
presiding)

W. G. BURGERS*—It seems almost certain that this investigation shows the way which finally, when more analogous data have been obtained, must lead to the understanding of many features of preferential growth-directions of crystals and of the occurrence of recrystallization textures.

In this connection I should like to mention that Mr. Tiedema in my laboratory succeeded in developing an analogous method for preparing crystals in aluminum plates with a chosen crystallographic plane and direction parallel to

the surface of the plate (to be published in *Cryst. Acta*). If such crystals were grown in high purity aluminum and test-pieces containing a few crystals such as the authors describe were prepared for this metal, it might be possible that due to the absence of growth obstructing particles, even in this low-melting point metal boundary displacements approaching equilibrium positions might be realized.

With regard to the apparently marked drop in surface energy for orientation differences approaching zero degree, and orientation differences approaching those existing between twins, it seems of interest to remark that in aluminum a crystal growing at the expense of fine grained material cannot (or can only very reluctantly) absorb grains in either ap-

proximately (within 5–10°) parallel or spinel twin orientation (May, Tiedema and Burgers, *Nature* (1948) 162, 740 and *Cryst. Acta* in press). Consequently with aluminum the method of preparing a crystal with a definite orientation does not succeed when the new crystal has to absorb its own texture; for example it is not possible to grow in a polycrystalline wire with a [111]-texture a crystal with a [111]-direction parallel to the wire axis (Tiedema: *Cryst. Acta*, in press). Finally I should like to mention the well-known fact (Burgers: *Proc. Acad. Amsterdam* (1947) 50, 723) that prolonged annealing of recrystallized nickel-iron sheet with cube-texture never succeeds in transforming this into one single crystal of the same orientation; if, by "secondary recrystallization," large crystals are formed

* Laboratorium Voor Physiche Chemie, Delft, Holland.

in this process, their orientations differ considerably from the [100]-orientation. In other words, elimination of the boundaries between nearly equivalent blocks appears to be impossible. This again confirms the occurrence of a drop in surface energy for small differences in orientation.

C. G. DUNN and F. LIONETTI (authors' reply)—The authors wish to thank Dr. Burgers for his kind remarks and his very interesting discussion on the problem of recrystallization and grain growth processes. It is a pleasure to hear of the successful work done in his laboratory on growing aluminum crystals in plate specimens with each crystal having a predetermined orientation. Application of this method to the problem of grain boundary energy measurements in aluminum would be very desirable and, as Dr. Burgers indicates, the purity of the system could be controlled more completely than it can in silicon iron. Results different from our present ones might also be expected because of (1) a different type lattice and (2) a one element system.

The illustrations of lack of growth for near twins and for grains of nearly the same orientation are very welcome and we are in complete agreement with the idea expressed about low boundary energies playing an important role. For example, the presence of relatively stable island grains of near twin orientation, described by Burgers* in connection with samples supplied by P. A. Beck, is understandable on the basis of a low amount of boundary energy for twins or near twins. Further, when island grains form in a growing grain as may occur in exaggerated grain growth, a certain amount of grain boundary energy is lost for purposes of advancing the boundary and this may be important for general growth. Speculating a bit on the assumption that growth occurs, it would seem that the number of island grains would increase with sharpness of texture of the matrix provided the growing grain has about the same or a twinned orientation of the matrix texture. In such a picture not only would the total available energy drop with increasing sharpness of texture, but the amount used for general growth would also drop. From an energy standpoint, these two factors appear to explain the failure of a large grain to grow at the expense of its own texture as Dr. Burgers stated was the case.

However, Dr. Burgers is well aware that something beyond grain boundary energy appears to be involved if we consider the case when the matrix is strained. Quoting from his reference in *Nature*, "It appears from various experiments that the ease with which a crystal can grow in

a deformed matrix depends on the mutual orientation of growing and disappearing lattice domain." This idea has been stated before by van Arkel⁷ and Barrett⁸ and used recently by Dunn⁹ and Beck¹⁰ in discussing recrystallization phenomena. We believe from an energy standpoint alone, for instance, that a strained single crystal should be able to recrystallize readily to its own orientation through a nucleation and growth process. However, except for certain recovery processes,¹¹ which are very slow, recrystallization does not occur except through a change in orientation. A growing nucleus actually must build up a grain boundary energy and the amount of this increases with difference in orientation. Additional knowledge of the nature of the strain energy is needed, of course, for an understanding of this phenomenon even though such energy might be considered to reside as sub-boundary energy and be largely due to differences in orientation.^{12,13} Geometry of these sub-boundaries would be expected to be important. Geometrical relations might even provide the key to this phenomenon of orientation relations being so important to the movement of atoms from one lattice to another. On the other hand, part of the picture may be concerned merely with the rate at which atoms can leave one lattice and join another. This means that, with the same strain energy available, the nature of the boundary where atoms are moving may play a major role.

The importance of the role of orientation relationships for atomic movement also stands out for those cases where boundary energy and internal strain energy both favor the shifting of atoms. An example of this type is the strained island grain (Laue asterism), which appears to be relatively stable in a strain-free single crystal matrix of near twin orientation (see Burgers' report in *Nature* referred to by him).

A. J. SHALER*—My colleagues and I have also been doing some work on the surface energy of solid metals and we wish to assure Dr. Dunn and his collaborator that we fully appreciate the importance of their work. I should like to ask the authors if they have made any measurements of the angles formed at the intersection of the boundary with the free surface at the edges. In general, their edges were notched in the specimens shown, so that these measurements could probably not be made on them. The relation between the angles and the surface energies should be the same at these intersections as at interboundary intersections. The advantage in making such measurements would be that the boundary energy could be directly com-

pared with the surface energy of the metal (itself in the presence of hydrogen or argon). The paper by Udin, Shaler and Wulff which will be presented later shows a method of measuring directly the surface energy of the metal in the presence of its vapor or another gas. From those measurements and the measurements of the angles I am speaking of, we could then get absolute values of the grain-boundary energies.

C. G. DUNN—We observed one thing which has already made some of our next work on this problem much easier—it is the formation of grooves in the surface by thermal etching (reported also by Chalmers, King, and Shuttleworth in England for the case of silver). It seems to offer an ideal way of studying the positions of grain boundaries as well as this relationship between free surface and interboundary energies about which Dr. Shaler asked his question. I think Dr. Shaler is asking about the angle relationships of grooves at either the edge or on the large flat surface. We have measured no groove angles, but others are doing this. Our connection with this problem so far is to supply samples of silicon iron with known orientation relationships between grains. From the surface energy between the atmosphere and the metal and the groove angles, one can obtain the grain boundary energy for a particular grain boundary. If the energy of one grain boundary of our group could be determined in this way, then all our values for silicon iron could be put on an absolute basis. This we hope to do eventually. If the groove is not too near 180°, this technique may have pretty good accuracy. On the other hand if the dip is very shallow and the angle is near 180°, then I think this method would not be very accurate for determining every type of grain boundary.

Using the groove angles—if they can be measured—it should be possible to check the form of curve that we have obtained. To do this, two-grain groups suffice as specimens. You have a fixed orientation relationship for each two-grain group, and you determine γ for each configuration. If the grain boundary energy varies with orientation difference, this will cause the groove angles to vary also. Consequently, the variation of γ with orientation difference could be determined.

L. D. JAFFE—Dr. Dunn, with your techniques it seems it would be possible to control the orientation of the boundaries since they come out at about 90 and 180° angles. In any case you can adjust the orientations of the grains with respect to the boundaries. Are you planning any work in which you will simultaneously control the boundary orientations and the orientations of the grains?

C. G. DUNN—I am glad you asked

* *Nature* (1948) 162, 740.

* Massachusetts Institute of Technology.

about that. We are attempting to grow two grains from one end of the specimen in such a way that their boundary will be in a given crystallographic orientation. I think we have already succeeded in getting pretty good pseudo twins by this method. We maintain control of this direction pretty well if on subsequent annealing the motion of the boundary stays parallel to this line, otherwise control is lost. You cannot control all grain boundary orientation in three-grain groups because some have to change to establish the equilibrium angles. However, it might be possible to control one

boundary fairly well.

The other thing to do is to determine from prior data a configuration that should be fairly close to an equilibrium condition. It should be possible to grow a three-grain group near this configuration in order to obtain equilibrium conditions on a larger scale and perhaps more easily. I do not know whether you had that in mind, but it is a possibility.

Influence of Composition on the Stress-corrosion Cracking of Some Copper-base Alloys

By D. H. THOMPSON and A. W. TRACY

DISCUSSION

(A. Wachler presiding)

E. A. ANDERSON*—At the outset, I note that you are using a humid atmosphere containing ammonia but that you make no reference to the variable of carbon dioxide content. Edmunds in his work in this laboratory found very marked effects on the rate of failure due to variations in carbon dioxide in the environment. This point is, of course, strongly related to the overall corrosion rate problem since the role of the carbon dioxide seems to be to permit the formation of hygroscopic salts which give a controlled moisture film on the specimen surface, which in turn seems to support the intergranular penetration more consistently than would otherwise occur.

(2) Your results with various copper binary systems are very striking. It is curious, however, that the time-to-failure minima all occur at percentages of the alloying element which are considerably below the solubility limits as given in the conventional equilibrium diagrams. If your theory regarding the presence of these impurities in some concentration in the grain boundaries is correct, then

either the existing diagrams are not accurate in the room temperature region, or there is a difference in solubility in the grain boundaries as compared with the grains. A study along these lines might be very revealing.

(3) The undesirable effect of silicon in copper calls to mind our own observations on the influence of silicon on the stress corrosion cracking resistance of alpha brass. In this case, silicon was found to have a very marked beneficial effect, particularly when a heat treatment capable of producing a grain boundary constituent was used. I should appreciate it if in the discussion of your paper this point should arise, you would attempt to clarify the difference between the copper-silicon binaries and the copper-zinc-silicon ternary alloys.

D. H. THOMPSON and A. W. TRACY (authors' reply)—(1) We have no data on the constancy of the carbon dioxide content of the air used for the test atmosphere but have believed that the normal carbon dioxide content of the air was as constant as could be obtained by using Edmunds' method of removing carbon dioxide from the air and then adding a measured quantity. In any event, the test atmosphere was the same for all specimens in a test run. We agree with Mr. Anderson that the carbon dioxide content is important in the formation

of a hygroscopic film on specimens.

(2) We can imagine that there could be a concentration of solute atoms at the grain boundaries which would be so small that present methods would not detect it even if it exceeded the solubility limit of the alloy. There could be somewhat greater solubility at the grain boundaries for an interstitial solute. There is a possibility that phosphorus dissolves in this way but we believe that none of the other solutes studied does. In our present studies we hope to find out something about conditions at the grain boundaries of some of the systems mentioned in the paper.

(3) Mr. Anderson points out that silicon brass, which has had a high temperature heat treatment followed by a quench, is highly resistant to stress-corrosion cracking. Although the test conditions used by Anderson* et al were different from our test conditions, it is noted that the silicon brasses which had not had the special heat treatment were less resistant to stress-corrosion cracking than copper containing approximately equal amounts of silicon.

G. R. GOHN†—Nonferrous metallurgists and particularly, materials engineers, have been accustomed to thinking

* Symposium on Stress-Corrosion Cracking of Metals. (1944), ASTM-AIME, p. 173.

† Bell Telephone Laboratories, Inc.

that copper-base alloys containing more than 85 pct copper were relatively free from spontaneous cracking under the combined effect of prolonged, high stress and corrosive attack. The data presented by the authors indicate that we must now reorient our thinking and consider that, under certain adverse conditions, copper and all copper alloys may be susceptible to stress-corrosion cracking.

For many years we have used the mercurous nitrate test as described in A.S.T.M. Designation B154 as a means of determining whether or not the residual stress in a fabricated copper-alloy part such as a rod, a tube or a manufactured piecepart was reduced to a safe level so that stress-corrosion cracking would not occur in service. Now obviously, as pointed out by Dix,* failure in this test is not caused by corrosion and hence the mercurous nitrate test leads to no understanding of stress-corrosion cracking. However, experience has indicated that fabricated parts similar to those which withstood 15 min. immersion in the mercurous nitrate test without failure, seldom failed in service; while those which did crack in the test frequently failed in service unless the residual stresses were reduced by subsequent annealing, or corrosive attack was prevented by the use of an appropriate protective finish. Tests made by Gohn and Arnold* on strip samples indicated that all of the common copper base alloys could be stressed in bending to values approximating the yield strength of the material without failure in the mercurous nitrate test and this finding correlates well with service observations. Only in the case of cylindrical and spherical parts, or screws and studs under high internal or external stresses, were stress-corrosion failures observed either in the laboratory or in service.

The findings of the authors that stress-corrosion will occur in copper and copper alloys stressed at values well below the yield strength when the corrosive agent is an atmosphere containing ammonia, water-vapor, and air is, therefore, of considerable significance and should greatly aid in the study and understanding of the mechanism of stress-corrosion cracking in copper and copper alloys. Their findings do, however, leave unanswered the relation between time-to-failure and service life. It would be interesting to know if the authors are in a position to evaluate their results in terms of expected service life.

D. H. THOMPSON and A. W. TRACY (authors' reply)—The paper describes a series of laboratory experiments designed to study fundamental causes and not intended to predict service failures. The fact that phosphorus-deoxidized copper will crack under specified

laboratory conditions does not in the least affect the probability of its cracking in service. Experience shows that the alloy does occasionally crack in service, but the event is rare indeed.

It appears that one of the necessary factors in service failures by stress-corrosion-cracking is that during cold work the alloy acquires a high internal stress, which is not relieved by subsequent creeping or relaxation. Such metal is prime for cracking. In general, phosphorus-deoxidized copper is not capable of maintaining such a residual stress and so it does not fail.

Mr. Gohn's remarks on the mercurous nitrate test cover the subject well. It is a test for the presence of internal stress in some alloys; it is not a research tool for work on stress-corrosion cracking.

H. L. BURGHOFF*—The authors have presented a large amount of data which are a most welcome addition to the available information on stress-corrosion cracking of copper alloys.

I should like to emphasize the point which they have brought out with regard to the rarity of stress-corrosion failures of phosphorus deoxidized copper. This class of material has enjoyed widespread use for many years and has a merited reputation for dependability. The only case of stress-corrosion cracking of copper in service which I definitely recall is that of a soft copper tube of small diameter. This sample was of deoxidized copper containing 0.027 pct phosphorus and had several transverse cracks which originated from the outer surface. These cracks were entirely intercrystalline in nature.

The authors mentioned the low yield point of annealed copper as making impossible the attainment of high internal stresses, thus accounting to a great degree for the scarcity of service failures of the stress-corrosion cracking type. However, such phosphorized copper is used in the cold worked condition for which the yield strength as conventionally defined is a high percentage of the tensile strength. Externally applied stresses can be high without significant deformation of the metal although residual internal stresses would be expected to be low because of the relatively low resistance of copper to stress relaxation. Stress-corrosion cracking of hard phosphorized copper is most certainly a rarity. Its extensive service record indicates great dependability in this respect.

The experiments on the effect of precipitation of iron phosphide in copper as described in the paper and summarized in Table 10 might have been more significant if the authors had used greater amounts of iron than 0.006 pct for the formation of iron phosphide with 0.024 pct phosphorus. As Fe_2P is the most likely combination of iron and phos-

phorus in copper, approximately 0.09 pct iron would be required to obtain the maximum precipitation effect with 0.024 pct phosphorus.

The test results presented for the copper-silicon series are interesting and worthy of special comment. A minimum of resistance to fracture in the ammonia atmosphere is indicated at about 1 pct silicon and work on a somewhat similar program in our laboratory is in agreement with this. The observation, however, cannot be transferred to prediction of actual service behavior of commercial silicon bronzes without consideration of other factors. For example, two important groups of silicon bronzes have nominal contents of 1.5 and 3 pct silicon respectively and their general service behavior when used as bolts does not at first glance confirm the authors' relationship. This may be due to their being used more in the cold worked state than in the annealed state, with the degree of working normally being greater in the case of the lower silicon content. The 3 pct silicon alloys, while being very serviceable, have shown a number of stress-corrosion cracking failures, whereas such failure of the 1.5 pct silicon alloys seems to be as much a rarity as in the case of copper. As far as laboratory stress-corrosion tests in ammonia atmosphere are concerned, our results on two silicon bronzes containing 1.5 and 3 pct silicon respectively and 1 pct zinc as a third element in each, indicate that the two materials will fracture in approximately the same time at a given applied stress when they are cold worked to the same level of hardness or tensile strength.

The occurrence of transcrystalline stress-corrosion cracks in alloys such as Arsenical Admiralty, as illustrated in the authors' Fig 13, is of importance in the proper diagnosis of service failures by cracking. There was a time not too long ago when transcrystalline cracks penetrating metal from a surface roughened by corrosion were considered direct evidence of corrosion fatigue. Undoubtedly the wrong conclusion has been reached in some instances on the basis of such evidence. It should not be inferred, however, that all cases of stress-corrosion cracking of such materials will be transcrystalline, for intercrystalline cracking may also be encountered in them.

Information on grain size and mechanical properties such as tensile strength and yield strength of the test material was not included in the paper. These factors may not have a great bearing on the trends which were developed, but they may be of significance in a more complete evaluation of stress-corrosion characteristics of these and other materials. It is to be hoped that the authors will tabulate them and add them to the discussion of their paper.

D. H. THOMPSON and A. W. TRACY—Dr. Burghoff points out that

* Symposium on Stress-Corrosion Cracking of Metals, ASTM-AIME (1944).

* Chase Brass and Copper Co.

the internal stress in cold-worked copper is relieved by stress relaxation and that internal stresses of the order of magnitude of the yield point therefore do not exist. Certainly it is agreed that copper rarely cracks in service. Does not the same mechanism operate in the case of silicon alloys? Our records show that service failures of cold-headed bolts containing 3 pct silicon were ended when a 1½ pct silicon alloy was substituted, paralleling the case Dr. Burghoff cites. We had ascribed this behavior to the ability of the lower silicon alloy to relax and relieve stresses both during cold heading and after installation.

The matter of iron and iron plus phosphorus requires additional work. Several heat-treatable alloys have been tested but evidence is generally lacking that precipitation or solution heat-treatments have an appreciable effect on the cracking rate of copper alloys.

The grain sizes and Rockwell hardnesses are given in Table 12. It will be observed that nearly all the grain sizes are between 0.010 and 0.040 mm.

The mechanical properties of the phosphorus alloys are given in Table 13. Samples were annealed for 1 hr at 500°C. The values are averages of two tests.

J. T. KEMP*—The paper by Messrs Thompson and Tracy is the latest in an important series on corrosion cracking. It follows in logical sequence the impressive group of reports presented at the AIME-ASTM symposium in 1944. In reading this paper it is well to look over the volume containing the earlier ones once more.

Two considerations appear to have been overlooked when one reviews these several papers with attention directed to the theory offered: 1. That the path of cracking, whether intergranular or transcrystalline, may be influenced by the structural history of the metal. 2. That the potential relationship, grain boundary to grain body, is probably inconstant, and that the intensity of anodic corrosion at the bottom of a crack may decline as the ohmic resistance of a lengthening circuit builds up.

Now the consensus of opinion regarding corrosion cracks that follow grain boundaries seems to be that such cracks are caused by localized action resulting in one way or another from precipitation or concentration of solute atoms in the grain boundary regions. It seems to be assumed that the susceptible metal was in structural equilibrium at the close of the last previous period of structural change due to the heat, that is, that the grains have been established, that the boundary precipitation or concentration has progressed to a condition approaching stability. Perhaps such conditions may be

‡ Final anneal 750°C.

attained in standard laboratory operations, perhaps not. How certain can we be that more than a semblance of equilibrium has been reached in a recrystallized metal, that solute atoms have migrated from previous positions along previous grain boundaries to new positions along new grain boundaries in sufficient numbers to establish the potentials or the tensions indicated? A very considerable degree of mobility must be assumed to get the solute atoms or precipitates from place to place as new grains form in recrystallizing metal, and then to follow the boundaries as the grains grow. Is it not possible that solute atoms gathered in well established grain boundary regions, assuming that that is where these atoms do congregate, during one interval at annealing temperature may be left more or less in place during cold working and a subsequent interval at temperature, still occupying something of their original planar or zonal positions in the mass and lying across the new grains as much as along the new boundaries? If this were so, it would seem plausible to assume that the residual arrangements of solute atoms, or precipitates, would cause lattice strain within crystals and so offer favorable paths for transcrystalline cracks.

Micrographs of transcrystalline corrosion cracks, however, do not often suggest that the crack follows the polygonal alignment of former grain boundaries very faithfully. Perhaps a residual planar arrangement of residual solute in one crystal at or close to the exposed surface is enough to establish a notch in a stressed metal. The notch effect may predominate once the crack is established. It is not to be expected that the residue of any mesh work of grain boundaries would retain sharp definition through later structural changes. The traces of old boundary systems should disappear as later structures develop. Yet the persistence of coring in the wrought nickel-silvers is an evidence of the persistence of inhomogeneities in alpha copper-base alloys.

As to the electrical circuits and the progress of inter-granular cracks to considerable depth, say through and below the second layer of grains, it may be asked whether microcurrents do or do not obey the general laws governing the flow of macro-currents. Presumably they do. It must be borne in mind that there is an analogy between the flow of current in three dimensional conductors, that is, local currents in a mass of conducting metal, and the flow in restricted circuits that can be measured with precision. Specifically, it would appear that the grain boundary-grain body potential difference could operate only to promote corrosion in a crack to a depth at which the resistance of the lengthening circuit (up through the electrolytic, over the edges to whatever cathodic areas lay adjacent and back through the mass of

Table 13 . . . Mechanical Properties of Copper-phosphorus Alloys

metal) would reduce the active current to ineffectual values.

A simple anode to cathode circuit may exist only at the inception of a corrosion crack. As soon as appreciable depth was attained there would be modifying potential relationships between the more intensely anodic metal at the bottom of the crack and the less intensely anodic walls until the crack had widened by the removal of enough of the anodic wall metal to reveal cathodic crystal body. When this occurs, if indeed there has been no neutral point at which opposing emf's within the crack stop attack on the walls, the simple anode to cathode circuit can become re-established. Other modifying factors, chemical reactions, polarization, adsorption, and others, may all assert themselves in one or another order or intensity, perhaps inconstantly, to modify the progress of the crack.

Again, cracks that are established by potential differentials may propagate in response to other forces such as stress concentration at the sharp bottom of the notch. In any case, there should be no sharp transition from one to the other regardless of the time rate of progress in any system not subject to fluctuating external influences.

There will be many special cases—perhaps every one observed will be special in some sense—and the wide mouthed crack mentioned above is one.

No potential differences within grains have been reported in our series of corrosion-cracking papers. They would be difficult to identify and measure. Such potential differences are conceivable and have their parallels in other physics. If boundary-to-body potentials exist because of boundary precipitations or concentrations, then a similar potential should exist within a crystal if an interior concentration existed and came through to an exposed surface.

The whole subject becomes more involved the more it is studied. Perhaps the whole has become so wrapped up in words that only a clear sighted prophet can disentangle facts from fancies. May such a one emerge from the laboratories soon and reduce the laws of corrosion cracking to simple language.

D. H. THOMPSON and A. W. TRACY—In the alpha solid solutions of copper alloys, remarks about equilibrium, submicroscopical precipitation, or grain boundary concentration are all pure supposition. Perhaps the observed effects are associated with such causes; as yet proof is lacking.

In some aluminum alloys the conditions can be seen under the microscope. In his 1940 Institute of Metals Lecture,⁴ Dix shows a micrograph (Fig 2) in which

over-aging of an aluminum alloy containing 1.6 pct copper has resulted in a fine, randomly distributed precipitate that has agglomerated at the grain boundaries and left a solute-depleted zone. As Dix states in the present discussion, either the depleted zone or the precipitate may be the anode that starts stress-corrosion cracking. It is obvious, however, that the atomic movement necessary to form this precipitate and depleted zone is small, and that a solution heat-treatment would readily redissolve the precipitate. Thus, a precipitate can form and be redissolved with only small atomic movements.

In the case of copper alloys there is reason to believe that small amounts of impurities may be swept along ahead of an advancing grain boundary during grain growth. Presumably, this can occur because there is more room, more vacant lattice sites in the discontinuity of the boundary. If this mechanism takes place no precipitation heat treatment is necessary, foreign atoms are concentrated at the grain boundaries by a simple anneal. It is quite possible that the same mechanism explains why some solute atoms inhibit grain growth.

As to the lengthening current path in the deepening crack, an answer can be only conjecture, but certainly this process does not stifle the attack even in the absence of stress. In the presence of stress it has been shown (unpublished work, The American Brass Co.) that the rate of crack propagation is accelerated quite rapidly. Presumably this is the effect of the ever-increasing stress on the notch at the bottom of the crack. Mr. Kemp's idea that the walls of the crack may become cathodic and reduce the length of the current path to the corroding anodic area at the base of the crack is logical. At any rate, it is certain that if the resistance of the circuit increases, that is not the primary factor in determining the rate of crack propagation.

E. H. DIX*—The authors are to be congratulated upon a very nice piece of work which adds tremendously to our knowledge of the subject of stress corrosion cracking. I was a little bit intrigued by the introduction of the paper in which the authors refer to season-cracking of brass as being associated with internal residual stresses and stress corrosion cracking as a proper terminology when the stress is from an externally applied load. I suppose some of us who have been worrying about intergranular corrosion for a good many years do draw a distinction between ordinary intergranu-

lar penetration which occurs fairly general along the surface and not too deep in most cases, in comparison with stress corrosion cracking of a material that is susceptible to intergranular corrosion, but where the crack goes through fairly rapidly because of the applied tension stress.

There is reference here to the theory that we proposed some time back, but I think there is more emphasis put on the question of whether or not precipitation occurs than we had intended. In aluminum alloys, especially the aluminum-copper system, I think we have demonstrated pretty conclusively that the anodic condition at the grain boundaries is caused by precipitation. In that case the aluminum-copper compound is precipitated, but it leaves a depleted zone along the grain boundaries which is anodic to the remainder of the grain. In some other systems, in the aluminum alloys the precipitate is anodic. That is particularly true in the aluminum-base magnesium alloys. They are of interest because transgranular as well as intergranular cracking occurs and the transgranular cracking follows slip planes along which there is precipitated constituent. I would like to be permitted to read the conclusion from the paper since I subscribe to it 100 pct, and really it is about all that we tried to put out as a generalized theory:

"Any of these conditions makes the grain boundary region anodic to the grain bodies. Localized corrosion is accelerated and grain boundary penetration ensues. The presence of a tensile stress still further accelerates penetration by opening cracks and forming highly stressed notches."

D. H. THOMPSON and A. W. TRACY—The definitions of season cracking and stress-corrosion cracking are used by the ASTM³ and The Corrosion Handbook.²

Attack in the absence of stress cannot, of course, be called stress-corrosion cracking nor does it have the appearance of cracking. The paper refers to it only as intergranular penetration.

We agree entirely with the quoted conclusion, but we are still eager to find the cause of the shift in potential of the grain boundary in the anodic direction in copper alloys.

The authors are grateful to the several discussers for their valuable contributions to the paper and to the subject itself.

The subject can be summarized by saying that highly localized corrosion cells result from the chemical or metallurgical condition of the metal in a selected environment. Stress accelerates the failure. The paper shows how the composition of the metal may have a large effect on the formation of such cells.

Oxide Films Formed on Metals and Binary Alloys. An Electron Diffraction Study

By J. W. HICKMAN

DISCUSSION

(A. Wachter presiding)

A. SQUIRE*—I am afraid I missed the explanation of the significance of Fig 3. I do not quite understand what the effect of the thickness of the film is, specifically your interpretation of the effect on the transformation of the oxide, from one type to another. In regard to tungsten copper materials, that is not a true alloy. It is just a mixture of tungsten and copper. Is there a real significance in trying to determine thermodynamic data in a mixture of that sort?

E. A. GULBRANSEN† (replying for author)—Fig 3 to which you refer, shows that the Fe_3O_4 to FeO transformation is a function of the oxide thickness. An oxide film of 4000 Å in thickness shows a transformation temperature of 500 to 550°C while an oxide film of 428 Å shows a transformation temperature of 350 to 450°C. The temperature for the thicker film is approaching the normal value of 580°C. We have noted this effect several years ago and have checked the experimental evidence several ways. I would like to interpret this phenomenon as follows: Two equations are involved in the Fe_3O_4 - FeO equilibria.

The free energy data for these reactions are well known. The logarithm of the equilibrium constants K_1 and K_2 for the two reactions are given as a function of temperature in Table 6:

Table 6 . . . Equilibrium Constants
 $\text{FeO-Fe}_3\text{O}_4$

| t°C | [12] log K_1 | [13] log K_2 |
|-----|-------------------|-------------------|
| 400 | -0.63 | 17.63 |
| 450 | -0.43 | 16.00 |
| 500 | -0.22 | 14.56 |
| 550 | -0.04 | 13.30 |
| 600 | +0.09 | 12.21 |

* Westinghouse Electric Corporation.

† Westinghouse Research Laboratories.

Eq 13 is thermodynamically possible even in oxygen pressures found in the best of high vacua at all of the temperatures shown. Eq 12, however, is thermodynamically feasible only below 570–580°C and not above. The temperature dependence of log K_1 is small and even at a temperature of 400°C log K_1 is -0.63. This is equivalent to a free energy change of 1940 calories per mol. At temperatures of 450 and 500°C the energy changes are $\frac{2}{3}$ and $\frac{1}{3}$ of the value calculated at 400°C. One may say then that the $\text{FeO-Fe}_3\text{O}_4$ equilibria is rather unique in the flatness of the free energy curve and that small energy changes associated with thin films of matter may explain the change in transformation temperature.

In regard to the question about the use of tungsten-copper materials, Dr. Hickman mentions on p. 11, of the paper the fact the metals do not form a real binary alloy and that the reactions studied may be indicative of those that obtain with a mechanical mixture of these metals.

S. E. MADDIGAN*—I will have to apologize to Mr. Gulbransen. In discussing the oxide films formed on iron he has pointed out that the transformation temperature for polymorphic transformations within these films seems to depend upon film thickness. His thermodynamic explanation for this is not quite clear to me. Although I have not had an opportunity to check the relative lattice parameters for iron and the oxides in the films, I believe that a suitable explanation can be provided by correlating crystal geometry and thermodynamic potentials. It is well known that for thin films the curves for thermodynamic potential may be displaced if suitable geometric relations exist between the substructure and the material of the deposited film, or in the present instance the chemically formed film. For instance, if one deposits a film of a polymorphic material on a suitable substructure such that the space group of the substructure has a close geometric relationship to that of one phase of the polymorphic material, and if the lattice spacings concerned

differ by only 10 to 15 pct, then one finds that the transformation temperature of the polymorphic transition is shifted quite appreciably from that normally found for gross samples of the polymorphic material. I would suggest that something of this nature is occurring in the present instance. In the first thin films mentioned by Dr. Gulbransen, from the thickness one would expect the substructure of the iron to have quite an influence on the overall thermodynamic potential. On the other hand for later thicknesses of the order of 4,000 Å, the forces operating within the volume of the oxide itself assumed the major role and the transformation temperature is then approximately the normal value, so that the film assumes the structure of the normal stable phase.

E. A. GULBRANSEN—I find myself in complete agreement with Dr. Maddigan. My previous remarks were made in order to show that small energy differences could explain the observed phenomena. The lack of matching of the two lattices may account for this difference in energy noted.

R. I. JAFFEE*—I would like to ask if these alloys, particularly those containing chromium and molybdenum and tungsten were analyzed chemically. It seems to me there is a very good possibility of losing a lot of chromium in the preparation from the powders due to the volatilization.

E. A. GULBRANSEN—Dr. Hickman does not say that the alloys have been analyzed chemically. They were prepared at our Bloomfield Lamp Division where many alloys of this type are prepared. The alloys, in both cases, were prepared by slurring in carbon tetrachloride, the molybdenum or tungsten powder together with the chromium metal powder and also the lubricant. The resulting mixture was dried and pressed into compacts which were subsequently prefired and then sintered in hydrogen atmosphere. According to the ASM Handbook 1948 Edition, both the chromium-

* British Columbia Research Council.

* Battelle Memorial Institute.

molybdenum and the chromium-tungsten systems show a solid solution equilibrium diagram.

R. I. JAFFEE—In connection with the chromium tungsten alloy, we once had occasion to try to make a 10 pct Cr-90 pct W. In an attempt to get the alloy dense it was necessary to sinter at higher and higher temperatures until finally after a dense product was obtained it was found by spectroscopic examination that there was not any chromium left as it had volatilized away. Chromium is very difficult to alloy with a high melting material such as tungsten by straight

sintering techniques.

A. SQUIRE—I might be able to shed a little light on that. Dr. Lustman of our Research Laboratories has done some rather extensive work on the preparation of molybdenum-chromium alloys. I believe one of his methods at least was actually to chromize the material, and he obtained molybdenum-chromium alloys in the entire range. On the other hand, I am almost positive that he has obtained a complete series of alloys by mixing chromium powder with molybdenum powder and sintering at a high temperature.

R. I. JAFFEE—I was referring to tungsten-chromium alloys particularly. It is necessary to get the alloy to a much higher temperature with tungsten-chromium, so that the vapor pressure of chromium is appreciably higher than it would be with molybdenum-chromium alloys.

E. A. GULBRANSEN—I have contacted our Bloomfield Works relative to Dr. Jaffee's question. They do not indicate that they had any great difficulty with the volatilization of chromium.

Magnesium-lithium Base Alloys—Preparation, Fabrication, and General Characteristics

By J. H. JACKSON, P. D. FROST, A. C. LOONAM, L. W. EASTWOOD, and C. H. LCRIG

DISCUSSION

(L. D. Jaffe presiding)

R. S. BUSK*—I wish first to congratulate the authors of this paper both for the work done and the presentation of that work. We have also been working on this type of alloy development, but any technical contribution I might have is better reserved for a separate paper which is planned in the near future.

However, I would like to insert a word of caution. The alloys described in this paper are still very much in the laboratory stage. There still remains the quite vexing problem of property stability at slightly elevated temperatures which must be solved before the properties quoted can be effectively utilized. These alloys are extremely interesting and I am confident that the problems can be solved. However, the present existence of those problems must not be overlooked.

I have one question with regard to the work-hardening test. If the work hardenability of magnesium is compared to aluminum using a more standard test such as the Meyer Analysis the magnesium is found to work harden the more rapidly. Is the test developed for this work truly a work-hardening test or a measure of something else?

J. H. JACKSON (authors' reply)—I am sure we appreciate the comments of Mr. Busk and we are pleased that the Dow Chemical Co. has also undertaken work in this field. It is a big field. We, of course, are continuing our research for the Navy Bureau of Aeronautics, since, as clearly shown in the paper, the alloys are not completely developed.

With regard to Mr. Busk's comments on the relative work-hardenability of aluminum and magnesium, the comparison we cited in the paper was intended merely to show that the results obtained by our method of testing were independent of the yield strength of the materials. We believe that this test method afforded a rough indication of the work-hardenability of the magnesium-lithium base alloys. It is not known whether this method affords greater or less accuracy than the Meyer Process, which is based upon a hardness-test impression. It is quite possible, since work-hardenability is a function of metal purity, that our results, obtained for commercial aluminum and magnesium, would be different if high-purity metals had been used.

A. C. LOONAM—Lithium has some very interesting effects on magnesium. The paper showed that even small percentages increased ductility. These small amounts changed the axial ratio of the

hexagonal magnesium from 1.624 in the pure metal to 1.606 in the saturated alpha solution, a value close to that of titanium, which has a ratio of 1.601. You will recall an article in the January, 1949, issue of the *Journal of Metals* where it was stated that titanium can be cold-rolled over 90 pct without any significant edge cracking. At 4.9 or 5 pct lithium, a change begins in crystal structure—from a hexagonal close packed to body centered cubic. There are two phases over a short range of lithium content, but at 10 pct the structure becomes completely cubic. The melting points of alloys in this range of lithium content are relatively high. Alloys even up to the six ratio have melting points above 500°C; this represents a relatively small reduction in melting point from pure magnesium itself. The magnesium-lithium system has a number of very interesting characteristics. This is only a very small part of the story.

J. H. JACKSON—I would like to remind you that Mr. Loonam is one of the authors of this paper, and the fact is that this work is based on many of his ideas. I am sure we appreciate his additional comments in this discussion.

R. LEITER*—I am interested in Fig 19 in which Mr. Jackson compares

* Dow Chemical Co., Midland, Mich.

* Philadelphia, Pa.

strength properties of various alloys after correcting for differences in weight with aluminum as the base. I have been close to the application of stainless steel in light weight structures and this chart appears to me not quite to do justice to stainless steel, particularly in the comparison with 24S-T4 and 75S-T6 aluminum alloy and SAE 1040 steel. For SAE 1040 steel to show up so well it must be in the quenched and drawn condition and the draw must be fairly low. The properties of the aluminum alloys appear to be typical rather than minimum values. The stainless steel properties as shown in the chart are fairly typical of type 301 in $\frac{1}{2}$ hard temper. However, the $\frac{3}{4}$ hard temper is about the equal of 24ST4 and full hard temper is superior to this aluminum alloy.

J. H. JACKSON—Mr. Leiter's remarks are well taken especially with regard to the comparison between stainless steel and 24S-T4. Table 11 gives the typical and minimum properties based on the most recent available data.

The typical property data for stainless steel shown in this tabulation were supplied by Mr. Leiter as being typical of

Table 11 . . . Typical and Minimum Properties

| Material | Yield Strength, psi | | | | Tensile Strength, psi | | | |
|--------------------------------------|---------------------|---------|--|---------|-----------------------|---------|--|---------|
| | Actual | | Compared to 24ST on a Strength to Weight Basis | | Actual | | Compared to 24ST on a Strength to Weight Basis | |
| | Typical | Minimum | Typical | Minimum | Typical | Minimum | Typical | Minimum |
| 24S-T4 bare | 48,000 | | 48,000 | | 68,000 | | 68,000 | |
| 24S-T4 clad | 42,000 | | 42,000 | | 64,000 | | 64,000 | |
| 75ST bare | 72,000 | | 73,000 | | 82,000 | | 83,000 | |
| 75ST clad | 67,000 | | 68,000 | | 76,000 | | 77,000 | |
| Stainless (Type 301) $\frac{1}{2}$ H | 123,000 | 110,000 | 43,000 | 39,000 | 165,000 | 150,000 | 58,000 | 53,000 |
| Stainless (Type 301) $\frac{3}{4}$ H | 145,000 | 135,000 | 51,000 | 47,000 | 185,000 | 175,000 | 65,000 | 61,000 |
| Stainless (Type 301) FH | 152,000 | 140,000 | 53,000 | 49,000 | 195,000 | 185,000 | 68,000 | 65,000 |

Budd experience. The typical data for the aluminum alloys were obtained from the publications of the Aluminum Co. of America. The data which we used originally in constructing Fig 19 were taken from the National Bureau of Standards Circular No. C147.

The relative properties shown in Fig 19 for SAE 1040 steel were for the quenched and drawn condition, the drawing temperature being about 600°F. The relative properties shown for the

stainless steel were for the $\frac{1}{2}$ -hard condition. In the $\frac{3}{4}$ -hard condition the relative properties of the stainless steel would be about equal to those of 24S-T4 but inferior to those of 75S-T6.

We wish to point out that the purpose of Fig 19 in the paper was to indicate that the magnesium-lithium alloys are comparable on a strength to weight basis with the aluminum alloy 75ST and superior on this basis to the aluminum alloy 24ST and to stainless steel Type 301

Hydrogen in Aluminum

By Y. DARDEL

DISCUSSION

(L. D. Jaffe and D. W. Smith presiding)

R. EBORALL*—The determination of the hydrogen content of aluminum alloys is of considerable technical value, particularly in the study of casting and welding processes, and any reliable method for its determination is to be welcomed, particularly if it is simple in operation and utilizes techniques which are available in any laboratory.

Modern vacuum hot extraction methods have proved very suitable for the determination of hydrogen in aluminum,^{21,22} and not only are highly reproducible results obtained by any one laboratory but there is quite good agreement between different laboratories using very different conditions of extraction.²³ Success depends upon good vacuum tech-

nique and upon extreme care in the preparation of the surface. It is standard practice to use a surface turned without lubricant—although other methods, if standardized, may be perfectly satisfactory—and to avoid touching the surface by hand at all. Under these conditions the contribution of the surface to the quantity of hydrogen obtained is constant for all practical purposes. As an illustration of this constancy, and of the reproducibility of the method generally, it may be stated that in these laboratories duplicate hydrogen determinations, even on material as thin as 0.125 in., for which the surface correction is about 0.08 cm³ per 100 g, generally agree within 0.01 cm³ per 100 g. Ordinary commercial wrought materials in this country commonly run from 0.2 to 0.5 cm³ per 100 g of hydrogen, except for high magnesium alloys which may contain rather more, so that for ordinary hydrogen determinations the method has more than adequate accuracy.

I have made this point about accuracy at some length, because Mr. Dardel emphasizes rather strongly the errors to which the work of Ransley and myself

may have been subject from variations in "surface" gas. Nevertheless, we did not claim any particular accuracy for the determinations of solid solubility, which were of a preliminary kind and a very small part of an extensive program. In fact we said: "The results do little more than indicate the order of magnitude of the solubility, since it is so small that the errors inherent in the method become serious."* Now that a series of accurate determinations has been made by Ransley and Neufeld,²⁴ there seems no reason to be dissatisfied with our earlier preliminary results.

The validity of the hydrogen contents determined by vacuum extraction receives confirmation, if any is needed, from observations obtained with a simple method for estimating hydrogen in solid wrought metal, which has been developed by my colleague A. J. Swain.²⁵

* The method referred to consisted of holding specimens in hydrogen without prior degassing, and subsequently measuring the hydrogen content. The greatest single potential source of error, in the light of later experience, was probably the formation of voids due to some of the hydrogen originally present coming out of solution at inclusions.

* Head of General Metallurgy Section, British Non-Ferrous Metals Research Association, London, England.

²¹ References not in the paper are at the end of discussion.

The principle of this method, which should be applicable to most of the aluminum engineering alloys, is to heat a thin piece of the metal for a short time in a dichromate bath at a temperature about midway between solidus and liquidus. Blisters are formed, the volume of which is a measure of the hydrogen content. It turns out that the pressure in the blisters, calculated from the known gas contents of the materials used for calibration, is about 1.1 atm. at the test temperature. The hydrogen can thus be converted into blisters which anyone can see for himself. The same sort of thing happens in castings;^{24,26} one can measure the density and find the "percentage voids" and one can measure the hydrogen content: on the average, for sand castings, a pressure between 1 and 2 atm. in the voids is obtained.

In the discussion, contained in his penultimate section, Dardel states that the values found by methods other than his own, including the vacuum hot extraction method, are greater than those which correspond to the solubility (in the solid at the melting point and at atmospheric pressure). That is commonly so. He concludes that the bulk of the hydrogen extracted therefore necessarily comes from the surface layers. That is nonsense. Some of it does of course—for our own technique we have measured the quantity and allow for it. But in a casting gas may be present in pinholes as well as in solid solution. In wrought metal it may be present in solid solution at "internal pressures" far greater than atmospheric: the metal can, and frequently does, absorb hydrogen in the solid state by the reaction with water vapor,²¹ which has ample energy,²⁷ and, moreover, the hydrogen present in pinholes in a gassy casting may be forced into solution during hot working. There are no doubt other ways in which extra hydrogen can be accommodated.

Dardel quotes Kljatschko and others to the effect that the metal is riddled by channels, increasing its surface area, and that gas is obtained from this extra surface. I thought we had disposed of this point successfully,²⁸ and do not wish to go over the same ground again. Klyachko's ideas are contrary to classical gas-metal theory and are based upon his colloidal or micellar theory of metals which is incompatible with the generally accepted one (that is, according to Klyachko's theory a metal is not truly crystalline). Tamman and Brede-meier's results, adduced in support of Klyachko, are very extraordinary; if one is to believe them, any metal is permeable throughout to large dye molecules. Since sound metals including aluminum have no detectable permeability to inert gases including helium,^{29,30,31} I suggest that the results need not be taken too seriously. Of course, if the metal contains continuous shrinkage porosity, or severe lamination owing to cold shutting, bad extrusion

practice or the like, that is a different matter.

Incidentally the author misrepresents Ransley and myself²¹ when he heads his Table 1 "Amount of Adsorbed and Dissolved Hydrogen," and continues throughout to write of "adsorbed hydrogen"²² when referring to our work. It is true that alumina formed at low temperatures is highly adsorptive, and it may be that the alumina surface film contains adsorbed hydrogen which is subsequently extracted, but we would prefer to think (and in this we agree with Klyachko) that the "surface hydrogen" is produced on heating the specimen, by the reaction of adsorbed water with the metal.

Mr. Dardel's method for determining hydrogen contents is of great ingenuity, and has the advantage that the apparatus is extremely simple. It is not however an absolute method, since it depends in the first instance upon the solubility of hydrogen in the liquid metal, which must be determined by some other method. For this, a number of published results have been averaged. In Fig 1 of the paper, representing some of the data available, the scatter is not very obvious; however, actual results at just above the melting point of aluminum are highly discordant. At 700°C they range from 0.08 cm³ per 100 g (Röntgen and Braun) to 0.95 cm³ per 100 g (Baukloh and Oesterlen); there is thus an uncertainty represented by a factor of 12, and this must be reflected in the values for hydrogen content obtained by Dardel's method. If the results of the more recent and very careful liquid solubility determinations of Ransley and Neufeld be accepted, the highest of these figures is correct and the equation used by the author yields results over three times too low.

If the results reported in the paper are multiplied by three, they accord quite well with experience. Thus in Table 4, giving the amounts of dissolved hydrogen after casting, alloys *A* and *B*, which were directionally solidified but from gassy melts, would have hydrogen contents of 0.19 and 0.16 cm³ per 100 g respectively, whereas *C*, which contains gas porosity, would have 0.38 cm³ per 100 g. These figures are entirely reasonable.

It seems rash to assume, however, that the hydrogen contents of alloys *A* and *B* are equal to the solid solubility. There may be slight supersaturation during solidification, and bubbles of gas may be trapped by the advancing crystals; only if these effects could be proved absent could the figures be accepted as representing the solid solubility. However, to return from the results to the method itself, there is a limit above which it is impossible to measure the hydrogen content of solid metal by this method; for if the hydrogen content exceeds the solubility in the liquid at the melting point, and if Mr. Dardel's assumptions are correct, the excess will boil off during melting before the pressure reading is taken. This

may not be a very serious limitation in practice, however, since such high figures (over approximately 0.69 cm³ per 100 g²⁴ are seldom encountered.

There are also further difficulties. One concerns the nucleation of a bubble. The author attempts to show that there is no nucleation difficulty; this may be true in some instances, but the experiments reported on 99.99 pct aluminum suggest that it is not always so. We do know that, in melts of commercial alloys, primary particles of one kind or another are generally present at temperatures well above the melting point; it has been possible to concentrate them with a centrifuge so that they are readily visible under the microscope.³² With high purity alloys, or even, it may be, with ordinary alloys without certain additions or impurities, these particles may not be present, and nucleation may accordingly present an obstacle to the formation of bubbles.

Another possible source of error is the possible gain or loss of hydrogen from the surface, before the pressure reading is taken. The author assumes that the metal is protected by an impermeable alumina film. That may well be true for many alloys, but no check appears to have been made on it. For some alloys, however, particularly those with high magnesium, the assumption appears of very doubtful validity, since a magnesia film may be formed and this is not likely to have a protective effect.

In short, I think this is an interesting and potentially valuable method, but that not the slightest reliance can be placed on the figures so far reported.

I should like to see the method thoroughly tried out by making a series of estimations, but using the latest liquid solubility data,³¹ and comparing the results with those obtained on the same materials by vacuum extraction. If this is not feasible, a more direct evaluation of the possible sources of error should be made.

There is great scope for a really good method of estimating rapidly the hydrogen content of molten aluminum alloys, for foundry control purposes. The ordinary Straub-Pfeiffer reduced pressure test (the author's "vacuum sample") with the 1 mm or the pressure normally used, is as the author points out, very much too sensitive for practical purposes. For a good many years we have used this test in these laboratories with a pressure of 20–60 mm of mercury, for aluminum and magnesium base alloys; actually we recommended the use of such pressures in a report issued to our member firms in 1941. At this pressure the test gives a very useful rough measure of the hydrogen content of the melt, but does not give a quantitative result (unless density measurements are subsequently made). Dardel's method on the other hand, provided it can be established on a sound basis, is ideal for this kind of purpose. It is simple,

rapid and gives a quantitative result. The apparatus, like that for the reduced pressure test, could be made robust and easily portable, so that it could be moved around a large foundry to furnaces or casting machines, to take samples at any stage in the melting and casting process and give the answer on the spot. But that answer needs to be the correct one.

M. B. BEVER*—The author finds by the method described in this paper that solid aluminum just under the melting point dissolves 0.058 cc of hydrogen in 100 g of metal. Recently Ransley and Neufeld²⁴ published solubility data for hydrogen and aluminum that were measured by a very careful equilibrium method. These authors found a hydrogen solubility of 0.036 cc in 100 g of aluminum just below its melting point.

In place of an exhaustive critical evaluation of the method described in this paper, attention will be called only to two major factors. These factors seem of such an important nature as to transcend any conclusions drawn from a statistical analysis of the experimental results. In this connection it should be emphasized that the two factors to be discussed oppose each other and under favorable conditions may partly cancel out in the resulting value of the hydrogen content.

In the first place, a marked weakness of the method is its inability to distinguish between different gases since the assumption that aluminum evolves only hydrogen is probably less well founded than the author believes. Secondly, it is inescapable that surface tension inhibits the formation of gas bubbles as Brower and Larsen³³ have shown quantitatively for the evolution of carbon monoxide from liquid steel. The presence of nuclei reduces the inhibiting effect of surface tension but does so in an unpredictable manner which cannot be reproducible under all possible conditions. In view of uncertainties such as these it seems that results obtained by the method suggested in this paper do not lend themselves to a rigorous analysis.

C. E. RANSLEY† and N. D. G. MOUNTFORD†—We have read this paper and also Dardel's previous one,¹⁹ with some care, since the subject is one with which we are closely concerned. The method he suggests for the measurement of the hydrogen content of aluminum and aluminum alloys is simple in concept, and if capable of giving reproducible and accurate results would have attractive possibilities for foundry control work. Since the publication of this paper therefore, we have constructed an apparatus similar to that described by Dardel and have carried out some experiments to determine what relation exists between

the true hydrogen content of a bath of molten metal and the value predicted by the author's bubble-pressure method. The results we have obtained are of some interest, and we would like to take this opportunity of presenting them. We may say now that we believe that the method proposed by the author is open to some criticism on fundamental grounds, and that our experiments demonstrate this. However, we have admittedly carried out only a limited number of tests, and we would welcome any comment Mr. Dardel has to make on our interpretation of them.

Before giving these results, there is one point we would like to emphasize. The method is based upon the assumption that the first bubble is formed in the liquid metal when the external pressure is reduced until it is equal to, or perhaps a little less than, the "internal pressure" of hydrogen in the melt. The value predicted for the gas-content will thus be a direct function of the value of the solubility of hydrogen in the metal at the temperature of test. The author has taken the mean value of solubility from the early published data (ignoring, however, the results of Baukloh and Oesterlen³ and Baukloh and Redjali¹³) and has derived his equations and constructed his nomograms on the assumption that these data are reliable. They are, in fact, considerably in error, particularly at the lower temperatures, which are the most important from the practical point of view. In these Laboratories we have recently²⁴ remeasured the solubility of hydrogen in liquid aluminum by an orthodox procedure and have established values which are considerably higher than those previously accepted; since the publication of our paper we have confirmed these values by an independent method, details of which we hope to publish shortly. We find that the solubility at 700°C, for example, is 0.92 cc per 100 g, whereas the value assumed by the author for this temperature is only 0.27 cc per 100 g. In other words, the values of gas-content calculated by Mr. Dardel (assuming that the deduction is otherwise valid) are wrong by a factor of more than 3. It is quite obvious, indeed, that the gas contents he quotes, that is, those given for duralumin, in his first paper, are far too low, since they are much less than the values obtained by hot-extraction measurements; the latter are now established on a firm basis and yield results in good arithmetic agreement with porosity values. We do not want to stress this point any further in the present contribution, since we have already dealt with it in the discussion of our recent paper.²⁴ We would like to make it clear, however, that we consider the values of solid solubility deduced by Mr. Dardel to be quite without significance. It is true that they are of the right order, but that is due entirely to a fortuitous combination of

circumstances.

The bubble-pressure apparatus we have constructed is very similar to that described in the paper. The vacuum chamber is exhausted by means of a rotary oil pump and the pumping line arranged so that the pressure can be reduced at a reproducible speed, that is, to 380 mm in 15 sec and to a limiting pressure of about 5 mm in 30 sec. The temperature of the metal sample is measured by means of a thermocouple inserted into a re-entrant tube in the base of the cast-iron crucible; we have kept this at about 700°C in all the tests we have so far carried out.

We used 30 lb charges of metal melted in a gas furnace for our experiments. When commencing a bubble-pressure test, a sample of the melt was taken in a small ladle and some metal poured into the crucible in the apparatus, which was preheated to the appropriate temperature; the remainder of the metal in the ladle was then cast into a chill mold to form a sample suitable for subsequent measurement of the gas-content by hot-extraction. Two commercial grades of aluminum, 99.2 and 99.8 pct, have been investigated and the results of the various measurements are summarized in Fig 9 and 10. In these figures we have plotted the true gas contents, as determined on the chill-cast samples, against the values predicted by the bubble-pressure measurements. The predicted hydrogen content m (cc per 100 g) has been calculated from the pressure observations on the assumption that it is given by the following equation derived for our own solubility results:

$$\log_{10} m = \frac{-2760}{T} + 1.356 + \frac{1}{2} \log P_{H_2} [12]$$

where P_{H_2} is the "internal pressure" of hydrogen in the melt, which is assumed to be identical with the pressure at which the first bubble is observed.

It will be seen that the results on the 99.8 pct purity metal (Fig 9) are very widely scattered and, in fact, in 4 out of 8 experiments no visible bubble had formed at the limiting pressure of the apparatus (5 mm mercury) although the hydrogen content of the samples varied from 0.16 to 0.63 cc per 100 g. The bubble formation in this alloy was obviously very irregular and the measurement worthless as a measure of gas content. This is, however, perhaps not unexpected in view of the experience of the author with 99.99 pct purity metal, and his general observation that the accuracy of the method decreases as the metal purity increases.

The results on the 99.2 pct purity metal (Fig 10) are of some interest. Unfortunately the melts used for our experiments with this metal had only a limited range of gas contents (about 0.25 to 0.45 cc per 100 g with one exception)

* Massachusetts Institute of Technology.

FIG 9—True gas content vs. predicted gas content. 99.8 aluminum.

FIG 10—True gas content vs. predicted gas content. 99.2 aluminum.

and it is therefore difficult to draw any firm conclusions from the data obtained. It will be seen that in this case the bubble formation is not entirely random. If the one "rogue" point is ignored, there is statistically a significant correlation between the predicted gas content and the true gas content; in fact, knowing the relationship given by this curve, the true gas content of a melt could be predicted with a standard deviation of about ± 0.04 cc per 100 g, but this only holds over such a restricted range of true gas content that the measurement is of little value. The calibration curve is very flat, and in addition, the data plotted in Fig 10 suggest that no formation of bubbles can take place unless the gas content of the metal is greater than about 0.26 cc per 100 g. Further work would be necessary to confirm this, however, and we have not had time to carry out the necessary experiments.

It seems probable that the predicted gas—true gas relationship in the case of alloys such as duralumin will be of the same type as that shown in Fig 10. If so, it becomes possible to understand degassing curves of the type which the author has presented, such as that given, for example, in Fig 2 of his earlier paper,¹⁹ which purports to show a sevenfold decrease in the gas content of a duralumin-type alloy held in an electric furnace for 2 hr. If the values on this curve are corrected to a proper solubility basis, and then converted to true hydrogen contents with the aid of Fig 10 the decrease in gas content on standing then becomes from 0.31 to 0.27 cc per 100 g instead of from 0.07 to 0.01 cc per 100 g. Although this derivation involves several assumptions of uncertain validity, the result is very much of the order that one would predict from practical experience.

We do not propose to attempt a full explanation of the results we have given here. It seems very probable that the relationship between the gas content as predicted by bubble formation and the true value is very much influenced by the experimental conditions. For example, the loss of gas from the sample by diffusion during evacuation will obviously be a function of the rate of reduction of pressure. A fast rate of pumping is therefore desirable from this point of view. On the other hand, if the diffusion of hydrogen to a given point is a rate-determining factor in bubble-formation, a fairly slow rate of pressure reduction would be indicated. Mr. Dardel gives no information as to the rate used in his apparatus and we are unable to say how our conditions compare with his; we should be interested to have some details on this point. From the results of our tests, however, we conclude that although bubble formation is, as one would expect, influenced by the amount of hydrogen dissolved in the metal, there is another factor involved which makes it impossible to apply the simple theory proposed by the author. This factor is, we believe, primarily a question of the stability and surfacing of the gas nuclei which must pre-exist in the melt if bubble formation is to take place at all, and which a simple calculation shows must be of quite appreciable radius. The nature of these nuclei is not known with certainty, but they may well originate from particles of hydrated oxide, which enter the metal mainly from scrap additions. It is of some significance in this connection that in high-purity melts, which are likely to be entirely of virgin ingot material, bubbles are formed only with considerable difficulty. The author

has noted this effect in his paper but has not attempted any explanation as to its cause. But whatever the correct explanation may be, it seems clear that a complication exists which makes the proposed method of measuring gas contents of little value as a quantitative tool.

H. UDIN*—There is apparently a misprint in the paper on p. 5, bottom of the first column. This equation should read

$$4702 (dT/T^2) = 2.5 \text{ pct}$$

The method of determining solubility of a gas in solid metal by measuring the internal gas pressure in the remelted ingot is a very ingenious one. However, the assumption that the surface tension in the nucleating bubble can be neglected because it does not influence the scatter of the experimental results is not necessarily a valid one for several reasons. In the first place, it would be true only if there are relatively few artificial nuclei of widely different sizes present in the melt. However, experiments on undercooling indicate that this is not the case, particularly in metals which have not been especially treated to eliminate centers of nucleation.

If a batch of metal contains n artificial nuclei per unit volume (on the average), then, in measuring any phenomenon dependent on the size distribution of these nuclei, statistical theory indicates that, if the experiment is conducted on a unit volume, there will be a probable error of $1/\sqrt{n}$. If we have as few as one potential nucleus per cubic millimeter, n will equal 35,000 for a 100 g sample, and the probable error is 0.5 pct. This amount of

* Massachusetts Institute of Technology.

scatter would hardly be noticeable in the 5 pct scatter due to other factors. The surface tension term in the author's Eq 2 can thus have a real effect on the pressure without appreciably influencing the scatter of the experimental results.

We can also question the validity of the hypothesis of Eq 3 by drawing on well-known nucleation theory. The minimum size of nucleus which can grow into a bubble is determined by the balance of surface tension with the difference between external pressure and activity of the dissolved hydrogen. Relatively large nuclei may already be present as cavities on the surfaces of solid impurities. If the largest artificial nucleus is of the same order of size as the smallest stable nucleus in every experiment, little dispersion will be found in the determinations, but the error in the basic hypothesis behind Eq 3 may still be large.

Excessive pumping speed may also play a role in minimizing the dispersion of the results. Under these conditions the rate at which a bubble will grow to visible size under a favorable pressure differential would then be determined by the diffusion rate of hydrogen in aluminum as well as by the magnitude of the pressure drop. The difference in the times required for a bubble to grow to observable size from nuclei of even considerable size difference is undoubtedly small, since the volumes of the nuclei are negligible compared with the volumes of the observed bubbles. In this case the surface tension term can again effect the final answer without introducing any experimental dispersion.

Would Mr. Dardel please inform us as to whether his pumping speeds are low enough to permit an equilibrium bubble size to exist at all times?

Mr. Dardel also implies that the surface of the melt is covered by a film which is impervious to hydrogen loss by diffusion. Would he please tell us on what evidence he bases this opinion.

The author's technique may well prove to be of benefit to students of gases in metals. It is therefore of considerable importance that these theoretical questions be cleared up.

F. N. RHINES*—In connection with what has just been said, I think perhaps it is worthwhile to point out that all of the various methods that have been used for determining hydrogen in aluminum failed to take into account one imponderable which is the amount of hydrogen, perhaps combined as water, perhaps as hydrogen, which very likely exists in the oxide film. The critical experiment, it seems to me, that should be run by someone is to compare the apparent solubility by any one method for samples of varying ratios of volume to surface area, so as to find out whether there is a real effect of moisture dissolved

in the oxide film. We know, of course, that aluminum oxide is very efficient in capturing water vapor. It is my recollection that the method used by Ransley did not entirely eliminate the possibility of such contamination. Certainly in this case, it seems that some contamination of the oxide film is quite possible. Whether or not hydrogen from that source could turn up in the final analysis is still another question, but I think it needs to be proved one way or the other whether the oxide film can contribute to the apparent analysis.

E. A. GULBRANSEN*—I think one has to consider certain chemical reactions as sources of gases in aluminum. Let us consider the reaction of aluminum with water vapor from the vacuum system to form the oxide and hydrogen. This reaction is possible from thermodynamic considerations and the necessary water vapor is present if the degassing experiments are carried out in the vacuum of a rotary pump.

There are other reactions of this same type forming other gases. I feel that in discussing the liberation of hydrogen and other gases from metals one must consider the fact that certain chemical reactions may occur on the surface forming new gases.

Y. DARDEL (author's reply)—I should like to express my thanks to all contributors to the discussion on this paper for their interest and the care with which they have examined the results described.

Reply to Messrs. Ransley and Mountford:

The first point discussed by Messrs. Ransley and Mountford is of course the solubility of hydrogen in liquid aluminum. At the time of the experiments reported in the paper, the values of Röntgen and Braun, Röntgen and Möller, Bircumshaw as well as Winterhagen, were considered as the most reliable, for they gave approximately the same mean solubility, while the values of Baukloh and Oesterlen were far higher and those of Baukloh and Redjali intermediate. But the determination apparatus suggested being one of relative and not of absolute character the establishment of new and more accurate calibration curves can only be welcome. Therefore as the last measurements of Messrs. Ransley and Neufeld²⁴ confirm the values given formerly by Baukloh and Oesterlen it might be better to adopt these new values. However, before taking up this step it must be noted that the two sets of data (Röntgen and collaborators as well as Bircumshaw on one side, Baukloh and Oesterlen as well as Messrs. Ransley and Neufeld on the other) do not agree very well with the Borelius' law,³⁴ while intermediate values do (Fig 11). Of

course the Borelius' law is only an empirical one and any departure from it may be observed, but these differences should be pointed out.

The value of the solid solubility given in the paper depends of course upon the value adopted for the liquid solubility. When the solubility at melting temperature in liquid metal is equal to 0.17 cm^3 per 100 g, the solubility at the same temperature, but in solid metal, is equal to 0.058 cm^3 per 100 g. On the other hand, when the datum of 0.69 given by Messrs. Ransley and Neufeld is to be accepted the values of this paper give then 0.15–0.20 cm^3 per 100 g in solid metal. Besides, there may be a slight supersaturation as pointed out by Mr. Eborall and the values given might be a little too high. But if the liquid solubility at melting point is as high as 0.69 cm^3 per 100 g a solid solubility of only 0.036 seems rather low as can be shown from the value of the solubility ratio (Table 8 and Fig 11).

The solubility ratio $\frac{\text{liquid solubility}}{\text{solid solubility}}$ increases with the decrease in solid solubility at melting point, but it does not seem that the decrease occurs as quickly as pointed out by the datum of 19.

During the experiments reported here, the exact pumping speed has not been measured, but as all the authors who have contributed to this discussion have rightfully pointed out its importance, I shall explain at length the method used to choose the proper one.

The pressure is read at the moment given by the observer of the sample surface. The time elapsing between the observation of the bubble formation and the time of pressure reading (or dead time) must be of course so much the shorter as the speed of pressure diminution is higher. When the variation of pumping speed is rapid in the medium pressure range ($1 < p < 150 \text{ mmHg}$) where the measures are usually carried out, the values read at the higher pressure (and therefore with the higher speed of pumping) can be quite different from the actual ones corresponding to the time of bubble formation, while the measures made at lower pressure (and therefore with the lower speed of pumping) may scarcely differ from the actual one. The computation of such results can only lead to misinterpretation.

At the beginning of the experiments (preliminary experiments not reported in the paper), a one stage rotary pump without the gap G (Fig 3) was used; the variation of the speed of pumping varied rapidly with the pressure in the range of pressure measurements and the determinations were wrong.

For instance an Alpax (13 pct Si) was held at 750°C and its hydrogen content was determined at different temperatures between 750 and 580°C . In that way it was possible to vary the formation pressure of the bubble for a given amount

* Carnegie Institute of Technology.

* Westinghouse Research Laboratories.

FIG 11—The solubility of hydrogen in different metals.

of hydrogen, the formation pressure being so much higher as the temperature was lower.

The results are given in Fig 12. The measured hydrogen content seemed so much lower as the pressure was higher, for at high pressure the value measured was much lower than the actual one.

On the other hand, the speed of pumping must not be too low because the diffusion of hydrogen through the surface makes the appearance of the bubble more difficult.

The speed of pumping is then limited only by the dead time of the measurement.

In a commercial apparatus it would be absolutely necessary to simplify the method of pressure reading. A push button operated by the observer would cause a hand to stop, thus giving the actual pressure.

The results of Messrs. Ransley and Mountford on hydrogen determination in high purity aluminum (99.8 pct) confirm my own results (99.99). In a similar case I have written that "any hydrogen determination with an acceptable accuracy is impossible."

Regarding the results of the determination carried out on a 99.2 pct aluminum, the departure of the correlation line from a 45° straight line can be due either to an increasing error of pressure reading when the hydrogen content rises, or to a variation in the nucleation conditions.

When the hydrogen content is higher than 0.30 cm³ per 100 g (Mr. Ransley's scale), the bubble pressure apparatus

gives, for 8 measures out of 9 with exception of the "rogue point," lower values than the hot extraction process. But I have pointed out previously that an increase in the error of reading can easily occur with an increase of pressure when the speed of pumping is too rapid. The bubble pressure determinations reported in Fig 10 have been all carried out at about 700°C, therefore the pressure bubble formation increased with the hydrogen content and likewise a possible error of reading.

For hydrogen contents lower than 0.3 cm³ per 100 g nothing can be said, for in Fig 10 all these values are distributed at random; that would mean that for hydrogen contents lower than 0.30 cm³ per 100 g according to Ransley's scale and 0.090 cm³ per 100 g according to my scale, the bubble pressure apparatus could not be used. However Fig 2 and 3 of my first paper show that almost all the values are smaller than 0.090 and are not distributed at random but follow perfectly logical laws: hydrogen content increases during heating in a gas furnace

FIG 12—Variation in the determined hydrogen content, when the conditions of pumping are wrongly regulated.

and decreases during holding in a gas furnace (burners out) or in an electric furnace.

If the values of Fig 10 are not considered lower or higher than 0.3 cm³ per 100 g, but as a whole, the calculation of the correlation shows that they cannot give correct results. The application of the coefficient of correlation to the values given on Fig 2 of the paper would give a loss of only 0.04 cm³ per 100 g (Ransley's scale) or 0.012 (my own scale) by standing 2 hr in an electric furnace.

Such a small hydrogen decrease cannot be detected on the properties of an aluminum alloy (see for instance Fig 9 of the Ransley and Neufeld paper), while the effect of a 2 hr holding is well known by all aluminum foundrymen and can be very easily noted in the appearance of a vacuum sample.

Concerning the formation of a hydrogen bubble in an aluminum bath, it has been recalled in the paper that the hydrogen pressure in it was equal to

$$P_{H_2} = p_A + \frac{2n}{r}$$

and that the unobservance of the term $\frac{2n}{r}$ introduces a supplementary error which has been included in the term $\frac{df}{f}$ estimated by means of dispersion measures.

Therefore any direct comparison between bubble pressure and hot extraction measurements would be particularly welcome. Such a study would allow the analysis of the source and variation of

Table 8 . . . Value of Solubility Ratio

| Metals..... | Mn | Fe | Ni | Cu | This Paper | Al Ransley and Neufeld |

error represented by f , particularly the effect of the unobservance of $\frac{2n}{r}$ on its value.

It may be that this study would allow the estimation of the $\frac{2n}{r}$ value and through the introduction of a corrected pressure in Eq 4 more accurate results than those illustrated in Fig 5 might be obtained.

Reply to R. Eborall:

Mr. Eborall's discussion may at first seem to indicate that the determination by hot extraction of hydrogen contained in aluminum gives very accurate and indisputable results. However an examination of the papers cited by Mr. Eborall do not lead to such a conclusion. Sloman,²² whose work on hydrogen determination in steel samples is now considered a reference in all laboratories of the Continent, tried to determine the gas content of aluminum samples with an

apparatus similar to that used for steel. This author is quoted by Mr. Eborall as having given very accurate results. However, if Sloman's publication is one of the first to have cleared up the problem of gases in aluminum, the absolute values given are far from accurate in view of Ransley's work. For instance Table IV (Fig 40+) of Sloman's paper states that hydrogen in excess of that which fills voids of a porous casting is equal to 0.47–0.50–0.51. However, according to Ransley and Neufeld this value is about 0.12 cm³ per 100 g and, according to my own experiments expressed in Ransley's scale, about 0.15–0.20. The discrepancy is important. Regarding the results cited in Ref. 9, instead of discussing the difference between "adsorbed" and "surface" hydrogen—the first coming from hydrogen present in the atmosphere and adsorbed as such, while the second would come from the decomposition by heating of adsorbed water vapor—it remains that the surface correction was of the order of

the measured value and Ransley and Neufeld²⁴ could write: "Eborall and Ransley estimated the solubility in commercial aluminum at 600°C to be approximately 0.10 cm³ per 100 g, but their method involved the subtraction of a large and rather uncertain correction from their measured value"; and Ransley and Neufeld now give a value of 0.026 as solubility at 600°C.

I have recalled these values not to point out these differences, but only to make clear that a hot extraction determination remains delicate even with the most accurate apparatus and is therefore always subject to error.

The method of estimating hydrogen content by measurement of the density of an aluminum sheet after heating between liquidus and solidus is perfectly logical and is of interest to all laboratories which do not possess a hydrogen determination apparatus. It proceeds from the old qualitative method of hydrogen estimation by observation of the appearance of a sheet heated at 560°C for one hour.

The method of Mr. Swain gives the total amount of dissolved hydrogen, but can be used only with wrought material (Fig 13 and 14). Any heating of a sheet milled in as cast material leads to the formation of channels through which dissolved hydrogen escapes (Fig 15–16).

On the other hand the measurement of the density of a casting gives only the amount of gas above the limit of solubility at melting point provided that no oversaturation occurs. In fact the hydrogen content of duralumin sheet must be far lower to make sheet weldable without any defect (Fig 17).

The penultimate section on hydrogen determination by hot extraction must not be separated from the context. It has to be applied to the usual hot extraction apparatus having an accuracy of only 0.2 cm³ per 100 g.

Regarding the amount of hydrogen which can be extracted from a sample I have shown (Table 4) that hydrogen content can be higher than the solubility limit at melting point when pores are present in casting. On the other hand with commercial aluminum and duralumin I have never observed less absorption of hydrogen even by one day heating in a vapor atmosphere (and subsequent turning of the sample). Sloman's Table VII²² also could not detect any absorption of hydrogen after dipping of the samples in different solutions. Therefore if this way of gassing a sample is very common with iron, it is far from likely with aluminum.

The work of Klyachko has not been quoted to affirm that in any case aluminum is riddled by channels but only to make clear that in some cases, chiefly with castings on X ray examination, very high hydrogen content is sometimes observed. This can be explained by absorp-

tion of water vapor in microshrinkage which of course is not necessarily going throughout the metal.

The dispersion range of the liquid solubility data has already been discussed elsewhere. Therefore it will be enough to recall that the mean solubility datum given by Braun is not 0.08, but 0.24 cm³ per 100 g at 700°C, 0.08 being only one of the figures. Moreover, the dispersion range of Röntgen and Braun, Röntgen and Möller, Bircumshaw and Winterhagen is rather small. However, it may be better to adopt the new values of Ransley and Neufeld, which confirm those of Baukloh and Oesterlen. If such a step is adopted all the data reported in this paper are homogeneous to those given in Ref. 24 and can be compared to them.

The difficulties due to nucleation have already been discussed in the reply to Messrs. Ransley and Mountford and therefore will not be repeated.

I should like to point out that I agree completely with the opinion of Mr. Eborall on the respective use of an accurate hot extraction apparatus and a bubble pressure apparatus. The new hot extraction apparatus giving absolute data would be used to provide calibration curves and check the results of a bubble pressure apparatus. But while the former can be used only in a few specialized laboratories, the latter can be employed not only in any laboratory, but also on any pouring platform.

At the time the experiments were begun, this distinction could not be made since the old hot extraction apparatus had an insufficient accuracy.

Reply to M. Bever:

I think that the internal pressure of all gases except hydrogen is very small in an aluminum bath. The gases according to Sieverts' law can be dissolved only as atoms or more likely as protons and the stability of oxide and nitride shows that all dissolved oxygen and nitrogen are practically bound to metal. Only methane can also be present in the bubble, but its pressure is about 100 times smaller than that of hydrogen (Fig 4). On the other hand, the dissociation pressure of Al₂O₃, and Al N or the pressure of CO due to the reaction of oxide or carbide is extremely small and can be neglected.

The experiments of Sloman as well as those of Eborall and Ransley confirmed this point: "Hydrogen in fact, appears to be the only gaseous element which is appreciably soluble in the metal in the temperature range normally considered."

It is quite certain that surface tension inhibits the formation of the bubbles, and I have admitted that the size range of the artificial nuclei was wide open and therefore that the effect of surface tension could be reflected in the dispersion of the determinations. However, as has been very clearly pointed out by Mr. Bever, the effect of surface tension on the scatter

FIG 15—Aspect of surface of an as-cast duralumin sample after heating at 560°C for 4 days. (Machined down to 3 mm thickness.)

FIG 16—Formation of pores in cast duralumin after heating at 560°C for 4 days. (Machined down to 3 mm thickness.)

FIG 17—Relationship between the incipient melting temperature of an aluminum alloy and the maximum amount of dissolved hydrogen permissible for welding.

of the results remains small if all artificial nuclei have approximately the same size. Observations of oxides removed from an aluminum bath show that their surfaces present cavities which are not wet by the metal and which have a quite different size. However, a direct proof of the hypothesis which is the basis of Eq 3 can be made only through comparison of the results obtained by accurate hot extraction analysis and bubble pressure determination.

On the other hand I do not think that the experiments of Brower and Larsen can be opposed to the basic hypothesis as the experiments of Körber and Oelsen²⁵ show. According to these authors no formation of CO occurs when steel is melted under a silicate slag because the metal is enveloped in a hull of glassy silicate presenting no cavity acting as nuclei, while the boil starts as soon as the steel bath comes in contact with the crucible wall. An aluminum bath contains solid impurities presenting cavities and not glassy ones, therefore if the surface tension inhibits the formation of bubble, this inhibition remains small.

In fact, according to Ransley and Neufeld's determinations, the hydrogen content of an aluminum casting just free of pores varies between 0.12 and 0.18 cm³ per 100 g (Fig 9 of their paper), while the determinations of this paper (Table 4) expressed in Ransley's scale give 0.15–0.20 cm³ per 100 g. This agreement seems to offer proof that the hypothesis, which is the basis of Eq 3 can be accepted in first approximation, provided of course that the liquid solubility

given in Ref. 24 is the correct one.

No calculation of the speed of hydrogen diffusion into the bubble has been carried out, but the speed of pumping being rather low the equilibrium in the bubble size does exist at any moment.

The very low diffusion speed of hydrogen through an oxide film has been clearly shown by Ransley and Neufeld. Fig 3 of their paper confirms the old hypothesis that the gassing and degassing rate of an aluminum bath is controlled by a surface phenomenon.

Reply to F. N. Rhines:

Mr. Rhines rightfully points out the importance of the adsorbed film on the result of a gas analysis, but I think that it would be very difficult to establish whether "surface hydrogen is coming from adsorbed hydrogen or from adsorbed "water vapor." On the other hand Schmid and von Schweintz as well as Chandron and Moreau have made an extensive study of the effect due to the ratio $\frac{\text{volume}}{\text{surface}}$ of the sample. As has been shown in the paper, the sample must be turned out and as soon as the ratio $\frac{\text{volume}}{\text{surface}}$ is lower than a certain value a correction factor has to be introduced.

Reply to E. A. Gulbransen:

Mr. Gulbransen points out that certain reactions can be the source of gases in hydrogen. In fact, as I have already explained in the reply to Mr. Bever, hydrogen is the only dissolved gas able

to give bubble. On the other hand, the reaction of the water vapor of the atmosphere with the metal can occur only through the alumina film which, already impervious to hydrogen, shall be still more impervious to the diffusion of any big molecule.

Plastic Deformation Waves in Aluminum

By A. W. McREYNOLDS

DISCUSSION

(R. S. Busk presiding)

E. OROWAN*—I observed the phenomenon of jerky yielding many years ago with zinc²⁶ and cadmium single crystals. A significant point was that the jerks occurred not only when the stress was raised but also (sometimes, after a pause of many minutes during which no trace of creep was observable) at constant stress. The phenomenon may be closely linked with the inertia of the testing machine and of the specimen, although

the inertia alone cannot account for it. If, during the test, the resistance of the material to plastic deformation suddenly diminishes while the applied force remains constant, a sudden deformation follows until the yield stress has risen, by strain hardening, to the level of the applied stress (= the value of the previous "upper yield point."). When this is reached, the rate of deformation has attained a maximum value because, up to this moment, the applied force was higher than the plastic resistance of the specimen, and the difference was used for accelerating the moving parts of machine and specimen. The kinetic energy accumulated is now transformed into

plastic work by further deformation; that is, the deformation overshoots the point at which the plastic resistance equals the applied static force. When the kinetic energy has been used up, therefore, we are left with a specimen the yield stress of which is higher than the applied stress, and no further deformation can occur (apart from a little creep) until either the applied stress has been raised to the new yield stress level, or the yield stress has fallen by thermal recovery to the level of the applied stress. While this occurs, a new upper yield point can develop, for example, by precipitation.²⁶

²⁶ A. H. Cottrell and D. F. Gibbons: *Nature* (1948) **162**, 488.

* Cavendish Laboratory, Cambridge, England.
²⁶ E. Orowan: *Zitsch. f. Phys.* (1934) **89**, 634.

There is no intrinsic contradiction in the assumption that thermal softening (by the removal of internal stresses) and precipitation hardening can occur simultaneously. The hardening effect of precipitations may be overcome by a small deformation which tears away the encircling dislocations from the precipitates,²⁷ and then the softness of the material, acquired by thermal recovery, may reveal itself. In this way, the inertia of the testing machine and of the specimen may contribute essentially to the development of upper yield points during the test, not only to the size of the jerk when an upper yield point is overcome.

Jerky extension need not be connected with the propagation of a plastic wave along the specimen. I investigated this question in 1940 for Cd crystals; the work was interrupted by the war and has not been published. I stuck nearly close-packed rows of minute shiny spheres of pure tin (about $\frac{1}{1000}$ in. diam each) to single crystal wires parallel to the wire axis; the spheres were produced by dropping filings of tin into a bath of molten stearine, the top part of which was above, and the bottom part below, the melting point of tin. The single crystal with the row of tin beads was illuminated with a distant pointolite lamp, and photographed, at about $\times 20$ to $\times 50$, with a rotating drum camera; the reflections from the beads traced extremely sharp lines on the recording paper, and the record showed directly which parts of the specimen had undergone plastic deformation: every pair of beads acted as an extensometer over a gauge length of a few thousandths of an inch. The records showed that the extension jerks were localized in a very short part of the specimen where, as a rule, many consecutive jerks occurred.

The presence of an upper yield point, if this is not re-formed during the experiment, need not cause any further jerking of the deformation. We are carrying

out experiments on the propagation of Lüders bands in mild steel wires in the Cavendish Laboratory (with Mr. W. Sylwestrowicz); in these experiments, only one Lüders band arises (usually in one of the grips, unless the ends of the wire are provided with electrodeposited heads), and this spreads over the wire in a perfectly continuous way, as slowly as is required, under a practically constant load. An essential condition of this, of course, is that the testing machine and the dynamometer must be very rigid.

E. H. DIX*—We think there is a rather clear-cut correlation between the irregular yield point elongation and the tendency to form Lüders lines. In the case of aluminum alloys containing several per cent magnesium, we get quite jagged yield point elongations and also the formation of strain lines in certain articles in which the metal is stretched in some locations during forming. In the case of annealed material, a small amount of cold work by rolling, or even by running the sheet through a series of offset rolls, that is, a roller leveler, the tendency to form Lüders lines is reduced.

Another observation is in connection with the duralumin-type alloys. Immediately after quenching, while they are in the rather unstable condition, there is a marked tendency for the Lüders lines to form, and if you watch a specimen being tested in tension you see the lines running up and down the gauge length of the specimen. It is a very interesting phenomenon to watch. After a few hours of aging that tendency disappears, and certainly after a day of aging the Lüders lines are not seen, and the yield point portion of the curve is smooth and not jagged.

R. S. BUSK†—It seems to me that one of the important points in this paper is that the phenomenon of yielding and the increase in stress necessary for subsequent yielding are so uniform. Any explanation must take into account the fact

that the steps increase in a linear fashion. I wonder if simply tensile machine inertia forces would result in such a uniform step pattern.

A. W. McREYNOLDS (author's reply)—As Dr. Orowan points out, there is considerable diversity in the manner in which irregularities in the stress-strain curve occur in different materials, as illustrated by his interesting observations on cadmium, zinc, and mild steel. It seems nevertheless profitable to view the spread of deformation through the metal as propagation of a plastic wave, even though the wave extends only through a limited region, as in Orowan's observations on cadmium and the author's observations on aluminum-copper, or spreads very slowly, as in mild steel. Whatever the mechanisms of thermal softening, precipitation hardening, and others, involved it seems clear from the continuous spreading of deformation that plastic yielding of the hardened lattice does not occur uniformly over an extended region but is initiated in the small region of inhomogeneous stress at the boundary between deformed and undeformed material. Thus a complete explanation of the phenomenon must take account of stress concentrations ahead of the plastic wave in addition to such overall properties of the material as yield stress.

As both Mr. Busk and Dr. Orowan commented, inertial effects in the tensile machine and even in the specimen itself may strongly influence the discontinuous yielding phenomena. It seems likely that most of the results to be found in the literature are complicated by this factor. The soft tensile machine used in the present experiments was specifically designed, however, such that inertial effects are eliminated insofar as possible by applying tension through a coil spring to eliminate both mass and variations of load on yielding. It is believed that, as a result of this and other special precautions, the instrumental inertia effect had no significant effect on the observed irregularities in plastic yield.

Homogeneous Yielding of Carburized and Nitrided Single Iron Crystals

By A. N. HOLDEN and J. H. HOLLOMAN

DISCUSSION

(R. S. Busk presiding)

A. H. COTTRELL* and A. T.

* Dept. of Metallurgy, Birmingham Univ., England.

CHURCHMAN*—We have been making some experiments recently very similar to those reported by Messrs. Holden and Holloman. Wires of Armco iron, 0.077 in. diam. were decarburized in wet hydrogen until the yield point was

removed; they were then extended $3\frac{1}{4}$ pct and annealed at 880°C for 120 hr in dry hydrogen. This process produced large crystals which extended through the cross-section and were about $\frac{3}{4}$ in. in length. Since the length of each crystal

was thus about ten times its diameter, wires prepared in this way behaved as single crystals in tensile tests and no attempt was made to grow longer crystals. The wires were carburized by heating at 720°C for 1 hr in propane and then annealed at 680°C for 65 hr in argon. This treatment was sufficient to cause the return of a sharp yield point in polycrystalline specimens.

Before testing the crystals preliminary experiments were made to develop a method of mounting them in the testing machine; the criterion taken for a satisfactory technique was that it should permit the observation of a very sharp yield point, considerably higher than the lower yield point, on a carburized polycrystalline test-piece of the same form as the single crystal specimens. Eventually a procedure was adopted which used a 5 in. wire, the ends of which were tinned for a distance of 2 in., as a test piece. Each end was inserted to a depth of 1½ in., and soldered, in an axial hole in a ⅜ in. diam steel rod, 3 in. in length, the other end of which was attached to a shackle of the testing machine by a 5 in. piece of fine, flexible steel cable. A standard lever machine was used and the extension was measured by a screw attached to its cross-head, no extensometer or other attachment being mounted on the specimen. With this arrangement very sharp upper yield points at stresses of about 30,000 psi could be obtained consistently on polycrystalline specimens, the corresponding lower yield points occurring at about 25,000 psi.

Several single crystal specimens were tested by this method and Fig 15 shows typical results obtained. No yield point was observed on hydrogen treated specimens and extensive plastic flow began at a stress of about 4500 psi, in agreement with Holden and Holloman's results; furthermore, no yield point was developed by unloading overstrained specimens and aging them at 100°C for a few hours (curves 3, 5 and 7).

The carburized crystals, on the other hand, showed yield points. Fig 1 shows an example of this, together with the effect of overstrain in removing the yield point (curves 2, 4, 6, 8 and 10 were taken immediately after unloading) and the return of the yield point at a higher stress level on strain aging (curves 3, 5, 7 and 9 were taken after aging the unloaded specimen at 100°C for a few hours). The lower yield point is first observed at a stress of about 7500 psi, but a clearly marked upper yield point does not appear until the yield point has been raised, by strain aging, to about 15,000 psi.

While these experiments have shown the existence of inhomogeneous yielding in carburized iron crystals, they raise several questions, quite apart from the fact that they give a different result from that of Holden and Holloman's experiments. For example, why is the yield

point so small at first, compared with that of a polycrystalline specimen, and why does the upper yield point only appear after strain aging? To help answer these questions, we are at present examining the effects on the yield point of such factors as, for example, the depth of penetration of the carburized region or the condition of the surface of the specimen.

L. D. JAFFE*—It is very gratifying to be able to deduce from these new experiments that the old idea that the yield point in steels is associated with the grain boundaries, is apparently correct. It is not so gratifying, however, if we try to draw some general conclusions about the nature of the yield point phenomenon, when we remember that in brasses the yield point does appear in single crystals, and perhaps more so in single crystals than in polycrystalline material. That is unfortunate, because we would like to have similar explanations for similar phenomena. Would Mr. Holden give us any ideas he may have as to why this difference exists between behavior in brass and steel?

A. N. HOLDEN (authors' reply)—The yield point has been observed of course in single crystals of materials other than iron. For many years the yield point has been known to occur in cadmium and zinc crystals. I believe in these cases it was observed only as a consequence of strain aging. Cottrell and Gibbons¹¹ found that nitrogen was a necessary impurity in the case of cadmium.

Unfortunately I have no ready explanation for the phenomenon Mr. Jaffe described concerning yield points in brass crystals.

E. OROWAN†—The authors have performed an experiment of great importance to the theory of the yield phenomenon in steel. As far as I know, Dr. Cottrell and his collaborators in Birmingham, England, have been working on the same experimental problem for the last year or two, and it will be interesting to compare their results with the present ones.

With the experiments of Holden and Holloman, the situation in the theory of the yield phenomenon has become particularly interesting. With steel, the phenomenon occurs only in a sufficiently fine-grained polycrystalline material; with zinc and cadmium, only in single crystals.¹² It seems fairly clear why it is not observed in polycrystalline zinc or cadmium. Having only one set of easy slip planes, the grains of these metals cannot conform easily with the deformations of

the neighboring grains, so that the yield stress of the polycrystalline material is many times higher than that of a single crystal of average orientation. Since the upper yield point of Zn or Cd crystals is never more than 30 to 50 pct higher than the lower yield point, it cannot be observed in a polycrystalline metal which does not yield in any case before the average yield stress of the individual grains is exceeded by several hundred per cent.

It seems that there are (or, there had been before the experiments of the authors) three survivors among the numerous theories of the yield phenomenon. The oldest among these is the hypothesis that there is a thin film of cementite at the grain boundaries which breaks when the upper yield point is reached (Ludwik, Nádaí, and Kuroda). Edwards, Phillips and Liu¹³ abandoned this view when they observed that the yield phenomenon occurred in several nonferrous alloys only after a slight preliminary straining followed by annealing. In place of the cementite boundary layer hypothesis, Edwards, Phillips and Liu introduced the assumption that the yield phenomenon was due to a precipitation along the active slip planes.

In Cottrell's view,³ invisibly thin films of cementite could not account for the high values of the upper yield point observed in steel. He attributes the yield phenomenon to the accumulation of carbon atoms on the tensile side of dislocations where the atomic lattice is expanded; this process would reduce the energy of the dislocation, and an additional stress would be necessary to tear it away from its carbon atoms. If this is the cause of the yield phenomenon, single crystals ought to show it equally well; in fact, for the reason I have mentioned in connection with zinc and cadmium, they ought to show it rather better than polycrystalline material.

At first sight, it would seem that there is very little difference between the slip plane precipitation hypothesis of Edwards, Phillips and Liu, and the hypothesis of Cottrell; in reality, the difference is very significant. Of course, the particles precipitated in operative slip planes must have been nucleated at dislocations, for the presence of these is the only thing that makes an operative slip plane differ from plastically undistorted parts of the crystal. With this, however, the common ground of the two hypotheses ends. Cottrell assumes that a perfect crystal would be very hard; only the presence of dislocations makes it relatively soft, and it must become harder if the dislocations are made less effective by being clogged with carbon atoms. On the other hand, the slip plane precipitation hypothesis assumes that the "softest" individual slip planes in the

FIG 15—Load elongation curves showing the yielding behavior of carburized and decarburized iron crystals.

material, on which slip starts first, are subsequently immobilized by local precipitation hardening. The hypothesis of the clogged dislocations cannot be applied whenever prestraining is necessary for the development of the yield point; in an annealed material, there should be either no dislocations present, or only a few clogged ones, and in either case there should be an upper yield point. On the other hand, it is not easy to see how the slip plane precipitation hypothesis could explain the yield phenomenon in annealed (unstrained) materials.

Both the hypothesis of the clogged dislocations and that of slip plane precipitation might seem to face difficulties in explaining the grain size effect. It appears, however, that an explanation on this basis is not quite out of the question. In a polycrystalline metal, the interference of the neighboring grains may reduce the planes of easy slip to a small number which can be immobilized by precipitation; in a single crystal there may be numerous almost equally favorable slip planes, and even if many of these are immobilized, there are still many left on which slip may start at a not much higher stress. In this way, the slip plane precipitation hypothesis might lead to a certain grain size effect. This possibility does not exist for the hypothesis of the clogged dislocations; a grain size effect could arise here only if the important dislocations are at the grain boundaries. Since the yield phenomenon in steel needs no prestrain to arise, these dislocations must be the ones determined by the geometry of the lattice misfit between the neighboring grains, and the hypothesis is then reduced to what amounts to a re-interpretation of the boundary cementite hypothesis.

The conclusion seems to be that the cause of the yield phenomenon in steel is probably different from that in zinc, cadmium, or silver. In the latter cases, the slip plane precipitation hypothesis is very plausible; in the case of steel, the effect is probably due mainly to the resistance of the grain boundaries to slip being increased by some precipitation, in the manner expressed crudely by the

cementite film hypothesis.

A. N. HOLDEN—I wish to thank Dr. Orowan for indicating the importance of those experiments to the theory of the mechanical behavior of metals. His remarks indicate the need for a thorough experimental attack on the problem of strain aging of single crystals.

A. N. HOLDEN and J. H. HOLLOMON—The experiments of Cottrell and Churchman are very interesting, since the explanation of the yield point by Cottrell³ was somewhat embarrassed by the failure of our carburized or nitrided crystals to yield discontinuously. The unfortunate circumstance of a difference in the results of Cottrell and Churchman and the authors now exists. Furthermore, in an as yet unpublished paper,* Schwartzbart and Low have observed a horizontal portion of about 0.2 pct in extent in the stress-strain curve of single crystals of iron upon initial yielding.

This discrepancy might be explained in several ways:

1. An unlikely source of the discrepancy is the aluminum content of our crystals (an element absent or low in Armco iron). Aluminum might be expected to affect the results of nitriding, but should have no effect upon the carburized specimens. Still another material, a silicon-killed steel, was used in making the crystals tested by Schwartzbart and Low.

2. Perhaps the fine wires employed by Cottrell and Churchman were strained before testing (deformation of the wires would be difficult to prevent in handling), and even the initial yielding of their crystals arose from strain-aging.

3. The difference in the heat treat-

* Unpublished at the time of AIME San Francisco Meeting, Feb. 1949.

FIG 16—Strain aging of a carburized iron crystal.

ments accorded the crystals in the several experiments might lead to the different results. It is quite possible that the rate of cooling from the homogenizing temperature could affect the results. For instance, rapid cooling might introduce quenching strains allowing the crystal to strain-age prior to testing.

4. It is also a possibility that the authors (Holden and Hollomon) did not align their crystals as accurately as necessary for specimens of the shape used in the experiments. Alignment of these specimens is a serious and difficult problem, particularly if the initial yield point elongation is very small. It must be admitted, however, that with a yield point elongation of 0.2 pct such as Cottrell and Churchman observe, the misalignment would have to cause differences of this amount in strain on the two sides of a crystal to obscure the effect. The authors feel that they achieved sufficient alignment to reveal a 0.2 pct yield point elongation, but they are continuing to direct their efforts toward the development of better means of axial loading.

5. No doubt Cottrell and Churchman have considered the consequences of carburizing so close to the critical temperature. After 1 hr at 720°C in a propane atmosphere their crystals would undoubtedly be saturated with carbon. During this treatment any accidental temperature fluctuation to approximately 725°C would result in the formation of polycrystals.

Cottrell and Churchman have shown that carburized iron crystals will undoubtedly strain-age. This information will be a valuable aid in understanding the yield point phenomenon.

Since this paper was written, many experiments have been conducted by the

authors on the strain-aging of iron crystals made of carburized aluminum-killed steel. It is of interest to compare the results of one such experiment with those

of Cottrell and Churchman. Fig 16 shows the yielding of a carburized crystal. Initially there was no sign of a yield point or discontinuity. After straining

0.18 pct, unloading, aging 15 hr at room temperature, and re-straining, a definite upper yield point was observed, together with some 0.1 pct yield point elongation.

Temper Brittleness of Plain Carbon Steels

By L. D. JAFFE and D. C. BUFFUM

DISCUSSION

(R. E. Leiler presiding)

M. G. CORSON*—The low temperature brittleness of carbon steels rapidly progresses with the increase in the carbon content. The presence of nickel greatly counteracts that brittleness. For this reason a comparison of a high nickel, low chromium steel of 0.39 pct carbon content to a carbon steel of 0.47 pct C is not warranted.

Having committed this error the authors ought to present at least a table of characteristics in the static test to show that the two steels were essentially identical.

Rockwell C values of 18–19 are rather meaningless. Brinell or Rockwell B figures should have been given.

The authors succeeded only in proving that a 0.47 pct C steel of unknown characteristics tempered at 675°C for a very short period after being water-quenched (this introduces irreparable amounts of brittleness anyway) was *sharply* brittle at about -60°C ; while an alloy steel containing less carbon and quite a lot of nickel was *not so sharply* brittle in the same range.

It might have been much more to the point if the authors had examined the relative brittleness of steels of the same carbon content, one without and another with a substantial amount of chromium, but just the needed amount of Mn (0.8 pct is much too much for a plain carbon steel). Then both steels should be oil quenched and tempered at a moderate temperature (about 400°C) followed by testing at room temperature, because it is fundamentally the brittleness of troostitic steels under normal conditions that causes misgivings.

Furthermore: Half size impact test-bars should be used only in such cases where the finished piece is very small in its cross-dimensions. It is almost a foregone conclusion that full-size test bars would have shown a rather different behavior.

L. D. JAFFE and D. C. BUFFUM (authors' reply)—It is always interesting to get a discussion from Mr. Corson. We will cover a few of the points he has raised. We were not aware that the presence of nickel counteracts temper brittleness in any sense. It has always been felt that there are considerable data indicating that nickel increases temper brittleness. With respect to manganese, the manganese contents were the same in the two steels, and they were within the specified limits for those particular S.A.E. steels.

Mr. Corson would like us to have used troostitic steels and test at room temperature. We explained in the paper why martensitic steels were desirable and why it is necessary to test over a range of temperatures. We also explained that half-size test bars had to be used in order to get martensite. A comparison was made of the behavior of those small size bars with that of full-sized bars, and the results are about to be published.¹⁴

J. K. Y. HUM*—We can substantiate the results Mr. Jaffe has given on using half-size sharp bars, except our steel was an SAE 1055 steel. We achieved comparable results with his with 1040, however there is a little question about this reduced toughness of plain carbon steels. At U. C. we investigated temper brittleness by the effect of alloy elements on high purity steels. We found that with plain carbon steels of high purity (without all the usual impurities that occur in the plain carbon steels), we got a decidedly greater toughness than normally occurs with commercial plain carbon steels. Regarding the effect of alloying elements changing the transition temperature, this is quite true with one exception, which is manganese. We found small amounts have a tendency to shift to a higher shifting temperature. There might be a qualifying statement to the alloying element in regard to manganese.

That has a tendency to put a question mark on what happens to the embrittled curve.

In regard to other elements, we have done a reasonable amount of work with carbon chrome steels. We found that there is a certain amount of chrome necessary before the steel shows temper brittleness. Normally with steels up to and including 3 pct chrome temper brittleness is not evident. With over 3 pct it becomes quite temper brittle.

L. D. JAFFE and D. C. BUFFUM—We interpreted Mr. Hum's last remark to mean that in the lower chromium steels with no other alloys present there was no appreciable difference in transition temperature between the specimens slow cooled and those quenched from the draw. This, of course, may not necessarily prove that the steels are not susceptible to temper brittleness. They may have been embrittled in both conditions.

J. K. Y. HUM—That was a full-sized bar. It was not until we changed over to the half-size that we discovered the embrittlement you observed.

E. OROWAN*—In the Cavendish Laboratory, Dr. J. Nutting has studied temper brittleness by making aluminum pressings from the surfaces of fracture and examining the aluminum oxide film replicas obtained from these by the electron microscope. In all cases of true temper brittleness, the fracture was substantially intergranular, while the ordinary "notch-brittle" fracture of steel is substantially intracrystalline (cleavage fracture). If Dr. Nutting's results can be generalized, temper-brittleness is due to a lowering of intergranular cohesion, probably by some precipitation. A polycrystalline metal has, in principle, two brittle strengths: one for intergranular, and another for intracrystalline fracture. Typical temper brittleness appears when the intergranular strength drops below the intracrystalline one. A certain treatment of the material may produce brittle fracture by reducing either the inter-

* Univ. of California, Berkeley, Calif.

* Cavendish Laboratory, Cambridge, England.

granular strength, or the cleavage strength of the grains. Only in the first case are we entitled to speak of temper brittleness in the usual sense of the word. I should like to ask Mr. Jaffe, therefore, whether he and Mr. Buffum have studied the nature of the fractures microscopically or electron-microscopically in order to recognize whether the fracture was mainly intergranular or mainly intracrystalline.

L. D. JAFFE and D. C. BUFFUM—We are most interested to hear of the Cambridge electron-microscope results, which are in accord with findings of the optical-microscope.^{15,16} Miss M. R. Norton at our laboratory has also been using the optical microscope in studying the path of fracture in temper brittle steels broken at temperatures below the transition range. She has not observed as clear-cut a distinction as Dr. Orowan indicates. The embrittled specimens had primarily an intergranular fracture but there was a considerable percentage of transgranular fracture. This was often somewhat rough, suggesting that a certain amount of local deformation occurred even though the fractures appeared brittle macroscopically and absorbed little energy. In the nonembrittled specimens very little of the fracture was along grain boundaries. These transcrystalline breaks appeared to be partly by cleavage and partly with local deformation.

In response to Dr. Orowan's last question, preliminary examination of the plain carbon steel fractures has been made by Miss Norton. The fracture path appeared to be predominantly intergranular on specimens which had been embrittled either by slow cooling or isothermally. Fracture in the unembrittled specimen was chiefly transgranular. Observations of the nature of the fractures

thus support the hypothesis outlined in the paper.

J. MALTZ*—The two hypotheses described by the authors are not the only possibilities. It may simply be that the plain carbon steels are inherently less tough than alloy steels—that is, have higher transition temperatures in the absence of any embrittlement reaction.

This third hypothesis can lead to predictions (3) and (4) and reject predictions (1) and (2) just as well as the more complex one advanced by the authors. Nor is it unreasonable. Small alloy additions increase the inherent strength of ferrite, so why not the inherent toughness?

If we compare Hollomon's data⁶ for a plain carbon steel (0.39 pct C, 0.85 pct Mn), water quenched, with the data of Archer, Briggs, and Loeb¹⁷ for a chromium-molybdenum steel (0.39 pct C, 0.65 pct Mn, 0.57 pct Cr, 0.15 pct Mo) sensitized for 10 hr at 1025°F and furnace cooled, we find that the carbon steel has the higher transformation temperature. According to the authors' hypothesis, then, the plain carbon steel has more nearly completed the embrittlement reaction than has the chromium-molybdenum steel—though the time at reaction temperature was smaller by a factor of many thousand. It would be surprising if so small an alloy addition had so great a retarding effect on any reaction.

The slight differences which the authors report in an SAE 1045 steel, before and after embrittling treatments, may be caused by the relatively high manganese content, 0.81 pct. Previously published work¹⁷ indicates that carbon steels do not show such differences if the manganese content is below 0.60 pct.

L. D. JAFFE and D. C. BUFFUM—It is true that small alloy additions increase the strength of ferrite. The reason is well understood: foreign atoms in solid solu-

tion within a lattice make slip more difficult. There are no theoretical basis and no experimental data to support the belief that alloys would make ferrite tougher. On the contrary, their strengthening effect would itself be expected to make the material less tough.

The data of Hollomon⁶ cited by Mr. Maltz refer to a plain carbon steel air-cooled from the austenitizing temperature, whose microstructure would consist of tempered pearlite and primary ferrite. The data of Archer, Briggs, and Loeb¹⁷ concern a fully-hardened alloy steel, whose microstructure would consist of tempered martensite. It is well known that pearlite-ferrite mixtures have much higher transition temperatures than tempered martensites¹⁸ (other things being equal), so Mr. Maltz's comparison throws no light upon the temper brittleness of the steels. It may be noted, however, that moderate additions of molybdenum do retard one reaction—the transformation of austenite to pearlite and proeutectoid ferrite—by at least a factor of a thousand.¹⁹

We agree with Mr. Maltz that the slight differences in the SAE 1045 before and after embrittling treatments may be caused by the relatively high manganese contents.

Before closing we should like to mention a discussion that was submitted to us through private correspondence by the late Mr. Ernest Teichert of Pennsylvania State College. Mr. Teichert asked about the effects of longer embrittlement treatment. If our theory is correct, he pointed out, the carbon steel should show no additional embrittlement. As a result of this suggestion we have given the plain carbon steel a treatment of 500 hr at 455°C. The transition temperature was the same as for the 50 hr treatment.

Some Factors Affecting the Rate of Grain Growth in Metals

By J. E. BURKE

DISCUSSION

(S. E. Maddigan presiding)

S. E. MADDIGAN*—Dr. Orowan

* Industrial and Scientific Research Council, Univ. of British Columbia.

made the remark that in the field of cold-working of metals there was still room for a great deal of work, and he estimated it would be at least two decades before the subject became a finished article. I think in the field of recrystallization and grain growth, while it may not take two

decades, there are still a great many questions to be answered, and it is extremely fortunate that since the war there have been several groups in this country able to devote attention to a continuous study of such fundamental problems. The present paper for instance

FIG 21—A time lapse micrograph illustrating a small grain in the plane of polish absorbing its larger neighbors.

The boundary migration of the small center grain is in a direction opposite that of the center of curvature of the migrating boundary.

is one of a series devoted to answering some of the questions connected with grain growth.

G. W. WENSCH*—It is readily apparent to those of us interested in the coalescence behavior of metals, that this paper is an excellent contribution to the literature. Furthermore, due to the fine control measures used in the experimental technique, the previous divergences existing between the data of Walker⁴ and Beck³ can be explained.

In observing many micrographs illustrating grain growth in metals it appeared that Harker and Parker's⁹ hypothesis was correct in that boundary migration moved in a direction toward the center of curvature of the migrating boundary. However in Carpenter and Elam's¹⁶ study on grain growth in antimony-tin alloys it was found that the migrating boundary can move in a direction opposite to that of its center of curvature as shown by Fig 21.

Since the existing theories do not satisfactorily explain the anomalous behavior cited above, could the author be induced to comment on this apparent oddity? Can the author now justify the use of Eq 3 as a basis for his derivation of Eq 7?

C. G. DUNN†—I would like to con-

gratulate the author for his beautiful piece of work on the source of energy, the driving force for grain growth. Regarding the source of energy, I might comment on the question just raised by Mr. Wensch in connection with the work of Carpenter and Elam. Their material was in a strained state, I believe. The picture is entirely different if the metal is strained for a boundary may then move away from its center of curvature. The process may still be of the nature of grain growth. Dr. Burke did some work himself showing that grain growth can occur in material slightly strained, and in cases of that type, the strain energy in the crystals adds to the driving force.

The type of grain growth considered in the present work was clearly stated in the text. Some comments on this subject, however, may be worth making. There are two types of grain growth. First there is normal grain growth, or continuous grain growth according to Professor Beck. The thickness of the sample is a limiting factor with normal grain growth. The second type is usually referred to as exaggerated grain growth, but Professor Beck calls this discontinuous grain growth. As Dr. Burke points out in the paper, the effect of sample thickness is different for exaggerated grain growth; the final grain size is entirely independent of the thickness of the material.

I would like to discuss the picture that Dr. Parker presented on the 120° angles because it is based implicitly on the assumption that the driving force or surface tension is a constant and is independent of relative orientation. Surface

tension, I believe, clearly depends on difference in orientation of adjacent grains. Data have been obtained showing that angles can depart quite far from the 120° value.¹⁷ Such variations complicate the geometrical picture a little, but I would agree with the author and Dr. Parker that the geometry is a very important factor in grain growth processes. I would question the 120° angle, however, as being particularly important. I think the 120° angle may be a sort of average value which may be seen more often than any other angle, but it is somewhat of a coincidence when only 120° angles are obtained.

E. A. GULBRANSEN*—I am concerned about the interpretation of the activation energy in Eq 2 and 8. It would be an advantage to relate the energy of activation found for the rate of grain growth to a diffusion process. If this could be done H would have a physical meaning and the value could be compared to values of H obtained from other experiments. The value obtained for H , namely, 60,000 cal per mol appears very large for a diffusion mechanism.

P. A. BECK†—The suggestion that the various structural changes occurring in cold worked metals upon annealing are the result of the surface energy associated with the internal surfaces appears to have been first clearly formulated by G. Tammann in 1912.¹⁸ As originally proposed, this theory was supposed to apply to both processes which usually take place under such circumstances, namely recrystallization and grain growth. Bengough and Hudson¹⁹ noted as early as 1910 that recrystallization may lead to grain refinement. The subsequent studies of Chappell²⁰ on iron and of Mathewson and Phillips²¹ on brass definitely proved that in the first stages of recrystallization after severe deformation, numerous small new grains are formed within each one of the deformed original grains. Mathewson and Phillips clearly realized that the "disintegration" of each deformed grain into numerous smaller ones during recrystallization is tantamount to an increase in the grain boundary surface energy, and that this energy increase must be supplied by that part of the strain energy absorbed by the metal during deformation. A detailed and lucid discussion of the energetics of recrystallization and of grain growth was given by H. Althertum in 1922,²² who carefully differentiated between these two processes, and correctly identified the driving force of grain growth (in contrast to that

† University of Notre Dame.

of recrystallization) as the surface energy connected with the grain boundaries. His views had been accepted by most research workers for a number of years, without much further investigation of the details of the grain growth process.

It was Harker and Parker's accomplishment^{22a} to give a more detailed picture of the mechanism of grain growth in terms of movements of individual grain boundary surfaces and vertices, as described in the present paper by Burke. Recently C. S. Smith^{22b} elaborated upon Harker and Parker's proposal and contributed important refinements to the theory. Burke's experiment with partially melted brass may be considered as the first direct proof of Harker and Parker's ideas. The old and familiar concept that small crystals, surrounded by the mother liquor, are unstable in the presence of larger crystals of the same species, will have to be discarded if the basic features of the Harker-Parker theory are correct. If both the small and the large crystals are idiomorphic, according to this theory the atoms at their corresponding crystal faces should be in equally stable positions. Even though the total surface energy would decrease with an increase in the crystal size, according to the theory discussed no mechanism is available to accomplish such a change. The system may remain indefinitely in a state which is stable with respect to other immediately attainable states. Considering the critical importance of this experiment, one would like to see it repeated and confirmed by experiments involving annealing times longer than 6 min., and also with materials other than metals.

In their original paper, Harker and Parker made the additional assumption that polycrystalline metals, when annealed, will actually attain a grain boundary configuration stable in the above sense. From this assumption they derived the conclusion that, when a polycrystalline metal is annealed, grain growth eventually stops, as the stable grain boundary configuration is reached. Subsequent experimental work with high purity aluminum and with some high purity solid solutions² failed to confirm the cessation of grain growth in the postulated manner. In the present paper Burke shows that it is possible to accept the Harker-Parker mechanism of grain growth without the necessity of also accepting the assumption that a stable boundary configuration would be actually reached in the course of grain growth. As a matter of fact, experiments by C. S. Smith with soap foams, as well as the above mentioned results with high purity aluminum, indicate that the unstable boundary configuration is self-perpetuating. The stoppage of grain growth postulated by Harker and Parker may be considered very unlikely.

There are, however, other causes which may bring grain growth to a halt. The

stoppage of grain growth by a dispersed second phase was observed long ago; it was first clearly described in 1916 by Z. Jeffries.²³ A great number of investigations dealt with the subject later. In recent isothermal studies at this Laboratory,²⁴ conditions were investigated under which an initial period of grain growth is followed by stoppage of grain growth as a result of the presence of a dispersed second phase in Al-Mn alloys. The stoppage of grain growth in commercial brass, observed by Walker, was confirmed and interpreted²⁵ in the light of these results as a second-phase effect. Burke's interpretation, in the present paper, of the inhibition effect found by Walker is in complete agreement with the interpretation referred to above.^{24,25} An increase in the number of second phase particles increases the inhibiting effect which can then successfully oppose a higher level of "growth force"; consequently, grain growth stops at a smaller grain size.²⁴ The extreme sensitivity of the rate of growth, when the grain size is large, to even the smallest amounts of a second phase is clearly shown by the inhibition effects Burke found in high purity brass. Zener's interpretation as described in Burke's paper, of the inhibition by second phase particles as a surface tension effect is a notable contribution to the understanding of these phenomena.

That grain growth will cease, even in the absence of a second phase, when the grain size becomes commensurate with the specimen thickness, was shown for high purity aluminum.²² The inhibition effect discussed above is, of course, by no means in contradiction with this specimen thickness effect. The two effects may occur independently in the same material, or they may overlap, according to the conditions. This is clearly shown by the data contained in Burke's Table 4. Under the heading "Equilibrium Grain Size"* the table gives the grain size values ultimately reached at various temperatures, with specimens of commercial brass of various thicknesses. If these ultimate grain size values are plotted for each temperature as a function of the specimen thickness (Fig 22), it becomes clear that, when the specimen thickness is very small, the ultimate grain size follows the straight line corresponding to the specimen thickness effect. Thus, in commercial brass, up to a specimen thickness of approximately 0.1 mm, where the grain size is limited solely by the specimen thickness, at 700 to 850°C the ultimate grain size is independent of the annealing temperature. On the other hand, at very large specimen thicknesses, the ultimate

grain size is practically independent of the specimen thickness, but it is determined instead, by the inhibiting effect of the dispersed second phase. Under such conditions the ultimate grain size is strongly temperature-dependent. The data also indicate that between these two ranges there is considerable overlapping, so that in the intermediate range of specimen thicknesses both the specimen thickness and the inhibition by a second phase have some effect on the ultimate grain size. J. Towers Jr. at this laboratory observed similar behavior in high purity brass, except that for this material the thickness range in which the grain size is determined solely by the specimen thickness, is considerably larger. The effect of inhibition on the ultimate grain size at 800°C is not felt until a grain size of about 0.6 mm is reached.

The empirical formula Eq 7, proposed by Burke, does give a vanishing rate of growth when the grain size approaches its ultimate value, as is evident from the differential form, Eq 6. However, this formula suffers from two important disadvantages. First, it does not fit the facts and, secondly, it is not consistent within itself. As seen in Fig 23, where the dotted curves represent values computed from Eq 7, at both 700 and 800°C, there are rather large deviations between the grain sizes experimentally determined by Dr. Burke, and the calculated curves. The nature of the trouble is clear if one considers that the logarithmic expression in Eq 7 gives a gradual, asymptotic, approach to the ultimate grain size, which is only reached after an infinite time of annealing. The data obtained by Burke for 800°C are in accord with similar data obtained at this laboratory with Al-Mn alloys, in that the ultimate grain size is reached after a finite period of annealing. During a considerable part of this period the grain size increases according to the simple power law $D = K \cdot t^n$. After the period of initial grain growth, the grain size remains constant for long periods of further annealing, within the experimental accuracy of grain size determination. There appears to be in most cases only a relatively short interval of decreasing slope between the ascending and the horizontal straight line portions of the logarithmic grain growth lines (Fig 23). This rather sharp break in the curve, which is also shown by Burke's own experimental data in Fig 20, is not reproduced by his formula. The second objection to this formula is that it necessarily leads to a slope of 0.5 for grain sizes small in comparison with the ultimate grain size. (In order to make the initial slope apparent in the graph, the zero point of the time scale must be chosen to correspond with zero grain size.) As known from earlier work with high purity aluminum²² and also from the present data on high purity brass, a slope of 0.5 is approached only with very high purity

* In the physical sciences equilibrium designates states to which the system tends to return, when disturbed. In the present case the grain size will obviously not tend to return to the so-called "equilibrium grain size" if, by some means, a slightly larger grain size was reached. The term "ultimate grain size" had been proposed by Dean and Hudson,²⁶ in 1924; there does not appear to be any reason for changing this nomenclature.

FIG 22—Ultimate grain size, D_n as a function of specimen thickness, for 70-30 brass of commercial purity, from data by J. E. Burke.

metals and solid solutions. In the presence of even small amounts of impurities forming a second phase, as in commercial brass, the initial slope becomes much smaller than 0.5. While the formula does, as intended, take into account the stoppage of grain growth after prolonged annealing periods as a result of a second phase, it represents the conditions during the period of initial grain growth as if no second phase particles were present. It is possible to devise empirical formulas, like the following one, which give considerably better approximation to the experimentally observed facts than Eq 7.

$$\log D = n \cdot \log t - C \cdot t^m + K \quad [9]$$

where n is the initial slope in accordance with the experimental data, parameters m and C are determined by the annealing time necessary to reach the ultimate grain size, and by the value of the ultimate grain size. The parameter K fixes the position of the initial ascending part of the grain growth line. This formula has the advantage of conforming to the simple power law to any extent required by the data. It has just the right number of parameters necessary to fit the data, and it reproduces the stoppage of grain growth after a finite time of annealing. Furthermore, the agreement is greatly improved by accepting the experimental fact that the ultimate grain size is temperature dependent, as discussed above. Fig 23 shows that the solid curves, calculated from Eq 9, fit Burke's experimental data for high purity brass at 700 and 800°C, considerably better than the formula proposed by him. In discussing his Eq 7, Burke introduces Eq 8 for the temperature dependence of his parameter K . However, he neglects the fact that D_f also varies with the temperature.

FIG 23—Comparison of grain growth data by J. E. Burke for high purity 70-30 brass with curves calculated from Burke's Eq 7 (dotted lines), and with curves calculated from Eq 9 (solid lines).

In earlier publications^{26,27} Burke proposed the following formula to take into account the initial grain size:

$$D - D_0 = K \cdot t^n$$

It has been shown⁸ that this formula does not fit the data for either high purity aluminum or for brass. It is gratifying to note that in his present paper, Dr. Burke finally abandoned this formula and that he now uses the method proposed earlier in the work on aluminum,²² to account for variations in the initial grain size.

It is a remarkable fact, discovered by Burke, that the slope of the logarithmic grain growth lines for high purity brass closely approximates the value of 0.5 over a rather wide temperature range. This value was previously derived²² for high purity metals regardless of temperature. But in experiments with high purity aluminum the slope was found to increase with the temperature, and the theoretical value of 0.5 was approached only by extrapolation to the melting point. It was observed, however, that with high purity Al-Mg solid solutions n approaches the theoretical value of 0.5 at a lower temperature and then remains almost constant near that value.²⁹ The temperature range, within which n is nearly 0.5 increases with increasing Mg content. It may be that Cu-Zn solid solutions behave similarly. If so, one might

expect that at relatively low temperatures the grain growth line for high purity brass containing lower amounts of zinc, such as 5 or 10 pct, would have a temperature dependent slope, lower than 0.5, but that, beginning with a certain temperature, the slope would approximate 0.5, and become independent of temperature. This temperature would then decrease with increasing Zn content, until it would fall below 500 or 450°C for 70-30 brass.

Burke gives a heat of activation value for grain growth in high purity brass (40 K cal per g atom), which is considerably lower than the value previously found by Burke and confirmed at this laboratory for commercial brass (60 K cal per g atom) in the range between 450 and 700°C. In the course of work with high purity brass done by John Towers, Jr. at this laboratory, using laborious and very careful grain counting techniques and a larger number of specimens, a value distinctly higher than that reported by Burke, namely 49.8 K cal per g atom, was obtained. When Dr. Burke's data were used to calculate a heat of activation from the time to reach a grain size of 0.1 mm, it was found by Mr. Towers that a value of approximately 46.5 K cal per g atom fits the data best. This is in better agreement with the above value, calculated by Towers from his own data, than the 40 K cal per g atom value given by Burke.

J. E. BURKE (author's reply)—In reply to Mr. Wensch, I believe the apparent migration of a boundary away from its center of curvature can be explained. C. S. Smith has pointed out that a surface may be curved about two axes at right angles to each other so that the net curvature at any point on the surface is zero. The surface is thus equivalent to a plane and will have no tendency to migrate. A plane will intersect such a surface in a curved line, however. Thus, on a plane polished surface of a metal specimen, it would be impossible to differentiate between it and a truly curved boundary which should migrate toward its apparent center of curvature, or even one which should migrate away from its apparent center of curvature. Any studies of grain growth on a polished surface are open to some doubt, also. A grain which intersects a surface has a different environment from a grain in the body of a specimen. Grain boundaries will intersect the surface at 90° at equilibrium, and an intersection at an angle of other than 90° may lead to grain boundary migration to readjust the angle. In reply to Mr. Wensch's second question, the quantity D which appears in Eq 3 is the same as the quantity D_i in Eq 7.

As Dr. Dunn has beautifully shown at this meeting, the surface tension of the grain boundaries does depend upon the relative orientation of the grains on opposite sides of the boundaries, and thus only rarely will the equilibrium boundary angle be precisely 120°, as called for on a simple, isotropic surface tension picture.

I agree with Dr. Gulbransen's concern about the physical significance of the activation energies presented in Eq 2 and 8. The value of 40,000 cal per mol (rather than 60,000 cal per mol for commercial purity brass) for high purity brass is very close to the reported heats of activation for diffusion of zinc in brass of that composition. One is thus tempted to suggest that grain boundary migration occurs by a diffusion mechanism. Against this is the uncertainty of the mechanism of grain boundary migration, and the fact that a change in number of inclusions with temperature may influence the temperature dependence of growth rate and the computed value of H . Later evidence which will be published shortly indicates that the temperature dependence of the rate of grain boundary migration in pure copper varies with the crystallographic direction of boundary migration. Since diffusion in cubic metals is isotropic, this indicates that grain boundary migration is not identical with bulk diffusion. However, in a two component alloy like brass, there may well be an adsorbed layer of zinc at the grain boundaries, so that this must migrate by lattice diffusion when the grain boundary migrates by any other mechanism. This could well be the rate controlling step, and thus one would

measure the activation energy for diffusion of zinc.

Mr. Beck's discussion is exhaustive, and in the interest of brevity I shall answer only those points which are pertinent to this paper and not already discussed in the body of the paper.

As was stated, a number of workers have postulated that surface energy is the driving force for grain growth, but contrary to Mr. Beck's statement, by no means all workers have accepted this explanation. In any case, it is preferable to use experiment rather than acceptance by workers in the field to test the validity of an hypothesis. The concept that the escaping tendency from a surface is a function of the curvature of the surface is not new. W. Thomson³⁰ showed that the vapor pressure of a liquid droplet is inversely proportional to its radius of curvature, and the formal proof of this may be found in most texts on Thermodynamics.³¹ Vogel and Harker and Parker applied this concept qualitatively to the migration of grain boundaries, and in the present paper it has been applied quantitatively.

It takes energy to create a new surface, therefore a small crystal, which has more surface per unit volume than a large crystal, will have more energy per atom than a large one. In solution where there is a constant interchange between surface atoms of the crystal and saturated solution, there will be a tendency for large crystals to grow at the expense of small ones. For this effect to result in an appreciable rate of growth, however, the small crystals must be very small, much smaller than the grain sizes in metals where grain growth is experimentally observed to occur at measurable rates. There is undoubtedly a slight tendency for a large grain to grow at the expense of a small one in a solid metal, across a plane interface, but the effect is so small that it is not observable, as evidenced by the fact that plane grain boundaries between grains of different length along a wire do not migrate. The greater stability of a plane surface over a curved surface is shown by the restoration of a fragment of a crystal into an ideomorphic crystal when the fragment is immersed in a saturated solution. The solubility of the curved faces and edges produced by fracturing is greater than the solubility of the perfect crystal. In polycrystalline metals the relatively rapid rate of grain boundary migration results from a convex surface (positive curvature) being in contact with a concave surface (negative curvature). The difference in escaping tendency between these two surfaces is much greater than the difference between two surfaces having similar curvatures of the same sign. As was explained in the paper, this accounts for the very low rates of grain growth in partially melted specimens. Nevertheless, if they were heated for very long periods, one would

expect small amounts of growth of the large crystals to occur at the expense of small ones.

Mr. Beck concurs with the statement in the paper that it is unlikely that grain growth will stop by the grain shapes fulfilling the Harker and Parker criterion for equilibrium, and quotes evidence from his own work that grain growth does not stop. One of the objects of this research was to reconcile the indication of his work that grain growth continues at an unabated rate until the grain size approximates the size of the specimen, with the fact mentioned by Mr. Wensch that grain growth frequently stops earlier than this. I am glad Mr. Beck now agrees that grain growth does not necessarily continue until the grain size approximates the size of the piece, and regret that his explanation of the phenomenon was not available until some time after this paper was submitted for publication. It is somewhat surprising that he agrees with the Zener formulation of the inhibiting effect of second phase particles, since it also is based on the assumption that grain boundary curvature is necessary for grain growth to occur.

As Mr. Beck mentions, the specimen thickness effect is by no means in contradiction to the inhibiting effect of inclusions, rather, as is explained in the paper, they are different manifestations of the importance of grain boundary curvature.

It is not clear what Mr. Beck intends to show by Fig 22. The data on specimen thickness were used in the paper to show that in very thin specimens the limiting grain size was a larger proportion of the specimen thickness than in thicker specimens, because in thin specimens the grain size is smaller and thus the growth force is greater. The results thus confirm the explanation given for the specimen thickness effect.

Mr. Beck objects to Eq 7 and has presented an empirical four constant equation which fits the experimental data better. It is agreed that there are numerous mathematical procedures for fitting a curve to a set of data, determining the equation for the curve, and evaluating the constants in the equation. The object in presenting Eq 7 was not to develop an empirical equation which would fit the data obtained, but to test the assumptions made as to the mechanism of grain growth. These assumptions were that the rate of growth is proportional to the effective curvature of the boundary, that is the difference between the present and the limiting curvature, and that the effect of temperature is to vary the specific reaction rate constant, K , according to the Arrhenius relationship

$$K = A \cdot e^{-H/RT}$$

The equation is semi-empirical, in that the constants K and H must be evaluated experimentally. The slopes of the curves, and the general shape are not controlled

by arbitrary constants as in the equation proposed by Mr. Beck. When the mechanism of the process is better understood, it should be possible to compute the value of H and K , and in principle, even D_f . For example, factors which will influence K are the surface energy of the boundary, and a geometric factor relating the rate of grain growth to the true rate of grain boundary migration. It is also obvious that if the temperature dependence of D_f had been taken into account a better agreement with the observed data would have been obtained. This has been stated elsewhere.³² The quite good agreement between the curves calculated from these assumptions and the observed data are taken to indicate, as stated in the paper, that these assumptions are essentially correct.

It should be pointed out that the earlier derivation of the slope of 0.5 for the log grain size versus log time curves⁵ was based upon the assumption that the rate of grain growth is proportional to the total amount of grain boundary present. The present hypothesis is that the rate of growth is proportional to the effective curvature of the grain faces. It possesses the advantage that the role of inclusions and changes in grain size distribution can be explained on this basis. Only in the absence of inclusions and only when the relative grain size distribution remains constant does the present assumption lead to a slope of 0.5 for the logarithmic curves.

The earlier heat of activation of 60,000 cal per mol (based on Walker's work, and confirmed by Beck) was shown in the present work to be influenced by solution of impurities as the temperature increases. The value of 40,000 to 43,000 cal per mol observed for the high purity brass in the present work is at least internally consistent at all temperatures. In recomputing a value from the present data, Mr. Towers has taken as his measure of rate the time

necessary to reach a grain size of 0.1 mm, and presumably measured his own value of 49.8 K cal per mol in a similar way. This method of comparing rates at different temperatures is less certain than the method of superimposing curves, since the curves must be extrapolated and there is considerable freedom in selecting the exact slope to the extrapolated. When the curves are superimposed, more of the data can be used.

It is felt that it is meaningless to give such activation energies to three significant figures, for several reasons:

1. The rate of grain growth (rate of disappearance of grains) is not the fundamental process for which an activation energy should be computed. The fundamental process is the migration of grain boundaries, and one must assume that the rate of grain boundary migration is proportional to the rate at which grains disappear.

2. There may be reasons other than a change in the number of activated atoms with temperature which cause the rate of grain growth to change with temperature. An example cited in the present paper is a change in the number of inclusions. Another possible one is a change in the mechanism of grain boundary migration.

3. Later work indicates that the activation energy for grain growth depends upon crystallographic factors, and that it may differ for different directions of migration of the same grain in a uniform matrix. Thus at best an average value will be measured in a polycrystalline material, and it might change with differences in preferred orientation.

Preferred Orientation in Rolled and Recrystallized Beryllium

By A. SMIGELSKAS and C. S. BARRETT

DISCUSSION

(E. Parker presiding)

J. T. NORTON*—I think Mrs. Smigelskas Fischer has done a splendid job in working out the pole figures from

rather difficult photograms which are common to beryllium. Is there not a mistake in Fig 2 in that the pole figures B and C have been interchanged?

A. SMIGELSKAS FISCHER (authors' reply)—Yes, there is such an error in the labeling of the pole figures of Fig 2. The correct plane for Fig 2b and 2c is the

plane in parenthesis above the figure numbers and not that in the figure subtitle.

J. T. NORTON—Also, I would like to mention another method of obtaining the data for pole figures which would be particularly applicable to this problem. It is a method which has been published only

* Massachusetts Institute of Technology.

recently and some of you may not be familiar with it. In the use of thin foils, such as are involved in this problem, it again involves making up a sandwich out of several sheets cemented together with the rolling direction parallel in all sheets and then cutting out small cylindrical rods just as Mrs. Fischer did. Several rods would be cut out of the specimen with their axes making various angles with the rolling direction. These rods are then put in an X ray spectrometer fitted with a Geiger counter tube and the intensity of reflection from a particular family of planes is recorded as the rod slowly rotates. For instance, if we were to make a basal plane pole figure corresponding to Fig 2 of the paper, the cylindrical rod with its axis parallel to the rolling direction would be mounted in the direct beam of the spectrometer with the rod axis parallel to the spectrometer axis. The Geiger tube would be set at the correct angle to receive the basal plane reflection and clamped. The rod is then rotated at a constant rate and the output of the Geiger tube recorded on the chart. The resulting curve represents the intensity variation and hence the pole density variation for a diameter of the pole figure perpendicular to the rolling direction. Similarly, each of the other rods will give information about other diameters of the pole figure. Since the rods are geometrically identical, no ab-

sorption correction is necessary and all of the curves will be consistent. By drawing lines at different intensity levels above the background and measuring the angles at which these lines intersect the curves, data are available for drawing accurate pole density contours on the final pole figure. Usually six rods are sufficient to give adequate coverage of the pole figure and no part of the figure is left out. For a material as transparent as beryllium, the rods could be made fairly large and since a considerable length of the rod can be illuminated, a good integration is obtained for fairly coarse grained materials.*

A. SMIGELSKAS FISCHER—Thank you very much for describing your method. It seems to be more effective than the one we have used inasmuch as it enables one to obtain quantitatively the variation of intensity of scatter about a mean which is important in determining the exact extent of preferred orientations. We were able to estimate this extent only by eye. However, this work, which was declassified only recently, was completed several years ago. At that time, we did not have the benefit of your nice technique nor a spectrometer with which to develop any similar method.

* J. T. Norton: *Jnl. of Appl. Phys.* Dec. 1948, 19, 1176.

E. PARKER*—Everything sounds so easy the way you described it in the figures. I once tried to roll some beryllium. That was not so easy; in fact we found it very difficult. Would you care to make some comments about how the beryllium was rolled?

A. SMIGELSKAS FISCHER—I am sorry, but that is still classified information,

E. A. GULBRANSEN†—Could you use any other radiation instead of molybdenum?

A. SMIGELSKAS FISCHER—We could use other radiation but we found molybdenum best suited for our purposes.

E. A. GULBRANSEN—Though with a small figure?

A. SMIGELSKAS FISCHER—Even though the figure is small the lines are sharp and we are able to differentiate between the diffraction rings. While using longer wave lengths would spread the figure, it would also tend to broaden the lines and weaken their intensity if the same specimen to film distance and the same exposure time were used. Therefore, we felt that we would not gain any advantage from a larger figure.

A Study of Textures and Earing Behavior of Cold-rolled (87-89 pct) and Annealed Copper Strips

By MING-KAO YEN

DISCUSSION

(S. E. Maddigan presiding)

S. E. MADDIGAN*—I think Mr. Yen should be complimented on doing a very excellent and a very comprehensive piece of work. I was particularly pleased to note the use of X rays in a somewhat less tedious technique than pole figures. In the past I think many workers have been diverted away from the use of X rays in such investigations because of the large amount of work involved in pole figures if one is dealing with a great number of specimens. The same thing, I think, applies to the determination of orientations by counting of twins which is also a very tedious procedure; as a result several

papers which have otherwise been of excellent quality have depended upon etching techniques for determination of orientation. The present paper indicates that the results reported in those previous papers were correct, but I think the use of etching techniques alone is a rather shaky basis for setting up theories in the literature.

W. M. BALDWIN, JR.*—This discussion will be a short note of correction and apology. In my discussion of Brick, Martin and Angier's paper I incorrectly reported the orientation of phosphorus deoxidized copper annealed at temperatures. When I learned that Mr. Yen was preparing the present paper I asked that he correct this previous error, which he

most graciously consented to do. However, through my ambiguity the correction noted on p. 59 of Mr. Yen's paper is still not the proper one. For this I take full responsibility. The orientation which I observed in phosphorus deoxidized copper at high temperatures is the (112) [11 $\bar{1}$] which agrees with the pole figure given in Fig 8a, on p. 65 of Mr. Yen's paper. Our observations were made on the basis of twin counts rather than X ray determinations and therefore serve as an independent confirmation of Mr. Yen's data.

M. K. YEN (author's reply)—The author wishes to thank Dr. Maddigan for his comments in regard to the application of glancing technique to textures. As a matter of fact, considerable work has been done recently in connection with

* Univ. of British Columbia, Vancouver, B. C.

* Case Institute of Technology.

the study of rolling, wire drawing and electrolytic deposition textures for copper and its alloys by this method or some modification of it. It is to be expected

that this technique may be developed to its full practical importance. In the case of copper, it was found that the approximate position and relative height of ears

in deep drawn cups, as well as grain size and degree of recrystallization, can generally be derived from a single X ray glancing photogram.

Pressure Distribution in Compacting Metal Powders

By POL DUWEZ and LEO ZWELL

DISCUSSION

(*L. S. Busch presiding*)

L. S. BUSCH*—A very interesting use of a new engineering material, the strain gauge, is, I believe, one of the first as applied to powder metallurgy.

J. WULFF†—We have here another valuable contribution to the fundamental data on powder metallurgy from Professor Duwez's laboratory at California Institute of Technology. I am particularly pleased with the measurements which relate to the vertical pressures but not with the measurements which relate to radial pressures on the die wall. In regard to the latter, we gave up similar attempts in our own laboratory to measure radial pressures by methods

similar to those used by the authors of this paper since we believed that their very method of measurement would introduce appreciable error. For this reason, one of my coworkers, Dr. Shank, studied the pressure on the die wall by using a cylindrical thick-walled die with a goodly number of closely spaced strain gauges on the outer wall. The strain distribution in the die wall was thus obtained during pressing from both sides. This enabled the determination of both frictional and radial forces acting on the die wall. The distribution of radial forces in this work appears to be quite different from that obtained by Duwez and Zwell.

A. J. SHALER*—I am very glad that we now have some stress distribution data on the bottom plunger of a cylindrical die during pressing. These data,

along with the side-wall pressure data which the authors have given, and which have also been obtained by the method just described complete the elements required to solve the entire stress strain problem in cylindrical compacts. In previous years Kamm, Steinberg and Wulff have solved the strain distribution problem. I wonder if Professor Duwez could be induced some time when he is not too busy to put some of his strain gauges in the top plunger as well. It would not be necessary, I think, to have the top plunger stress distribution in order to solve the entire problem, but these data would certainly provide a very useful check on the result.

P. DUWEZ (authors' reply)—I think those experiments could be done very easily by using a floating die and two moving plungers instead of one.

Lead-grid Study of Metal Powder Compaction

By R. KAMM, M. A. STEINBERG, and J. WULFF

DISCUSSION

(*L. S. Busch presiding*)

L. S. BUSCH*—We have had presented two methods of measuring these variations in powder compacts.

E. OROWAN†—In connection with the rolling mill research work carried out at the Cavendish Laboratory, Cambridge, with the help of the British Iron and Steel Research Association, Dr. E. A. W. Hoff, Mr. J. Los, and myself, have determined coefficients of friction at ex-

treme pressures for a number of liquid and solid lubricants, both by direct measurement, and by calculation from measured values of the roll force. The most efficient lubricants at these high pressures (for the small amounts of sliding that occur in rolling) were camphor and, in particular, borneol (Borneo-camphor). Perhaps such lubricants could be used with advantage in the kind of work described by Dr. Wulff.

L. S. BUSCH—I think Dr. Wulff has in the past mentioned experiments which have been performed in the extrusion and rolling of metals and which led to conclusions which can be applied to the

compacting of metal powder.

A. SQUIRE*—There have been some recent developments in the field of high pressure lubricants which indicate that boron nitride might be a very desirable material to employ as a die lubricant. At the present time its cost is prohibitive, but as the need arises for the material it will undoubtedly come down in price. The present price is \$200. a pound.

It is my understanding that one of the reasons for vacuum pressing both in ceramics and metal powders, is to prevent

* P. R. Mallory & Co., Inc.
† Cavendish Laboratory, Cambridge, England.

* Westinghouse Research Laboratories.

the formation of what we call pressure cracks on ejection. I have been assured by people who have done the work themselves in the field that it is possible to press powders at considerably higher pressures under vacuum than it is in air. Apparently the gases trapped during the pressing operation add sufficiently to the internal stress in the compact so that these pressure cracks are formed on ejection. In vacuum pressing this can be avoided.

L. S. BUSCH—I feel that Mr. Squire has a good point, but I also feel that there is another factor as far as pressure cracks are concerned and that is simple expansion as the piece comes out of the dye.

J. WULFF (author's reply)—We have not tried the borneol (Borneo-camphor) suggested by Dr. Orowan. The extremely high point pressures met with in pressing lead us to believe that it should be applicable.

In answer to Mr. Squire, we have found that boron nitride behaves as an abrasive and not as a lubricant in powder pressing. Its application to the lips of crucibles, since it is difficult to wet by molten metal, suggested its use. In an auxiliary research it was also used as a constituent of powder metallurgy bronzes which were tested for friction and wear.

No reduction in friction or wear was experienced. Indeed rolling boron-nitride torn loose from the compact accelerated the wear appreciably.

In regard to Mr. Squire's remarks on pressing, I must say that entrapped air can lead to fracture of the compact as it is ejected from the die or later during sintering. Our results indicate nevertheless that nothing is gained from a density standpoint by vacuum pressing of hard powders and little with soft powders that cannot be achieved readily by efficient lubrication.

Perhaps Professor Shaler would care to comment on Mr. Busch's remarks.

A. J. SHALER*—We have found that cracking upon ejection of the compact is not always due to the lateral elastic expansion of the compact as it comes out of the die, but must occur as soon as the pressure is released. The pattern of stresses set up in the compact when the load is removed from the die walls is such that cracks may form at the center of the compact and spread upward laterally outwards. The way to avoid cracks of this kind would not be to increase or decrease the pressure or change the lubricant, but simply to build dies of greater rigidity so that a lesser residual-stress pattern is created when the die

* Massachusetts Institute of Technology.

walls push back on the compact elastically after release of the pressure.

J. CORDIANO*—On the subject of pressure cracks in specimens on ejection from dies one of the simplest ways of preventing such cracks is to maintain a partial top pressure on the compact during ejection. One question I wanted to ask Dr. Wulff regarding pressing and sintering of these copper compacts is whether he noted bloating of the sintered specimens which were pressed at 60 tsi. Also, was there any difference in bloating tendencies when sintering in vacuum or hydrogen?

J. WULFF—The present tests on copper were sintered in a dilatometer set-up which did not permit close observation of the compact surface during sintering. I have, however, noticed the "bloating" mentioned by Mr. Cordiano on copper compacts pressed at pressure above 60 tsi and later sintered in hydrogen. Indeed, some of these specimens have even exploded in the furnace. Mr. Cordiano's remark that pressure cracks can be avoided by maintaining some pressure on the compact during ejection is well taken. S. K. Wellman has long advocated this technique in the pressing of thin specimens of large area.

Properties of Chromium Boride and Sintered Chromium Boride

By S. J. SINDEBAND

DISCUSSION

(E. Parker presiding)

J. WULFF*—It seems to me that the author could improve the quality of his high temperature material by using less nickel as a cementing agent in hot pressing. Furthermore, to avoid the presence of undiffused nickel which would not be oxidation resistant, permit me to suggest that he use a nickel-chromium powder containing a small percentage of boron. This would give him a liquid phase at a lower temperature and accelerate both sintering and homogenization. The commercial alloy known as colmonoy contains sufficient chromium to be heat resistant

and sufficient boron to be of low melting point. Such an alloy may be applicable as a cementing agent in increasing the quality of Mr. Sindeband's alloys. Finally I believe the author unfair to himself in expecting a porous material to have properties equivalent to one of 100 pct density.

S. J. SINDEBAND—Dr. Wulff's point is well taken. Early in the program we realized the fact that we were having difficulty with these low-melting alloys, and we had hoped, since the colmonoy alloys of which you speak are at the nickel-rich end of the diagram, that by going to the other end of the diagram (chromium boride-rich) we would not have this difficulty. Thus we tried to use very small percentages of binder; but

for reasons which are not exactly apparent we found that when we did this it was necessary to raise the pressing temperature to a point which we were unable to attain. For all compositions which we tried using nickel, or for that matter any nickel iron or cobalt containing material as a binder, we found that we would get low melting boride phases, which as you point out are the commercial "strength" of the hard-facing materials. I personally believe these owe a great deal of their behavior and even hardness to the nickel boride which is considerable evidence when an alloy of chromium boride is made with nickel. Nickel boride itself is very hard. We did try pure chromium as a binder and found there was considerable difficulty in handling it, particularly since we could not just hot press under

* Massachusetts Institute of Technology.

the atmosphere conditions obtaining there. We found that when we vacuum sintered chromium boride, we developed extremely brittle materials, and had to abandon that. It looked quite fruitful at one time. We attempted to make use of materials which either did not form known borides or which formed refractory borides and used those as binders. Apparently the chromium boride itself enters into entirely too many side reactions with binders to permit us to make use of chromium boride to get the ultimate result we were seeking in this particular field.

The comparison with vitallium is a cruel one, but nevertheless it is one which I chose to make simply to indicate the goal for which we are aiming. I believe that alloys of this variety will be able to achieve high temperature strength equivalent with materials such as vitallium and better than that. What we need to do is to find if we continue with borides, a material which does not lose its boron to the binder phase but which will enter into a cementing action with the cement chosen which is similar to that observed in the case of carbides. There actual re-precipitation occurs and much of their strength comes from the matrix and not from the binder.

W. J. KROLL*—It would be of interest to know how much oxygen the powdered chromium boride contained, as well as how much oxygen was present in the chromium powder used for sintering. Wet grinding of such active metals or alloys introduces large amounts of oxide and the contaminated materials may not bind in the sintering operation.

S. J. SINDEBAND—We spent a good deal of time attempting to determine the oxygen content of the boride. Unfortunately the oxygen was largely tied up in the form of oxides of the aluminum which was used for the reduction of the original oxides in thermite reduction, and as such we met great difficulty in making any determination. It was not too clear whether it was all tied up as aluminum oxide or as some complex silicates. However, the analysis of the powders indicated that there was an unaccounted for amount, I believe, of about 3 pct. The table directly under the X ray patterns indicated, for the thermite process, that the known elements added up to 97.25. How much oxygen was in that residue we could not know. As far as the chromium is concerned, we found standard electrolytic chromium unsatisfactory as a binder with which to press the powders. The procedure that we used was to purify this chromium powder by a reduction in

extremely dry hydrogen. We found that if we got the dew point down to the temperature of liquid air we could bright anneal the chromium powder and come out with a powder considerably more ductile. We were then able to press good compacts, but still the resulting sintered cold pressed products were very brittle. The transverse rupture strength was of the order of 27,000 to 30,000 psi, or perhaps a shade higher.

MEMBER—I am particularly interested in the field of wear resistance, and I wonder whether the author has done any work or considered any work in studying these chromium boride compacts as wear resistant materials. You have shown that you had some difficulties in making the high temperature resistant material, but this might be very good wear resistant material.

S. J. SINDEBAND—We have not made any actual wear resistance tests. I believe the wear resistance of this material could be assessed on the basis of the properties that have been presented. Hardness is of major importance. The toughness of the material would be indicated by its transverse rupture strength. I believe that material of this composition has been given some use in cast form by the Wall-Colmonoy people. I would expect that this material as hot pressed would be able to do anything that that material could do, and perhaps do it better by virtue of the finer structure which is attained in this material, much the same as you would expect to get in a comparison between a cast carbide versus a cemented carbide. The wear resistance, I think, of these materials should be good. I think it would depend entirely on the actual application. If there is any acid corrosion present under the circumstances under which you want wear resistance, I think this is a very good material. We did try it as a tool material just briefly, and it cuts well. Actually I believe that if you have anything of 89 or so Rockwell hardness and a transverse rupture strength above 100,000, you can cut and cut well with it. That is good enough, I feel sure.

A. SQUIRE*—I may be mistaken but in looking at that micrograph presented in the paper it seems to me the particles are larger than 3 to 5 microns. The micrograph looks similar to those of carbide where the particle size is possibly one to two microns. Did that micrograph show that much particle size or did the grains grow?

S. J. SINDEBAND—The 3 to 5 micron particle size was the starting point.

We did observe with this material the grain growth was obtained in the hot pressing operation.

R. KIESSLING*—Binary systems, composed of a transition element and boron have been studied for four years at the Institute of Chemistry, University of Upsala. The chromium-boron system belongs to those which have been investigated. As the results in some instances are different from those published in this paper, a short note may be of interest. (The results have been received by *Acta Chemica Scandinavica* for publication.)

Five intermediary phases have been found with relatively small homogeneity ranges and boron contents of 33 (δ), 40 (ϵ), 50 (ζ), 55 (φ), and 67 (θ) at. pct. The structure of the η -phase has been mentioned in connection with a report on the system zirconium-boron (*Acta Chem. Scand.* (1949) 3, 90). The structure of the ϵ -phase is in accordance with the data given by Mr. Frueh. The position of the boron atoms has been determined using Fourier methods. The boron atoms form parallel chains through the metal lattice. The structure is closely related to the structures of the δ -phase in the systems molybdenum and tungsten-boron. (*Acta Chem. Scand.* (1947) 1, 893).

The system behaves in accordance with Hägg's rule for a content of boron up to 60 at. pct and is more complicated than the systems molybdenum-boron and tungsten-boron. The latter two systems have the radius ratio closer to the critical value. The system zirconium-boron, with a radius ratio on the other side of this value has only one simple intermediary phase.

S. J. SINDEBAND—I was very interested to note that work is continuing on a broad scale on the binary systems with boron, at the University of Upsala; particularly since so much of interest emanated from that institution in this field in the past.

I was particularly interested to find that Dr. Kiessling had made an extensive study of the chromium boron system and that his data for the structure of the phase around 50 at. pct corresponded with the data given in the paper I presented, as obtained by Mr. Frueh. In none of the X ray investigations made on chromium boride did we note lines which would correspond with the other bordering phases he has reported. It is quite possible that the method by which the material is made has something to do with this.

I shall await with interest the publication of the complete data regarding these phases.

Solubility Relationships of the Refractory Monocarbides

By J. T. NORTON and A. L. MOWRY

DISCUSSION

(E. Parker presiding)

W. J. KROLL*—I think that since oxygen and nitrogen have a tremendous influence on the mechanical properties of these metals, it can be expected that tracers might have also considerable influence on the mechanical properties of these carbides, I wonder also how far residual oxygen and nitrogen may interfere with the determination of your lattice constants.

J. T. NORTON (authors' reply)—Thank you, Dr. Kroll, for bringing up this question about which we have thought a good deal. We have no specific analysis for oxygen on these carbides chiefly because I do not know how to do it. Maybe you have a suggestion. We do know however that in comparing careful measurements of lattice parameters of the carbides which are deficient in carbon, and where the carbon is undoubtedly

* Northwest Electrodevelopment Laboratory, U. S. Bureau of Mines, Albany, Oregon.

replaced by oxygen or nitrogen or both, there is a negligible change in the value of the lattice parameter until there is a very considerable deficiency in carbon. Titanium carbide is the one we have investigated most completely, and until about a quarter of the possible carbon atoms had been removed there was very little change in the parameter, but beyond that it drops very rapidly. It is believed titanium oxide, TiO and TiC can form a continuous series of solids. It has been investigated but the lattice parameter curve is not linear, and is almost flat at the carbon rich end. Our investigation is based on the carbides which are very nearly saturated with carbon. I am inclined to believe that these impurities which are undoubtedly present in our carbides have very little influence on the lattice parameter because both nitrogen and oxygen will replace carbon in these monocarbides atom for atom. If we had a good method for analyzing for oxygen we would feel a lot better about results of this type. Mr. Redmond of Kene-

metal Corporation has offered to provide us with some carbides made by Mr. Mackenna's process, the so-called Menstruum process you mentioned. It would be interesting to see if those carbides give any different results from the ones which we used.

J. WULFF*—Many of us peruse the literature of powder metallurgy and have been taught that double carbides of refractory metals can be made by the Menstruum method. Are we to believe from the work of the above authors that double carbides cannot be made by the Menstruum method?

J. T. NORTON—You put me on the spot. Certainly in the binary systems, which we have investigated here, there is no evidence of the formation of a double carbide. These are simple replacement solid solutions. There is no critical composition and there is only one type of structure observable over the whole range of compositions.

The Magnetic Properties of Sintered Iron and Iron Base Alloys

By W. ROSTOKER

DISCUSSION

(A. Squire presiding)

S. J. SINDEBAND*—(1) Discussing the properties of the powders used, Mr. Rostoker mentioned a silicon powder as being between 150 and 325 mesh. We always had much difficulty in measuring particle size of silicon powder by screen analysis, because of its tendency to agglomerate. I would be interested in the method used to measure these particle sizes.

(2) Mr. Rostoker maintains that the measurement of magnetic properties is more accurate in determining complete homogenization of an alloy, than is the X ray diffraction technique. I wonder whether this is really true. Even when diffusion is complete, magnetic properties

will change during continuation of the heat treatment, due to change in density and pore shapes, as has been demonstrated by Mr. Rostoker himself. Which effect is faster, the diffusion of the alloy components or the attainment of final density, will, in my opinion, depend very much on initial material and sintering conditions used. For magnetic applications, of course, the magnetic measurements are most suited for determining the point at which equilibrium conditions are reached.

(3) I was glad to see that Mr. Rostoker had used sample sizes which are similar to those I had used previously, and I believe that ring samples of about 2 in. od will become more or less standard samples for the determination of magnetic properties of powder metallurgy products. I should like to ask how the density was changed for the samples on which the effect of porosity was investi-

gated, and, further, why the sintering temperature used for this series of experiments was so low. It is somewhat surprising that a 24-hr treatment at $850^{\circ}C$ acts so much more to spheroidize the pores than a treatment for 1 hr at $1100^{\circ}C$. But the effect seems to be indisputable. I have made an investigation of the influence of sintering temperature for longer times on the maximum permeabilities of iron powder compacts which was presented at the International Powder Metallurgy Conference in Graz, in 1948, and I hope that these results will be published here within a short time. The results of this investigation are confirmed by Mr. Rostoker's findings that the change of time from 1 to 24 hr changes the permeability behavior considerably in the direction as indicated by Polder and Van Santen for spheroidization of pores. I do not quite understand Mr. Rostoker's explanation of the influ-

* American Electro Metal Corporation.

ence of "high" and "low" permeabilities on the shape of the curves for induction vs. density. Even for the large fields ($H = 100$), the permeability is still in the neighborhood of 100, that is, it is equal to the largest value Polder and Van Santen have used. I believe the fact that the permeability is not constant will make a refinement of Polder and Van Santen's theory necessary, though the general trend for flat and spherical pore shapes will probably be maintained.

(4) The densities obtained for any alloy material produced by Mr. Rostoker are rather low if compared with his excellent values for pure iron. This has to be expected, but points in the direction mentioned above, that homogenization is not necessarily connected with constant magnetic properties. An attempt to study diffusion in Fe-Si alloys by resistivity measurements was recently published by F. W. Glaser in the "Powder Metallurgy Bulletin." We are now studying the ferrosilicon materials over the full range of alloys, especially as far as resistivities and magnetic properties are concerned, and hope to publish something about these compositions within this year. Mr. Rostoker reports about a so-called anomaly in his Fe-Ni alloys with regard to the maximum permeabilities. These are inferior to data published in the literature, while, for instance, B_{100} and H_c are very close. In my opinion, the explanation for this behavior is the porosity of the alloys, as they are at the best 95 pct dense. Saturation and coercive force are much less sensitive to the influence of porosity than is maximum permeability. This might also give an explanation why there was no influence of nitrogen noticed in Fe-Co alloys, where the maximum density is still lower. The investigation by Mr. Rostoker, about the differences in properties obtainable by sintering in hydrogen or cracked ammonia, was especially interesting and might explain a number of discrepancies so far reported in the literature.

F. W. GLASER*—With regard to the preparation of the Fe-Si compacts, though not mentioned, I assume that Mr. Rostoker has mixed the Si and Fe powders by a tumbling operation. In view of the difference in density of these two powders, I myself have experienced great difficulty in obtaining the desired overall Si percentage, as it was theoretically calculated. Further, I wonder whether chemical analyses were run on the Fe-Si compacts reported. The exact overall Si content of the range of Si alloys reported in Mr. Rostoker's paper is extremely important, since as little as 0.25 pct Si in this region has quite an influence on the electrical resistivity. I should like to know to what extent Mr. Rostoker was sure that the Si percentages were really of the reported compositions.

F. N. RHINES*—I would like to say a few words in defense of the X ray method. I suppose that everyone who has thought about the problem of measuring homogenization in powdered compacts has thought of using the X ray method, and each person, in turn, seems to have become discouraged with it, but there is a basic advantage in its use, and I think we should not lose sight of it. Apparently, the thing that Mr. Rostoker has done has been simply to measure the position of maximum intensity in the reflection that he chose as his index and to watch the progress of that point of maximum intensity during heat treatment. It is fairly evident, and I think every one who has done this work has observed, that there is another phenomenon that takes place at the same time. The line first broadens so that it covers all of the parameter values from that of the pure solvent to that of the saturated solid solution. The broadened line first shows its maximum intensity somewhere near that of the pure substance; then, as time goes on, the maximum intensity shifts and, after the maximum intensity reaches somewhere near the point where it will stabilize in parameter value, the breadth of the line decreases, that is, the line becomes progressively sharper.

Now, if we could make good intensity measurements across the line we should have an index not only of the average change in composition of the material during homogenization but a detailed description of how much of each composition is present at any given time during the homogenization process. This information would be invaluable in making a complete statement of the state of homogenization at any period.

We cannot get that kind of information from any measurement which gives us only an over-all average figure, therefore it seems to me that in the long run it would be highly desirable to get the X ray method under full control and to use it for this type of research.

J. T. NORTON†—I do not believe that the X ray experiments described in this paper really indicate what the X ray method is capable of doing. A change in parameter is not a very sensitive measure of composition. As I understand this problem, it is one of determining whether or not a sample is of uniform composition; certainly the measurements of the line broadening would be much more sensitive. This is true provided the work on line broadening is carried out properly, and it is not an easy thing to do. It would require a very careful experimental technique, the use of truly monochromatic radiation and a really first-rate measurement of the line broadening as the homogenization of the compact proceeds. I believe a lot more could be

done by means of X ray than was done in this particular paper.

W. ROSTOKER (author's reply)—In reply to Mr. Steinitz, the particle size distribution of the silicon powder was determined by the use of a nest of standard screens vibrated for 15 min. No agglomeration difficulties were encountered.

Of the variables which might, in addition to inhomogeneity, affect the change of magnetic properties with time, Mr. Steinitz mentions density and pore shapes. Pore shapes at high temperatures become spheroidal early in the sintering history. The amount of porosity in the repressed and unsintered condition is 4.5 pct and after sintering for 24 hr at 1400°C is only decreased to 1.9 pct. The consolidation is therefore only slight. In accordance with the demonstrated linear effect of spheroidal porosity on permeabilities there should be little effect on the homogenization experiments.

In a similar vein, Mr. Steinitz would attribute the low maximum permeabilities of the heat treated nickel-iron alloys to porosity. Again, under the conditions of treatment the rings would be expected to, and indeed do, exhibit spheroidal porosity. The author feels that the experimental work presented definitely shows such pore shapes to exercise only slight influence on permeability at 95 pct of full density. It might also be pointed out that the maximum permeabilities of 65 and 78.5 pct nickel-iron alloys in the annealed state are quite normal. As a conjecture, the cause of this trouble might rather be in small scale inhomogeneity.

The density variations were effected by submitting samples to successively higher molding pressures. The very high densities required a double pressing operation with an intermediate short time, low temperature anneal. The final sintering times and temperatures were chosen to give conveniently the range and character of porosities.

Polder and Van Santen quantitatively calculated the effect of pore character and content on dielectric properties. They suggested that the effect on magnetic permeabilities at constant field would be analogous. There is no reason to expect that the analogy should be more than qualitative. For that reason, a permeability of 100 is referred to as "low" as compared with values of several thousands at low inductions and in accordance with usual magnetic parlance.

Mr. Steinitz implies that the large differences in maximum permeability between the sintered iron of full density and porous irons are due to differences in density. The author would rather attribute this to the extremely low carbon and oxygen contents (see Table 7) and the large grain size of the high density iron due to the prolonged heat treatment in hydrogen at 1420°C. In effect, the two

* American Electro Metal Corporation.

* Carnegie Institute of Technology.

† Massachusetts Institute of Technology.

irons are not of comparable purity. The true permeabilities of the porous irons would best be determined by extrapolation of the straight lines of Fig 7 to 100 pct of full density.

In reply to Mr. Glaser, the appropriate amounts of iron and silicon powders were weighed out and mixed for each ring individually. In this way, the required amount of silicon was introduced into each ring and it was not thought necessary to analyze the rings after heat treatment. There was no apparent segregation during the mixing operation or while pouring the powder mixture into the

molding die. The electrical resistivities do not appear to vary from other reported values by more than about 5 pct.

The author finds himself in full agreement with the comments of Professors Rhines and Norton concerning the proper study of an inhomogeneous state by X ray diffraction methods. He also feels that the experimental and interpretive difficulties involved would necessitate a separate project. Lack of proper equipment prevented the X ray studies presented here from being more detailed. But it should be remembered that this portion of the work was intended to

assist interpretation of the magnetic results. The main purpose in presenting the X ray data was to show that an apparently sharp diffraction pattern could be observed long before the structure-sensitive magnetic properties reached their ultimate values. Undoubtedly, a more careful examination of these apparently sharp lines would have indicated small scale inhomogeneity. But the pertinent conclusion to be taken was that small scale inhomogeneity affected structure-sensitive magnetic properties as severely as very small carbon and oxygen contents (T. D. Yensen, Ref. 5).

The Densification of Copper Powder Compacts in Hydrogen and in Vacuum

By C. B. JORDAN and POL DUWEZ

DISCUSSION

(A. Squire presiding)

A. J. SHALER*—I should like to congratulate the authors for having carried out such a precise set of experiments. It has been found useful, in sintering experimental compacts in vacuo, to make certain that the residual gas is not one which reacts with the metal. Since traces of oxygen can be kept away only with great difficulty, the technique is often adopted of using a "getter" of powder in the vicinity of the compacts, and, in addition, of permitting a small hydrogen leak to flow into the vacuum chamber. Did the authors use similar devices?

This paper brings up a question concerning the definition of the word 'sintering.' The authors restrict its use to the adhesion between particles. Kuczynski, in a paper presented at this meeting, applies the word to the growth of areas of contact between particles. I have used it to mean both these phenomena and also the dimensional changes which continue to take place after the first two have run their course. May I suggest that we should come to an agreement on the use of these words?

Fig 1 and 2 show an interesting feature: extrapolation of the curves to zero time does not give a densification parameter of zero. The higher the temperature, the higher is the intercept on that axis. These observations agree with the concept of a practically instantaneous densification taking place while the compact is being brought to heat. Such a change may be brought about by plastic deformation and primary creep. The

stress pattern causing this first rapid flow is, to my mind, due to the force of attraction between the surfaces of opposite particles in the regions immediately flanking their common areas of contact. The stress is not temperature-sensitive, but at room temperature plastic deformation only proceeds until the metal in the area of contact can support it elastically. As the metal is heated, the elastic limit falls, and further plastic flow occurs. At the higher temperatures, this is followed by primary creep, and finally by the steady-state rate-reaction which the authors are seeking. If they were to recalculate their densification-parameter values, using, not the initial density of the cold compact, but the density after the compacts have been brought to temperature, the systematic deviations from linearity in Fig 3 and 4 might be eliminated. Such initial densities might be obtained by extrapolating the curves of Fig 1 and 2 to zero time.

I am naturally pleased to see that such a very well done series of experiments leads to a heat of activation (for the densification process in hydrogen) that is much higher than that for self-diffusion, in confirmation of the less elaborate results reported by Wulff and myself (*Ind. and Eng. Chem.*, (1948) 40, 838).

J. T. KEMP*—I would like to comment on Dr. Shaler's remarks. There are apparently different interpretations of the word "sintering." It seems to me that an accurate definition of our word is essential in all metallurgy. May I point out, in this connection, that in practical metallurgy the word "sintering" has

been applied to a bonding process in the preparation of ores and flue dust for furnacing. It would be unfortunate if in the area of powdered metallurgy we should establish a definition that is essentially different in meaning.

F. N. RHINES*—I think that I can answer the question by saying that I see no essential difference between the use of the term "sintering" in extractive metallurgy and in powder metallurgy; physically the same things are going on. I admit sintering is used for different end purposes in the two cases. When we resort to the sintering of lead ore mixture we are doing so to obtain a chemically reactive, loose texture of some rigidity. This is only a difference in use. After all, in powder metallurgy we sometimes deliberately produce a very porous material which has just a little strength, just as in the case of sinter cake.

P. DUWEZ (authors' reply)—We agree that it would be helpful to have well-established definitions of such terms as "sintering." Since the question has now been raised, the time might be appropriate for its consideration by some suitable committee of one or more of the metallurgical societies.

In answer to Dr. Shaler's first question, no getter nor hydrogen leak was used in our vacuum experiments, except insofar as the guard disks (used to reduce friction between specimens and trays) may have acted as getters.

Dr. Shaler's statement that extrapolation of the curves of Fig 1 and 2 does not lead to zero densification at zero time apparently overlooks the logarithmic

* Massachusetts Institute of Technology.

* American Brass Co., San Francisco, California.

* Carnegie Institute of Technology.

time scale used in those figures. The intercepts he mentions are not on the line $t = 0$, but on the line $t = \frac{1}{4}$ hr. The densification parameter, as we have defined it, is necessarily equal to zero at $t = 0$, and the curves of Fig 1 and 2 would indeed intersect at $\sigma = 0$ if extended far to the left.

Since the shortest time employed in our

experiments was $\frac{1}{2}$ hr, we feel that our results should not be taken as either confirming or denying Dr. Shaler's concept of a practically instantaneous densification during the heating-up period. If the results of shorter-time experiments were such as to confirm this hypothesis, it would then be interesting to see whether the curves of Fig 3 and 4 are

more nearly straight lines if the values of σ are calculated on the basis he suggests. His idea that densification is the result of several processes which successively predominate, is in agreement with the opinion we expressed in the paper at the conclusion of the section on "Interpretation of Results."

The Surface Tension of Solid Copper

By H. UDIN, A. J. SHALER and J. WULFF

DISCUSSION

(A. Squire presiding)

G. KUCZYNSKI* and B. H. ALEXANDER*—This paper represents a most noteworthy attempt to evaluate experimentally the surface tension of a solid metal. Because of the great importance of such measurements, any proposed method should receive the closest scrutiny before the results can be considered reliable.

In regard to the experimental method, we think that the marking of the gauge length by means of tying knots in the wire may be the cause of some of the spread in the results. Such a knot may be expected to tighten slightly, and thus increase the gauge length, when placed under stress at high temperature. Although this effect would be very small, amounting at most to only a few times the wire diameter. A fairly tight knot in a wire will decrease the wire length by about ten times the wire diameter, thus only a slight tightening of the knot would cause considerable spread in the results.

Upon plotting the stress strain curves from the authors' data, the writers found that there was a fairly consistent tendency towards an S-shaped curve, instead of a straight line. Such an effect could be caused by the tightening of the knots.

The writers think, however, that the experimental results are fairly reliable, but that there may be other methods of interpreting them depending upon what mechanism is assumed to be responsible for the shrinkage of the wires. The authors have assumed that the stress due to surface tension results in viscous flow. It should be made clear that it has never been demonstrated that viscous flow can occur in metal crystals even at very high temperatures. The experiments of Chalmers¹³ on tin, which are so frequently quoted as giving evidence of viscous flow at low stresses are by no means

satisfactory. In his experiments, Chalmers found that only the initial rate of flow was approximately proportional to stress. He also found that the rate of flow varied markedly with time which, in his experiments, was less than 2 hr. Inasmuch as there is no proof of viscous flow in metals, and the authors have brought forth no conclusive evidence on this point, it may be worth while to investigate other possible mechanisms of material transport which would account for the shrinkage of the wires. The writers wish to point out that in these experiments the shrinkage of the wires can be adequately explained, according to a self diffusion mechanism. Thus, if we assume a concentration gradient for self diffusion which is a function of the radius of curvature of the wires, and assume that diffusion will occur so that the total surface area is decreased, we find the following expression for the self diffusion coefficient:

$$D = \frac{-kr_0^2 T}{\gamma \delta^3 l} \ln \epsilon \quad [19]$$

where k = Boltzmann constant

r_0 = initial radius of the wire

T = absolute temperature

γ = surface energy

δ = interatomic spacing

l = time

ϵ = strain at zero applied stress

Eq 19 may be used to evaluate the self diffusion coefficient of copper, using the strain measurements obtained by the authors for zero stress as obtained by extrapolating their curves for 5 mil wires. By inserting a reasonable value for the surface energy (1500 ergs per cm²) we find:

$$D = 5 \times 10^4 e^{\frac{-66,000}{RT}} \quad [20]$$

The activation energy is of the correct order of magnitude, but the frequency coefficient is much too high, indicating that surface diffusion may be playing an important role. This discrepancy in the action constant is much smaller than the corresponding discrepancy obtained by the authors for the viscosity coefficient.

The writers by no means propose that this proves that the shrinkage of the wires is due to self diffusion but we merely wish to point out that there are explanations other than that given by the authors. In this, as in any kinetic phenomena, it is necessary to study the rate of the process before anything can be said about the mechanism. The determination of surface tension given by the authors is based upon an interpretation of the data which embody the concept of viscous flow. The final proof of this concept will be obtained only after the time relationships confirming the authors' Eq 15 have been conclusively established. The rough linearity of the stress strain curves obtained by the authors for experiments run the same length of time should not be considered as proving that viscous flow is occurring.

H. UDIN (authors' reply)—All of the test specimens were annealed at 1000°C for an hour or more before preliminary measurements were made. During this anneal the wires recrystallize, and the greatest part of grain growth takes place. Also, the knots sinter at the cross-over points. This does not in itself eliminate the possibility of end errors, although it greatly decreases their probable magnitude. It is still possible that some extension occurs due to creep in shear at the sintered points. If so, this effect would be quite independent of and superimposed on the normal shrinkage or extension of the wire itself. Within the precision of the experimental results, straight lines satisfy the data as well as do any other simple curves. Until data of greater precision are obtained, it is futile to discuss any possible trends away from linearity.

The disagreement between Kuczynski and Alexander's Eq 19 and our Eq 18 is one of semantics and mathematics, not mechanism of flow, since Eq 18 is based on the self-diffusion concept of viscous flow. It would be interesting to learn how the mathematics leading to Eq 19 deviates from that of Eyring and of

Frenkel. The dependence of self-diffusion coefficient on specimen size in Eq 19 is somewhat startling.

As Dr. Orowan points out, neither the mode of flow nor its time dependence has any influence on the numerical values obtained for the surface tension of solid copper, because it is found from the interpolated value for zero strain.

A. J. SHALER (authors' reply)—Dr. Kuczynski has said, if I understand him correctly, that there may be a mechanism of material transport, no different from our atomic process, which would give him a logarithmic relationship between time and the longitudinal strain. I do not understand how he obtains an equation differing from our linear relationship. The experiments that were plotted here were carried out for various times, a random choice of times at the various temperatures. Within the limits of experimental error, these points fall on a straight line; there is no indication of a systematic deviation which would be indicative of a logarithmic relationship. I would like to ask Dr. Kuczynski if he would elaborate on why he expects this curve to be nonlinear by his method of material transport.

G. C. KUCZYNSKI—I want to say again that I do not claim that this mechanism is the true mechanism. As a matter of fact, I do not believe that it is. It is only given for the purpose of showing that something else is possible to explain the results. We have said that we are unable to distinguish which mechanism is the true mechanism because only the time relationship will give the answer to this question. The mechanism here suggested is very similar to that of closing of the cylindrical void by diffusion flow. This will take place in order to decrease the total surface area. Similarly in this case the wire by shortening its length and increasing the radius can lower the total surface. When we plot strength against stresses we may get a very similar plot to that obtained by Dr. Shaler.

L. D. JAFFE*—I first would like to congratulate the authors because this appears, if the work is correct, to be the first reliable determination of the surface energy of a solid, and I think that is going to be of tremendous importance in the years to come. I believe this paper will lay the foundation for a great deal of research both in physical metallurgy and in the more specialized field of powder metallurgy within the next few years.

I should like to raise a question with respect to one of the basic assumptions of the authors that the specimen will remain cylindrical while it is extending or contracting longitudinally. The behavior of the wires under test should be essentially analogous to the behavior of a soap film, but a soap film under the conditions

used will not remain a cylinder. A cylindrical soap film, if permitted to deform under the influence of surface tension will attempt to break down. It will develop a waist whether there is an overall extension or contraction. In fact, if the length/diameter ratio is large, as it was in the wires, the soap film will tend to break up in a series of droplets. Now, should not the wires also tend to break up into droplets? If so, then the equations used by the authors may not be applicable, and the value obtained for the surface tension may not be valid.

Dr. Kuczynski pointed out that solid crystals do not ordinarily flow in a viscous fashion. That is quite true, but it has been established by recent work of Kê that grain boundaries do behave in a viscous fashion. However, if the deformation measured by the authors is primarily due to grain boundary flow, it should not be considered as uniform on an atomic scale throughout the specimen. Also from the experimental standpoint, it would appear that the stress-strain-time relationship would then depend on the grain size of the material. Grain sizes are not mentioned in the paper. If the grain sizes were determined, would the authors give the results in their reply?

Finally, is there any possibility that the difference in the behavior of 5 mm and of 3 mm wires might be associated with differences in relative grain size?

H. UDIN—We measured the wires as carefully as we could and found no variation in diameter. That was one of the reasons why we knotted it instead of using nicks or grooves in the wire as gauge points. However, after this paper was written, we began a new series of experiments in which we nicked the wire circumferentially with a 30° angle blade. Our nicks were at least a thousandth of an inch deep in a five thousandth's diameter wire, so we were actually inviting trouble if there was any tendency for the wire to pinch off, and in every case we found the opposite tendency. The wire tended to restore its cylindricity rather than to break up at the nicks.

As to the grain size and shape, I should like to point out that after the anneal the grain boundaries are found to be perpendicular to the axis of the wire except in a few cases of twins, and I cannot quite see for this type of configuration how any grain boundary flow can occur, or at least how it can affect the length of the wire.

A. J. SHALER—If this grain boundary flow were to take place it should lead to a saturation value of strain as you proceed to longer times. Just by accident I happen to have a slide in my pocket showing the stress-strain rate relationship from these experiments. I think that this answers partly Dr. Kuczynski's question and partly Dr. Jaffe's question. There is no evidence, I think, within

experimental error of any saturation strain at long times (which are in this case coincident with high strain rates) either in compression or tension, nor of any departure from Newton's law of viscosity.

A. A. CENTER*—I wish to say that I am very interested in this attempt to measure the surface tension of solids. I am wondering about the analogy to soap filmed drops. They do have a tendency with increasing ratio of length to diameter of necking down and then of course of breaking up into droplets. The matter of the nicks in the copper specimens tending to heal under stress is certainly a very interesting observation and will require further study. We will hope to hear further on that. I have done some work in chemistry and physics of surfaces and think this is a very interesting attempt to measure the surface tension of solids. I hope there will be further work along these lines to see if they are actually measuring either surface tension or surface energy, or something else.

J. WULFF (authors' reply)—In answer to the last comment, we have been a long time trying to find quantitative measurement for the surface tension of solids. We have been worrying in our laboratory for the last five years over how we could approach this problem and we, of course, shall repeat many of these experiments, carry them on in different atmospheres, do them with silver and gold, do them with alloys. However, we are very thankful that we were able to get this far in five years.

E. OROWAN†—I should like to discuss some remarks made during the discussion, rather than the paper itself; first, however, I would say how much I enjoyed the report on this very ingenious piece of work.

The final result does not depend on the exact nature of the law of viscous flow; in principle, the method consists of observing that particular value of the applied force at which no flow occurs.

Viscous flow in a polycrystalline metal may be either sliding of the grains upon their neighbors, or crystallographic slip ("recovery flow," due to the continued removal of strain hardening by thermal agitation). Grain boundary sliding in general slows down with time, because the unevenness of the grain boundaries resists the continuation of the sliding movement; in the present case, however, the boundaries were nearly plane. On the other hand, they were also nearly perpendicular to the axis of tension, so that boundary sliding may not have played an important part; the main part of the deformation was probably by intracrystalline slip.

FIG 7—Energy involved in slip.

One can prove that the tendency to necking, which is typical of plastic deformation governed by a stress-strain curve of the usual type, is practically absent if the deformation obeys Newton's law of viscosity. Yet it is difficult to see why cylindrical single crystals should always retain a circular cross-section during flow. If they flatten, the value of the surface energy derived from the measurement will be different from that obtained with the assumption of a circu-

lar cross-section, although the difference will amount only to a factor of order unity.

What the authors have carried out is the counterpart of the well-known soap film experiment of Dupré. Let the forces F produce slip in a crystal with the operative slip plane indicated by the dotted line in Fig 7. If the resistance to slip is of a purely viscous nature, it vanishes for infinitesimally slow deformation, and then the forces F are opposed only by surface forces. Let ω be the (free) surface energy per unit of area of the slip plane. If the displacement between the parts 1 and 2 of the crystal increases by dx , new surfaces of area $b dx$ are laid open at the re-entrant corners a , where b is the width of the slip plane perpendicular to the plane of the figure. The increase of the total surface energy is $2\omega b dx$, and this must be equal to the work done, $F dx$; hence,

$$\omega = \frac{F}{2b}$$

This is identical with the relationship between equilibrium force and surface energy in Dupré's soap film experiment.

Clearly, the surface force that resists the applied forces F in Fig 7 must be the attraction of the opposite quadrants (shaded in the figure) resolved in the slip direction. In fact, it can be proved generally that the resolved attraction of two opposite space quadrants, per unit length of the edge, is equal to the specific surface energy of their boundary planes. This theorem, however, is valid only if the material is a continuum in the sense of the classical theory of capillarity, or at least behaves like a continuum (homopolar materials may do so; to ionic crys-

tals, the theorem cannot be applied).

A. J. SHALER—I think I speak for the other authors as well as for myself in thanking Dr. Orowan for his great interest in this work and for clearing up several points so much more beautifully than I could have done it.

Concerning the question of the cylindricity I should like to bring up once again that in the measurement of the surface tension the change from a circular cross-section to an elliptical one does not matter because at the point of measurement where zero strain occurs there is also no deformation in the cross-section. Therefore, the question of the strain pattern does not influence the measurement of the surface tension (or surface energy). If the process of flow is by slip there should be a barrier stress which would give us, in the curve of strain or strain rate against stress, a discontinuity on the zero-strain axis. It is very possible that this process is the actual one operating, and that our experimental measurement cannot detect the flat portion in the curve.

We have discussed the matter of calling our value surface tension or surface energy, and we have come to the conclusion that we ought to call it surface tension, for the reason that this measurement is a mechanical one. We are dealing with a force and surface tension is a force. An energy would only be exhibited at other than zero strain. We may be wrong. We intend to make surface tension measurements on metal single crystals and on silver chloride; we may be able then to untangle some of these problems by comparing the results between ionic crystals and metal crystals.

Self-diffusion in Sintering of Metallic Particles

By G. C. KUCZYNSKI

DISCUSSION

(F. N. Rhines presiding)

A. J. SHALER* and H. UDIN*—Bonding, and the increase in contact area, form two of the series of phenomena collectively known as 'sintering.' A third one of these is involved in changes in dimensions of the whole compact. Dr. Kuczynski's Fig 1, in which the center of the sphere does not approach the surface of the plate, shows that he is not concerned with the last of these phenomena. On the other hand, Frenkel's work is exclusively concerned with changes in dimensions. Dr. Kuczynski's rather unfortunate remarks about

Frenkel's work are therefore beside the point. The work of Wulff and myself, quoted by the author, has also been primarily concerned with what we call the 'second stage of sintering,' in which such systems as may be represented by Kuczynski's model of a sphere and a block are no longer in existence. The work of Pines also falls in this category.

Neither does Dr. Kuczynski's very masterful experimental work represent a solution to the problem of bonding. It does not seek to answer the question of why particles approach one another and form a weld in the first place. Such a study clearly reveals that the area of contact is initially rapidly deformed by direct mechanical flow caused by the same force of attraction. This initial

deformation is neglected here.

On the other hand, students of the phenomena of sintering must not underestimate the very important contribution that Dr. Kuczynski does make in this paper. It is a well-worked out study of the mechanism of 'spheroidization' of the voids, the first manifestation of which, during sintering, is the growth of the areas of contact, with no change in the dimensions of the compact. This study is very valuable as a basis for predicting the development of the strength of such compacts as filters and certain porous bearings, in which the second stage of sintering is never reached.

A few more specific points may be brought up here. If, in Table 4, the data are extrapolated to zero time, it is easily

* Massachusetts Institute of Technology.

seen that x is still considerable. I believe that this initial very rapid increase in x is due to plastic flow. If the author had used values of x/a based, not on $x = 0$ at $t = 0$, but on some value, based on later measurements, of $x = x_0$ at $t = 0$, his power relations would have been lowered. Thus, whereas he demonstrates that surface diffusion and what he calls volume diffusion are the mechanisms of spheroidization because the radius of curvature at the contact area shows a 5th or 7th power time-dependence, it is possible that, by taking into account the initial rapid plastic flow, the power relation may be considerably altered. Has Dr. Kuczynski made any calculations taking this into account? It is possible that such a treatment of the data would modify the tendency towards higher-powered relationships with finer particles.

Dr. Kuczynski has sought to demonstrate that with large particles the mechanism of vacancy diffusion is predominant in the growth of the areas of contact. Frenkel's viscous-flow theory also requires that the units of flow are diffusing vacancies. Yet Kuczynski categorically states that the viscous-flow theory is not valid. I wonder if he could clarify his position in this matter. Dr. Kuczynski states that if Frenkel's viscous-flow mechanism is responsible for sintering, the relationship between the radius of the area of contact and the time of heating should be a quadratic function. Although there is an error in the numerical constant in Eq 2, taken from Frenkel, this statement is true. Experiments which are based on this relation were published last year by Wulff and myself. They show a heat of activation for the flow process (in a hydrogen atmosphere) considerably higher than that for self-diffusion, found by the author. This (I quote the author) "by no means adequate test of theory" is strongly supported by the results of the much more adequate results found by Jordan and Duwez, which were reported at this meeting, and in which the heat of activation in hydrogen is found to be 80,000 cal per mol. These figures appear to indicate that the flow mechanism in the second stage of sintering is essentially different from the spheroidization process which Kuczynski has studied here, and for which he arrives at a heat of activation of 56,000 cal per mol for copper. I believe that our experiments, and those of Jordan and Duwez, indicate the existence, in the earliest stage of sintering, of a rapid flow rate, such as in conventional primary creep, followed by a viscous flow. These mechanisms are responsible for the densification or swelling of compacts. Superimposed on these, the spheroidization of voids proceeds by the two mechanisms adduced by Kuczynski. This spheroidization contributes to the increase in strength of the compact but

cannot explain changes in density. That these two processes are going on at the same time is shown by Kuczynski's Fig 2. His calculations are based on the relation between the radius of curvature at the edge of the contact area and the x/a ratio. Fig 2a shows a large radius of curvature and a small x/a ratio. Fig 2d shows, at a higher temperature, a much smaller radius and a larger ratio. These results are in direct conflict unless two mechanisms are at work, having different heats of activation. One is predominant at low temperature (the spheroidization), the other at high temperature (the viscous flow preceded by primary creep and perhaps by appreciable instantaneous plastic flow, in fine particles). Spheroidization produced no densification; that is, the sphere center does not approach the block in Fig 2a. Plastic or viscous flow does cause densification, and the center approaches the block, as in Fig 2d. It is not fair to base such a conclusion on two pictures which Kuczynski states to be unreliable because of lack of sphericity. But further evidence that one single mechanism may not be capable of explaining his results may be found in Fig 5, which presumably refers to copper and not to silver (the caption on Fig 4 being here applicable). In this figure the points referring to the 700° experiment at 4, 8, and 41 hr have not been plotted in accordance with the data in Tables 1 and 3. If the tables are correct, the points for 8 and 41 hr should be plotted much higher, and the average of the 5 points for 4 hr should also be higher. The line through these corrected points has a much greater slope than those shown, so that the dominant mechanism at low temperatures is not the same as at high temperatures. Plotting the widely scattering points found at 600° gives, at least initially, an even greater slope.

G. C. KUCZYNSKI (author's reply)—J. Frenkel in his paper entitled "Viscous Flow of Crystalline Bodies under the Action of Surface Tension" published in *Jnl. of Physics* (U.S.S.R.) (1945) IX, 385–391 does discuss the problem of bonding or as he calls it "welding" of the crystalline spherical particles without appreciable change of dimensions. He also states in this paper that the units of viscous flow are diffusing vacancies. The flow takes place by atoms moving to these vacancies preferably in the direction of the applied force. There is however another diffusion flow which does not require this acting force. If there is a gradient of vacancy concentration in a region of the body the atoms will move into this region. This type of mechanism was assumed in my paper. Obviously the kinetics of these two mechanisms and resulting time relationships are different. Viscous flow can produce sintering in the case of glass where the relationship

$x^2 \sim t$ predicted by Frenkel was indeed observed. In the analysis of any kinetic problem the time relationship is typical and far more important than the temperature dependence. The latter one may often be misleading.

As to the specific points stressed by Dr. Shaler I have to admit that Tables 1 and 2 contain three errors, all typographical. Some of them can easily be corrected by comparison with Table 3. In one case the diameter of the interface was introduced instead of its radius.

I have replotted the results from Table 1 and 2 on nonlogarithmic scale $\left[\left(\frac{x}{a}\right)^5 / t\right]$ and obtained straight lines which all pass through the origin, except for the curve for copper heated at 700°C. The deviations at 700°C occur for small periods of time when the diameters of the interfaces are small (few microns). Under such conditions the possible error is larger than in other cases. It is therefore quite possible that these deviations are not real.

Although the method described in the paper under discussion is not too accurate it most certainly is able to distinguish between two consecutive powers of the interface diameter.

M. BEVER*—The experimental methods described in this paper are of real interest. From the standpoint of techniques, any new quantitative use of metallographic observations is an interesting and welcome development.

A question should be raised concerning the choice of atmospheres in the sintering experiments. Hydrogen is soluble in solid copper and silver and oxygen is soluble in silver. Even if these gases are considered to have only negligible effects in solution, hydrogen can reduce oxides that may be present on the surface. It is well-known that such reduction leads to surface layers of very great activity. It is desirable to exclude even the possibility of such active surface layers from experiments in which surface phenomena may play a part.

G. C. KUCZYNSKI—I was aware of this difficulty. However I have run some silver samples in hydrogen and oxygen at 700 and 800°C for the same periods of time and no difference was observed; and recently a few copper specimens were run in an argon atmosphere at 900 and 1000°C. There was not any appreciable difference between these and those heated in hydrogen. Tentatively therefore I can state that in the case of these two metals any nonoxidizing atmosphere does not seem to have an appreciable influence upon the bonding of particles.

* Massachusetts Institute of Technology.

Evaluation of pH Measurements with Regard to the Basicity of Metallurgical Slag

CHARLES W. SHERMAN* and N. J. GRANT,* Junior Member AIME

The correlation of the high temperature chemical properties of slag-metal systems with some easily measured property of either slag or metal at room temperature has been the goal of both process metallurgists and melting operators for many years.

There are several rapid methods for estimating various constituents in steel in addition to the conventional chemical methods which are quite fast, but these do not reveal the nature of the slag as a refining agent, which is of primary interest to the steelmaker.

Furthermore, there are several methods for examining slag, the three principal ones being slag pancake, petrographic examination, and the previously mentioned chemical analysis. The main objection to the last two is the time required to make a satisfactory estimate of the mineralogical or chemical components. The objection to the first is the inadequacy of the information obtained.

A new technique has been developed by Philbrook, Jolly and Henry¹ whereby the properties of slags are evaluated from an aqueous solution leached from a finely divided sample of slag. It is known that the pH or hydrogen ion concentration (of saturated solutions that have dissolved certain basic oxides, notably calcium oxide) will indicate a pronounced basicity.

Philbrook, Jolly and Henry devised the pH measurement technique in order to supply open hearth operators with a fast, reasonably accurate method of estimating slag basicity. They offered the method as an empirical observation and made no claims as to its theoretical justification. The results were presented as an experimentally observed relationship which applied over an important range of basic open hearth slags. They found

that, in plotting the measured pH against the basicity, the best relationship existed between the pH and the log of the simple V ratio, CaO/SiO_2 .

Extensive investigation also showed that there were several variables in the experimental technique that influenced the results and necessitated following a standard procedure to obtain reproducible pH readings. These variables were: 1. Particle size of the slag powder used. 2. Weight of sample used per given volume of water. 3. Time of shaking and standing allowed before the pH was measured. 4. Exclusion of free access of atmospheric carbon dioxide to the suspension. 5. Temperature of the extract at the time the pH was measured.

In subsequent investigations of the pH method by Tenenbaum and Brown² and by Smith, Monaghan and Hay³ the general conclusions of Philbrook's work were reaffirmed. It was the object of the present investigation to extend the technique to a point where it could be used to evaluate slags of all types.

Experimental Results

PARTICLE SIZE OF SLAG POWDER

A large sample of commercial blast furnace slag of intermediate basicity (V-ratio 1.15) was selected for the

study. The slag had been put through a jaw crusher until all of it passed through a 20 mesh screen. Five fractions of this crushed material were separated, -20 to +40, -40 to +60, -60 to +100, -100 to +200, and -200 mesh.

A representative sample of 0.5 g was removed from each fraction and the pH determined using the method of Philbrook. Check pH analyses on the sample fractions varied due to the different amounts of shaking. To eliminate this variable, a mechanical shaker was employed. In order to know the exact time of contact between the slag and water, it was found necessary to filter the extract at the end of the shaking period. Using the mechanical shaker and a filtering apparatus, similar runs were made on the five fractions for contact times of 5, 10, 20, and 40 min. Random checks gave reproducible results within 0.02 pH. The data are plotted in Fig 1.

It can be seen from the plot that each slag fraction is hydrolyzed to an extent that is roughly proportional to the surface area exposed to the water. The (-100 to +200) mesh material changed very little in pH after 10 min. shaking time. The curves are symmetrical and lie in proper relation to one another. The -200 mesh curve appears to be somewhat flatter than the others, but this can be attributed to the portion of very fine material that is not present in the other fractions.

The closeness of the (-100 to +200) mesh curve to the -200 mesh curve and the fact that a -100 mesh sample would contain amounts of slag down to 1 or 2 microns in diam were considered sufficient reasons for selecting a -100 mesh sample as representative of the whole sample of slag for the purposes of this investigation.

New York Meeting, February 1950. TP 2715 C. Discussion of this paper (2 copies) may be sent to *Transactions AIME* before April 1, 1950. Discussion is tentatively scheduled for publication in November 1950. Manuscript received June 17, 1949.

FIG 1—Effect of shaking time on pH for various particle sizes.

FIG 2—Effect of weight of sample on pH for various particle sizes.

EFFECT OF WEIGHT OF SAMPLE ON pH

The same commercial blast furnace slag that had been used in the study of particle size was also employed in determining the effect of weight of sample on pH. Portions of the five screen sizes were removed and weighed carefully on an analytical balance. The smallest sample taken was 50 mg and the largest sample was 500 mg. (The procedure for weighing, shaking, and filtering remained unchanged, and the time of contact between the water and the slag was held constant at 10 min.) The data are plotted in Fig 2.

It can readily be seen from the plot that the curves assume the general characteristics of potentiometric titration curves for acid-base reactions. This type of curve has a straight line portion on either side of the neutralization point. It was considered important that the sample size selected as a basis for a standard should be well within the straight line portion of the curve in order to compare different slags satisfactorily. As a consequence, the weight of sample selected as standard for the rest of the investigation was 0.5 g.

In order to shift the neutralization point further to the left, it was decided that the distilled water should be boiled to reduce the amount of acid-forming CO_2 .

Any pH value on a slag extract of less than pH 9 should be considered of doubtful value since it occurs in a region where the curve bends toward the neutralization point.

STANDARD TECHNIQUE USED FOR pH MEASUREMENT

Weigh out a representative 0.5 g

sample of slag which has been powdered so that the entire sample will pass through a 100 mesh screen. The sample should be dry and free of contamination. Weighing of each sample is recommended in order to obtain reproducible results; however, an ordinary trip balance may be used satisfactorily.

Place the sample in a clean, dry 250 ml Erlenmeyer flask. Measure with a pipette 100 ml of previously boiled, distilled water and add to the sample in the flask. As the water contacts the slag, note the time of contact. After the pipette drains, stopper the flask tightly and place in a mechanical shaker. This type of agitation prevents caking and agglomeration of the sample on the bottom of the flask.

Remove the flask from the shaker at the end of approximately $9\frac{1}{2}$ min. and pour the suspension onto a glass frit filter as the timer reaches 10 min. This sets the exact time for contact between the water and the undissolved residue remaining.

The solution should be filtered under suction in order to complete the operation as rapidly as possible. The solution is caught in a test tube suspended inside an ordinary vacuum flask. Remove the test tube and stopper it tightly. Shake well to mix the solution thoroughly. Place a 3–5 ml sample in the test cup of a precision pH meter and measure the pH of the solution with the previously calibrated meter.

The time consumed for determining the pH on each sample by this method was about 15 min. This is exclusive of the time necessary for preparation of the slag powder and the time for weighing. It was found that results could be duplicated to ± 0.03 pH as long as careful attention was paid to

the various steps in the standard technique.

CORRELATION OF pH OF BLAST FURNACE TYPE SLAGS WITH COMPOSITION

Using the standard technique, as described in the previous section, a set of slags submitted in connection with the Doctor's thesis of Gerald G. Hatch was checked.

The analyses of these slags are reported in the paper of Hatch and Chipman⁴ and will not be repeated here. In general, the slag compositions covered a much wider range of values for the four main constituents than is found in the typical commercial blast furnace bisilicate slags, but they are free of MnO . These limits of composition variation are as follows:

| | Pct |
|-------------------------------|-------|
| CaO..... | 16–52 |
| MgO..... | 0–38 |
| SiO_2 | 14–53 |
| Al_2O_3 | 0–39 |
| S..... | 0–4.5 |

Fig 3 contains a plot of the pH of each slag against its molar lime-silica ratio. In a similar manner Fig 4 relates the pH to the general molar basicity ratio, $\frac{\text{CaO} + \text{MgO}}{\text{SiO}_2 + \text{Al}_2\text{O}_3}$. These two plots are included to illustrate the diversity of the slag compositions in comparison with the slags used by Philbrook, Jolly and Henry. These authors were able to correlate their values with a plot similar to Fig 3, as were Smith, Monaghan and Hay.³ In neither instance do Fig 3 and 4 show a relationship between the chosen basicity value and the measured pH.

In Fig 5, a plot of EXCESS BASE against pH was tried. The quantity, EXCESS BASE, in this case is similar but not the same as the quantity first

FIG 3—Effect of simple $\frac{\text{CaO}}{\text{SiO}_2}$ ratio on pH for blast furnace type slags.

FIG 4—Effect of $\frac{\text{CaO} + \text{MgO}}{\text{SiO}_2 + \text{Al}_2\text{O}_3}$ on pH for blast furnace type slags.

calculated by Grant and Chipman.⁵ In this instance, a neutral slag is assumed to be of the bisilicate type, that is, $\text{MgO} \cdot \text{SiO}_2$, and $\text{CaO} \cdot \text{SiO}_2$. Grant and Chipman had selected a monosilicate slag as a neutral slag in their treatment of open hearth slag. Otherwise, the term EXCESS BASE is computed in the same manner for the study of blast furnace type slags. The main reason for selecting a bisilicate slag as a neutral slag is that it is known that monocalcium silicate is more stable with respect to water than is dicalcium or tricalcium silicate. This treatment of solid slags in no way contradicts the assumption that Grant and Chipman used to explain the behavior of liquid open hearth slags.

It should be pointed out that Fig 5 is the plot of millimols of EXCESS BASE per 0.5 g sample against pH. One of the practical limitations of this type of basicity measurement is the variation in the number of millimols of slag in 0.5 g. The replacement of CaO by large amounts of the lighter molecule of MgO will make the number increase, whereas the replacement of SiO_2 by substantial amounts of Al_2O_3 will cause it to decrease.

The aqueous solubilities of the various oxides found in slags formed the basis of the basicity value used in plotting Fig 6. It was noted that $\text{Mg}(\text{OH})_2$ had the largest of the solubility products after $\text{Ca}(\text{OH})_2$, but even its value was not of sufficient order of magnitude to seriously interfere as long as there was a reasonable amount of CaO present. The pH of a pure aqueous solution saturated with $\text{Mg}(\text{OH})_2$ can be computed and is found to be between pH 10 and pH 11, depending on the data used. The presence of $\text{Ca}(\text{OH})_2$ greatly suppresses the hydrolysis of MgO. Since the extracts

are not at equilibrium and are not saturated, it can be assumed that the MgO does not have an influence on pH's over 9.

The relationship between millimols EXCESS CaO and pH in Fig 6 seems quite good when it is realized that many of these slags are not fully matured and do not represent final equilibrium slags.

The calculation of EXCESS CaO involves the same procedure as the calculation of EXCESS BASE. After the value for EXCESS BASE has been found, it is multiplied by the CaO fraction of the total bases present in the slag. For example, if the slag contains 80 pct (molar) CaO and 20 pct (molar) MgO of the bases present, then the EXCESS CaO will be four-fifths of the calculated EXCESS BASE.

It should be repeated that the pH values found here are not equilibrium values but can be applied to a particular set of conditions. Qualitatively, it can be stated that longer shaking times would decrease the slope of the line shown in the various figures while shorter times would increase the slope.

CORRELATION OF pH OF OPEN HEARTH TYPE SLAGS WITH COMPOSITION

The same investigation that was carried out on blast furnace type slags was repeated for a set of open hearth type slags that had been used in the study of sulphur equilibria by Grant and Chipman.⁵

The composition range found in these slags is far larger than would be found in the ordinary commercial open hearth slags. The most complex slags contain varying amounts of nine different constituents.

In the calculation of EXCESS BASE for this investigation, the assumption was made again that a bisilicate slag is a neutral slag. The compounds SiO_2 , Al_2O_3 , and Fe_2O_3 were considered acidic and equivalent to each other on a molar basis. Also, the compounds CaO, MgO, FeO, MnO, CaS, and CaF_2 were considered basic and equivalent to each other on a molar basis. In order to compute the EXCESS BASE for a given weight of slag, subtract the acids from the bases and the remaining is the value for EXCESS BASE.

The calculation of EXCESS CaO is made by multiplying the EXCESS BASE by the CaO fraction of the total bases present in the slag. The compounds CaS and CaF_2 are included with CaO in computing the EXCESS CaO.

A plot of EXCESS BASE against pH is shown in Fig 7. The scatter of points is similar in appearance to that found for blast furnace type slags. There are more slags with higher pH's. A large portion of the open hearth type slags have pH values between 11 and 12 while the more neutral blast furnace slags seldom exceed a pH of 11. There is no significant correlation between EXCESS BASE and pH.

In Fig 8, EXCESS CaO is plotted against pH and the resulting straight line relationship is found to be quite similar to Fig 6, except that the points occur in the upper portion of the graph.

Fig 9 is a combination of Fig 6 and Fig 8 plotted together. The straight line relationship found in each case separately is the same for both types of slag. A close inspection of the plot will show that there are blast furnace slags that extend up into the more basic region of the open hearth slags, and,

FIG 5—Effect of excess base on pH for blast furnace type slags.

FIG 6—Effect of excess CaO on pH for blast furnace type slags.

conversely, some of the more neutral open hearth slags are found in the region of blast furnace slags.

Discussion of Results

THE pH METHOD OF ESTIMATING SLAG BASICITY

As mentioned previously, the most serious limitation in the use of the pH method as a research tool would be the variation in the number of millimols of slag in a definite weight of sample when composition varies over a wide range of molecular species of widely different molecular weights. In other words, a chemical analysis would still be necessary to check the pH results if it were expected that significant variations might occur in the low molecular weight (MgO) or high molecular weight (Al_2O_3) oxides from heat to heat.

One of the criticisms leveled against the pH method is its inability to predict V-ratios closely. This is not the fault of the pH method, but perhaps is due to the inadequacy of the V-ratio. All previous investigators of the pH method^{1,2,3} have reported some sort of correlation between the pH of the slag extracts and the V-ratio in either its ordinary or modified form. However, Smith, Monaghan and Hay³ in discussing the results of their conductance measurements infer that CaO is the controlling constituent responsible for the conductance effect. They state that it appears that the extent to which the CaO is leached out of compounds and solid solutions in the slag is in some way proportional to the V-ratio.

Since it has been found that the pH method gives a satisfactory value of EXCESS CaO, it would be expected

that EXCESS CaO and the V-ratio would not correspond in all cases. This is what was found by Philbrook. The pH method proved satisfactory for his V-ratios of 2.5 to 4.

The institution of the pH method for estimating EXCESS CaO could be accomplished with several modifications in the technique reported in this investigation.

The accurate weighing of samples would not be necessary, but since the determination would be performed by laboratory personnel, the sample could be weighed in the same manner as for the iron oxide determination which commonly uses a 0.5 g sample.

Mechanical agitation of the sample is to be preferred to intermittent shaking because it prevents caking and agglomeration of the sample on the bottom of the flask.

Boiled distilled water is a safeguard against too much CO_2 in contact with the sample. A mechanical shaker and boiled distilled water usually are employed in the steel works laboratory for the determination of phosphorus. Their use would entail the purchase of no new equipment or reagents.

The filtration of the solution after a definite time of contact between the sample and the water could probably be eliminated. This step was used to determine the exact effect of time of contact on the resulting pH. However, the desirability of a set procedure should be emphasized.

The determination of the pH of the aqueous suspensions should be performed in a section of the laboratory where there is a minimum amount of acid fume. Free H_2S , HCl , NO_2 and other acidic gases have a very deleterious effect on the pH's of the basic solutions.

ANALYSIS OF BLAST FURNACE SLAG-METAL DATA IN TERMS OF EXCESS CaO

The quantity EXCESS CaO as measured by the pH method is limited in its general usefulness unless combined with additional information to determine the EXCESS BASE value for the slag. In certain instances, this might be practical to do. Whenever other oxides such as MnO or MgO remain low or are absent altogether, the EXCESS CaO value might be combined with the chemically determined FeO content to give a reasonable estimate of overall basicity.

When the basicity of the slag has been estimated in this way, any properties that vary directly with basicity can be determined. One of the prime interests of the steelmaker is sulphur control. It is known that sulphur distribution depends on basicity of the slag. With these considerations in mind, it might be expected that the use of pH values alone to determine limiting sulphur ratios would be restricted to the case where there is no FeO present, such as the typical blast furnace slag. The slags of Hatch and Chipman⁴ used in this study were free of MnO and FeO, but contained more than residual amounts of MgO . Comparing their slags in two different ways, they found that it was necessary to make some modification in the desulphurizing effect of MgO . Both the $\frac{CaO + MgO}{Al_2O_3 + SiO_2}$ ratio and the EXCESS BASE per 100 g values showed a rather wide scatter of points when plotted against the sulphur ratio.

Realizing that Hatch and Chipman, in formulating their value for EXCESS BASE, had made many of the same assumptions that were used in this

FIG 7—Effect of excess base on pH for open hearth type slags.

FIG 8—Effect of excess CaO on pH for open hearth type slags.

FIG 9—Effect of excess CaO on pH for blast furnace and open hearth type slags.

FIG 10—Effect of excess base per mol of slag on sulphur ratio for heats of Hatch and Chipman made at 1500°C.

investigation, it was thought that a better comparison might be obtained if the slags were referred to one mol of slag instead of 100 g, since there was a significant variation in the amounts of low molecular weight (MgO) and high molecular weight (Al_2O_3) oxides present. For the calculation of one mol of slag, it was assumed that the neutralized bases, CaO , SiO_2 , MgO , Al_2O_3 , and others, were one molecular species, and the "free" or EXCESS BASE was a separate molecular species.

Fig 10 shows the effect of EXCESS BASE per mol of slag on the sulphur ratio where the CaS is considered to be a base along with CaO and MgO . The point on the line drawn represents heat H-24 which has essentially no MgO . The two points that are very close to the line represent heats H-28 and H-51 which have approximately 1.5 pct MgO in the slag. Points progressively further off the dotted line show increasing MgO content.

Fig 11 is a plot of EXCESS CaO per

mol of slag against the sulphur ratio. The CaS present is considered as a part of the CaO . The relationship in Fig 11 is very good, passing through the origin and showing very little deviation from a straight line relationship.

In this particular instance (MnO free slags), the pH value will give a satisfactory estimate of the basicity of blast furnace slags. Fig 12 shows the relationship between pH and the sulphur ratio for these slags. The log of the sulphur ratio must be plotted against pH since pH is a log relationship. The scatter of points is due to the variation of the number of millimols of slag in 0.5 g sample.

A similar plot of EXCESS CaO against the sulphur ratio for the open

hearth slags was attempted, but the relationship was extremely poor, emphasizing the necessity for additional information to obtain the value for EXCESS BASE which has been correlated previously with desulphurization.⁵

Conclusions

1. The pH of the slag extracts has been studied over a very wide range of slag compositions varying from neutral bisilicate slags of the blast furnace type to the highly basic slags achieved in the open hearth process.

2. It has been found that the pH of an aqueous solution extracted from powdered slags, using a standard tech-

FIG 11—Effect of excess CaO per mol of slag on sulphur ratio for heats of Hatch and Chipman made at 1500°C.

nique, varies directly with the number of mols of EXCESS CaO present in the sample. EXCESS CaO is defined, in a manner similar to EXCESS BASE, as the amount of CaO remaining after subtracting the total mols of ACIDS from the total mols of BASES. The CaO is considered to be present in the EXCESS BASE in the ratio:

$\frac{\text{TOTAL MOLS CaO}}{\text{TOTAL MOLS BASES}}$ The expression, EXCESS BASE, was determined on the basis of the following set of rules.

a. One mol of base neutralized one mol of acid.

b. The compounds CaO, MgO, FeO, CaS, and CaF₂ were considered basic and equivalent to each other on a molar basis.

c. The compounds SiO₂, Al₂O₃, and Fe₂O₃ were considered acid and equivalent to each other on a molar basis.

3. In addition, it has been found that the quantity, EXCESS CaO, is useful in estimating the desulphurizing power of certain MnO-free blast furnace slags for it is shown that the sulphur ratio in these slag-metal systems is controlled by the EXCESS CaO per mol of slag. For the calculation of one mol of slag, these additional rules were followed:

d. The neutralized acids were considered one molecular species.

e. The EXCESS BASES were considered a separate molecular species.

4. For MnO-free blast furnace slags,

the pH of the slag shows a close relationship to the desulphurizing ratio; however, the pH is not closely related to the desulphurizing ratio of the basic open hearth.

Melting Points in the System $\text{TiO}_2\text{-CaO-MgO-Al}_2\text{O}_3$

H. SIGURDSON* and S. S. COLE,* Member AIME

Introduction

The melting points of mixtures of titanium dioxide and other titanates have been reported to a limited extent as binary systems and some results have been reported in conjunction with silicon dioxide. The limited data indicated that a low melting zone might exist in a ternary or quaternary system of $\text{CaO-MgO-TiO}_2\text{-Al}_2\text{O}_3$, since the eutectics reported in the binary systems of $\text{MgO-TiO}_2\text{-TiO}_2$, $\text{Al}_2\text{O}_3\text{-TiO}_2\text{-TiO}_2$ and $\text{CaO-TiO}_2\text{-TiO}_2$ were of about equivalent composition of TiO_2 . The importance of a low melting region with a high titanium oxide value in the developing of high titanium slags is fully appreciated by metallurgists. A comprehensive study was undertaken to establish basic information on low melting titanate mixtures.

Compounds in the System $\text{CaO-MgO-TiO}_2\text{-Al}_2\text{O}_3$

Preparation of the titanates of CaO , MgO and Al_2O_3 confirmed reported data that the following compounds could be formed under oxidizing conditions in solid state reactions:

Under oxidizing conditions it was not possible to react MgO with TiO_2 in mol ratios higher than 1:2 without having unreacted TiO_2 in the product, nor was it possible to form calcium or aluminum titanates with a higher mol ratio of CaO and Al_2O_3 to TiO_2 than 1:1.

By fusing mixtures of $\text{Al}_2\text{O}_3\text{-TiO}_2$ and MgO-2TiO_2 together a series of solid solution products were obtained, which showed an MgO-2TiO_2 X ray diffraction pattern shifted to smaller interplanar spacings.

Range of Investigation

Data in the literature¹ indicated that these titanates had melting points which ranged from 1645 to 1860°C.

Since the purpose of the study was primarily to provide useful data for smelting titaniferous ores, the work was restricted to the zone of the system which would include the crystalline phases present in the slags. The explored limits were bounded by $\text{CaO-TiO}_2\text{-MgO-TiO}_2\text{-TiO}_2$ in the base plane. The system was extended to a fourth component $\text{Al}_2\text{O}_3\text{-TiO}_2$ since many titaniferous ores contain appreciable amounts of Al_2O_3 .

In the quaternary system $\text{CaO-TiO}_2\text{-MgO-TiO}_2\text{-TiO}_2\text{-Al}_2\text{O}_3\text{-TiO}_2$, a tetrahedron was used to represent graphically the components, with one component at each point of the tetrahedron.

In the base plane, mixtures were pre-

pared to represent fairly uniform changes of composition over the desired range expressed on a mol percent basis. $\text{Al}_2\text{O}_3\text{-TiO}_2$ was brought into the system in increments of 10 mol pct up to 40 pct. Mixtures were then made up for each of the $\text{Al}_2\text{O}_3\text{-TiO}_2$ planes. The ranges employed were then represented by five planes cutting the tetrahedron at 10 mol pct $\text{Al}_2\text{O}_3\text{-TiO}_2$ intervals.

Choice of Equipment

Although it was necessary for all smelting work to be done in a strongly reducing atmosphere, it was decided that all melting point determinations should be done under oxidizing conditions. This decision was prompted by the fact that TiO_2 reduced to lower oxides in a reducing atmosphere with consequent changes in melting points.

The use of a micropyrometer and a platinum strip furnace for work of this type is adequately described in the literature.² With modifications, equipment was selected which provided a fairly rapid method of determining melting points of refractory oxides.

The final assembly, which was used, consisted of a platinum strip furnace and a Leeds and Northrup disappearing filament optical pyrometer attached to a special telescope which magnified the sample about 20 diam.

The furnace assembly consisted of a platinum strip $0.005 \times 0.3 \times 2.2$ in. mounted on brass posts on a refractory base. This was enclosed in a black steel shell which had a 2-in. opening at the top for purposes of sighting the telescope.

The platinum strip was in series with two 0.04 ohm nichrome resistors connected to the secondary of a 2 kw transformer which supplied 17 volts. The current to the primary was varied

by means of a 35 ohm variable resistor. Large increases of current in the system were made with this resistor. Very fine adjustments were made by means of the sliding contacts on the nichrome resistors.

Preparations of Mixtures

The compounds CaO-TiO_2 , MgO-TiO_2 , MgO-2TiO_2 and $\text{Al}_2\text{O}_3\text{-TiO}_2$ were prepared from spectrographically pure TiO_2 , and cp CaCO_3 , MgO and Al(OH)_3 . Stoichiometric amounts of the components were wet mixed, dried and pelletized. The pellets were then fired in platinum at 1500°C under oxidizing conditions for 3 hr to complete transformation to the compounds in each case. Chemical analyses of the compounds showed the materials to be on composition within 0.4 pct.

These compounds were then finely ground, wet-mixed in varying amounts to give the required compositions and sintered at 1200°C for at least 3 hr to give hard sintered products.

Determination of Melting Points of Mixtures

Fragments of the sintered mixtures, which had been screened through a 100 mesh screen, were placed on the platinum strip and spread evenly to insure close contact between the platinum and the sample. The temperature of the strip was then raised rapidly to about 1000°C . Time was allowed for the sample to reach temperature stability and the temperature rise was then adjusted to about 10°C per min. until the melting point was reached.

The temperatures at which melting occurred were obtained by sighting the pyrometer on the platinum strip adjacent to the sample at right angles to the length of the strip and in line with the particles under observation. These precautions were necessary since the temperature gradient across the strip was quite steep.

The emissivity of the platinum strip in the open conditions which prevailed was considerably less than in black-body conditions so temperature corrections were applied in accordance with Table 16, p. 13, of Bureau of Standards "Pyrometric Practice" No. 170. The emissivity corrections for platinum were checked against the following substances whose melting points are reported in the literature:

| Substance | Reported Melting Point $^\circ\text{C}$ | Observed* Melting Point $^\circ\text{C}$ | Deviation from Reported Value $^\circ\text{C}$ |
|------------------------------------|---|--|--|
| Gold | 1063 | 1060 | -3 |
| $\text{Na}_2\text{Ti}_2\text{O}_7$ | 1128 | 1125 | -3 |
| BaF_2 | 1280 | 1270 | -10 |
| $\text{CaMgSi}_2\text{O}_6$ | 1391 | 1385 | -6 |
| MgTi_2O_6 | 1660 | 1645 | -15 |

* Emissivity corrections for platinum applied to observed temperature reading.

The resolving power of the telescope was sufficient to permit the observance in the fluid melts of the points at which the last solid particles became molten. In these melts the particles formed spheres very sharply at the melting point. The temperature of formation of spheres and the disappearance of the solid phase coincided. As a check, the temperature of the sample was lowered through the melting point to note the temperature of appearance of the solid phase. Good agreement was obtained.

In the range of melts which were

classified as viscous, it was difficult to determine accurately the point at which the particles became spherical, since they showed a rounding of the edges at the softening point and the transition to spheres was not nearly as sharp as in the mixtures which were fluid. Chief reliance was placed on the observance of the point at which the last observable solid particles disappeared.

Quenching of the samples did not assist in determining if the mixtures were completely molten, since the crystal growth of the titanates was so rapid that isotropic phases could not be obtained. Hence the actual determination of the points at which samples were completely molten rested very much with the judgment of the operator.

Definition of Melting and Softening Points

The following definition of the melting point of a refractory material was used,² "The melting point of an irregularly shaped refractory particle is that temperature at which the viscosity (or crystalline rigidity) is overcome by the random motion of the molecules and at which the surface tension is sufficient to draw the particle into a globular shape."

In contrast to this, the "softening" point was considered to be "the temperature at which the corners of an angular piece of the refractory substance first became rounded." At this point there would be considerable unfused material present in the particle whereas at the melting point there would be only a trace of solid material in equilibrium with the fused portion.

FIG 6—Patterns of $\text{MgO} \cdot 2\text{TiO}_2$ - $\text{Al}_2\text{O}_3 \cdot \text{TiO}_2$ and intermediate series of mixed crystals. Spectrometer, $\text{Cu K}\alpha, \lambda = 1.5374 \text{ \AA}$, 2 rpm scan.

Differentiation between Fluid and Viscous Melts

Preliminary investigation of the melting points of mixtures of the titanates disclosed, in many cases, that if a sample were heated above the melting point, the surface tension was sufficient for several neighboring spheres to migrate into one mass.

If this occurred within 100°C of the observed melting point, the mixture was classified as "fluid." If this migration did not occur within this range the mixture was classified as "viscous."

Phase Relationships

Equilibrium conditions prevailing at high temperatures were not obtained, since any possible transitions could not be prevented by the quenching method. No attempts were made to determine these equilibria by a method such as X ray diffraction studies of compounds at high temperatures.

In mixtures which had been fused and subsequently cooled to room temperature, the following compounds were observed:

1. In the base-plane $\text{CaO} \cdot \text{TiO}_2$ - $\text{MgO} \cdot \text{TiO}_2$ - TiO_2 (See Fig 1).

(a) Below the $\text{CaO} \cdot \text{TiO}_2$ - $\text{MgO} \cdot 2\text{TiO}_2$ tie-line, $\text{CaO} \cdot \text{TiO}_2$, $\text{MgO} \cdot \text{TiO}_2$ and $\text{MgO} \cdot 2\text{TiO}_2$ were present in the proportions expected from the position of the mixture on the phase diagram.

(b) Above the $\text{CaO} \cdot \text{TiO}_2$ - $\text{MgO} \cdot 2\text{TiO}_2$

tie-line, $\text{CaO} \cdot \text{TiO}_2$, $\text{MgO} \cdot 2\text{TiO}_2$ and TiO_2 were present in expected proportions.

2. In the 10, 20, 30 and 40 mol pct $\text{Al}_2\text{O}_3 \cdot \text{TiO}_2$ layers of the System (See Fig 2, 3, 4 and 5).

Melts of the mixtures falling within these four planes crystallized to give $\text{CaO} \cdot \text{TiO}_2$, $\text{MgO} \cdot \text{TiO}_2$ and mixed crystals of $\text{MgO} \cdot 2\text{TiO}_2$ and $\text{Al}_2\text{O}_3 \cdot \text{TiO}_2$. X ray diffraction studies of mixtures of the series $\text{MgO} \cdot 2\text{TiO}_2$ - $\text{Al}_2\text{O}_3 \cdot \text{TiO}_2$, which had been fused and crystallized, showed that the two compounds form a continuous series of mixed crystals. The interplanar spacings derived from X ray powder diffraction patterns of representative members of the series are shown in Table 1 and Fig 6. Similar studies of mixtures falling within the above four planes, showed shifted patterns for $\text{MgO} \cdot 2\text{TiO}_2$ or $\text{Al}_2\text{O}_3 \cdot \text{TiO}_2$ depending upon the composition of the mixture. Uncombined Al_2O_3 was never present in a melt of these mixtures.

Conclusions

(1) The melting points of the various mixtures investigated are presented in Fig 1, 2, 3, 4 and 5. Mixtures which were classified as "fluid" in the molten state are within the clear areas of each figure. Shaded areas show the compositions which were classified as "viscous" in the molten state.

(2) In the base plane $\text{CaO} \cdot \text{TiO}_2$ - $\text{MgO} \cdot \text{TiO}_2$ - TiO_2 a eutectic at 1360°C was established between $\text{CaO} \cdot \text{TiO}_2$ and

$\text{MgO} \cdot 2\text{TiO}_2$ at 40 mol pct $\text{CaO} \cdot \text{TiO}_2$ and 60 mol pct $\text{MgO} \cdot 2\text{TiO}_2$.

It was found, however, that melting points at about 1375°C were obtained with mixtures much higher in TiO_2 than this combination (for example, a mixture of 13.5 mol pct $\text{MgO} \cdot \text{TiO}_2$, 20 mol pct $\text{CaO} \cdot \text{TiO}_2$ and 65 mol pct TiO_2 had a melting point of 1375°C). This gave promise of the feasibility of working with fluid combinations much higher in TiO_2 than would be encountered with CaO and MgO additions sufficient to place the resultant mixture on the tie-line between $\text{CaO} \cdot \text{TiO}_2$ and $\text{MgO} \cdot 2\text{TiO}_2$.

3. $\text{Al}_2\text{O}_3 \cdot \text{TiO}_2$ additions up to 30 mol pct did not adversely affect the melting temperatures of the mixtures, but a shift in the zone of fluidity toward the $\text{CaO} \cdot \text{TiO}_2$ part of the system was evident.

40 mol pct $\text{Al}_2\text{O}_3 \cdot \text{TiO}_2$ additions to the system caused a sharp decrease in the zone of fluid melts and a 50 mol pct $\text{Al}_2\text{O}_3 \cdot \text{TiO}_2$ addition gave only viscous melts.

Laboratory Smelting of Titaniferous Ores

D. L. ARMANT* and S. S. COLE,* Member AIME

Introduction

The smelting of titaniferous ores for the past hundred years has not been successful because of thickening of the slags in the furnaces. The interest in the utilization of these iron bearing materials has been due to the extensive deposits which have been found in various parts of the world.¹ The literature contains references² to the use of titaniferous ores in blast furnaces. None of these attempts has met with success due to the lack of sufficient information as to the cause of failures and to economic considerations. Evaluation of the published information, as to the probable cause of failure in various attempts, has indicated that the presence of lower valence titanium oxide and formation of titanium carbide contributed to the failure. It was apparent that severe reducing conditions which are present in a blast furnace had been one of the factors for such failures. The previous smelting operations had as a primary objective the recovery of iron from these ores. Under these conditions the highest recovery of iron could only occur with severe reducing conditions.

Application of Melting Point Data

The application of the melting point data, from the system $\text{CaO-MgO-Al}_2\text{O}_3\text{-TiO}_2$ reported in another paper,³ to the smelting of titaniferous ores required an extrapolation of these melting points due to the presence of other impurities from the ores. Likewise, a study of the effect of varying FeO and reduced titanium content of the slag was necessary before the data could be fully applied. The melting point data under oxidizing conditions had clearly indicated that a fluid slag with a melting point in the temperature range of 1370°C could be obtained. The smelting of a titaniferous ore had as a

primary objective the production of a high titanium slag which was fluid and substantially free of iron and low in trivalent titanium. Since production of a high titanium slag was of primary importance, rather than the recovery of iron from these ores, the smelting concept could be altered to a marked degree. The ferrous oxide could be maintained at higher levels than is the normal practice in iron ores slags without being detrimental to the slags, although a loss in iron recovery resulted.

During the reduction of the molten mixtures of ferrous iron and titanium, carbon acts as the reductant for changing the valence of the titanium and iron. The reaction can go further than in the case of the reduction which occurs in iron-titanium solutions. The formation of metallic iron removes iron from the system, so that the titanium oxide can be reduced to trivalent and divalent titanium oxides and also form titanium carbide which removes the titanium from the slags as a soluble constituent. The problem, therefore, resolves itself into maintaining the proper amount of ferrous iron in the slag thereby avoiding the formation of appreciable amounts of trivalent titanium and no divalent titanium oxide or titanium carbide. The latter two have been found in the viscous

slags which have been made from the titaniferous ores in blast furnace operation. The avoidance of the formation of Ti_2O_3 was also an important consideration since it is known that this oxide is homologous with Al_2O_3 . It would be expected that the formation of Ti_2O_3 would cause a viscous condition in a slag since this would be equivalent to addition of Al_2O_3 . Likewise, the presence of reduced titanium in the slag was to be avoided since this was not desirable in the final solutions obtained from the digestion of the slag.

Most titaniferous ores contain as normal impurities small amounts of Al_2O_3 , MgO , CaO and SiO_2 . Since the four component system which had been studied did not include SiO_2 , it was necessary in any preliminary calculations to assume that the SiO_2 would function the same as TiO_2 . This assumption was in slight error, but the characteristics of the slag produced were not appreciably affected. The titaniferous ores which were considered of primary importance in this study were the large ore bodies which are proven deposits in New York, Canada and Norway. Typical analyses of the ores used for the smelting are given in Table 1. The amount of Al_2O_3 in these ores with reference to the TiO_2 content varies slightly. The analyses have been calculated to show the TiO_2/CaO , TiO_2/MgO , and $\text{TiO}_2/\text{Al}_2\text{O}_3$ ratios. These ratios are the basic minima that would be obtained in a slag if no flux were to be used. The same information is utilized in considering the general composition that

should be adopted from melting point data. The ratio of $\text{TiO}_2/\text{Al}_2\text{O}_3$ is the most critical in considering different ores with respect to general smelting and production of a fluid slag. This is particularly the case in ores which cannot be dressed to produce a low Al_2O_3 content.

With this basic amount of $\text{TiO}_2/\text{Al}_2\text{O}_3$ in the final slags established it is necessary only to select the area in the four component system which will yield a low melting zone and in which the aluminum oxide in the final composition would fit into this range of composition. This necessitated considering the compositions that were in the 0, 5, 10 and 20 mol pct $\text{Al}_2\text{O}_3\text{-TiO}_2$ plane. The compositions which fitted in this region are given in Table 2 and Fig 1-4 and are for the region of the highest fluidity and lowest melting points. The data in Table 2 have the greatest bearing on the titaniferous ores which have been investigated.

The weight percent is calculated so that all TiO_2 in excess is considered to be in solid solution with MgO-2TiO_2 . The areas on the 5 and 10 mol pct $\text{Al}_2\text{O}_3\text{-TiO}_2$ plane are typical for most slags produced from ores. The areas were selected for varying the CaO and MgO additions because this was the lowest melting and most fluid zone. The slags from the ores would approach the 5 mol pct $\text{Al}_2\text{O}_3\text{-TiO}_2$ with respect to minimum $\text{TiO}_2/\text{Al}_2\text{O}_3$ and TiO_2/MgO . The flux additions were calculated so that the final slag would have a general composition within these areas, after correcting for SiO_2 and FeO in the slag. The usual practice was to add the minimum amounts of flux. This practice was followed since it was desirable to have as high a TiO_2 content in the slag as possible.

Smelting Practice

The investigation was primarily divided into two sections: first, the induction furnace work and second, the single phase arc furnace. Based upon the composition diagram which appeared to give the most fluid slags, a series of mixtures were prepared in which varying amounts of CaO and MgO were incorporated using petroleum coke as a reducing agent. The use of petroleum coke was practiced in order to avoid any introduction of ash from other types of coke.

The induction furnace utilized for this work was a standard Ajax 6KW high frequency induction furnace,

using a standard 2 lb graphite crucible (3 in. od \times 2½ in. id \times 3½ in. inside height \times 4 in. outside height). The period of time for a smelting test was varied in order to establish the change in ferrous oxide content of the slag and to observe the change in fluidity as the reduced titanium content increased. Normally the one pound batch required about 30–35 min. to form a molten mixture and this was held in a fluid state for 10–20 min. before removing from the furnace. A holding time of 15 min. was found to be the time required to obtain the necessary reduction of the iron to the metal. The molten slag and metal were poured into a small metal mold and allowed to cool. The metal formed a solid button which was readily separated from the slag above it. The various heats were analysed for TiO₂ and the total ferrous iron as well as carrying out

metallographic, X ray and digestion tests.

Results Obtained

The results from a series of mixtures which were smelted in order to study the influence of composition upon fluidity of the slag are given in Table 3. The shift in mineral composition is directly related to the amount of trivalent titanium in the slag.⁴ The formation of Ti(OC) also occurs when the slag is over-reduced. The fluidity of these slags was not noticeably affected by the high Ti³⁺ content. Longer holding in the furnace, however, did cause the slags to become viscous and even formed a sintered mass, which was predominantly Ti(OC).

The change in viscosity in the slag is shown in the results given in Table 4 in which the calcium content of the

burden was varied over the range of composition which would give viscous and fluid slags based upon the melting point data observations. The observed fluidity was obtained in accordance with predictions. The calculated slag composition agrees quite well with the observed values.

The maximum and minimum amounts of CaO and MgO required to give suitable slags from various ores was then established. Since the melting point data and fluidity observations appeared to be valid, it was necessary only to delineate the general results for a given ore. These data are given in Table 5 for slags made from the three ores. The maximum amount of MgO that could be used with minimum CaO addition was not established since it was desirable to keep the MgO addition at a minimum. The slags were fluid and furnace behavior was entirely

satisfactory. This series indicated that within limits a slag could be prepared of desired composition with proper fluidity if within the area of fluidity as indicated by the melting point diagrams. The absolute maximum amount of fluxes was not determined since the objective was to produce a high titanium slag.

Arc Furnace Smelting

The induction furnace tests had shown that the formation of a fluid slag which had the necessary chemical, mineralogical and digestible characteristics could be accomplished. The application of the observations of the induction furnace to arc furnace practice was the next step. A small arc furnace was utilized which was a modi-

fied Pittsburgh Lectromelt size "X" single phase unit. The power supply was a 440 volt primary transformer with variable secondary taps. The taps used for this smelting work was 78 volts with 60 pct reactance. The usual operation of the furnace was about 40 KVA utilizing a 1¼ in. electrode. The input to the furnace was controlled by manually raising and lowering the electrode.

The furnace was lined with graphite blocks forming a hearth approximately 80 sq in. and had a depth of about 9 in. The furnace was covered and an opening for charging the furnace was allowed through the top. The slag and metal were removed from the furnace through a tap hole in the bottom.

Since the ores of primary interest were the Canadian ore from Baie St. Paul and the MacIntyre ilmenite con-

FIG 5—Progressive reduction of Baie St. Paul ore during smelting in arc furnace.

centrate the arc smelting was limited to these two materials. The burdens selected for the tests were those which had shown the best properties from induction furnace tests and were as follows:

| | Baie St. Paul, Pounds | MacIntyre, Pounds |
|---------------------|-----------------------|-------------------|
| Ore..... | 50 | 50 |
| Petroleum coke..... | 7.5 | 7.5 |
| Limestone..... | 3.4 | 4.3 |
| Dolomite..... | 2.4 | 2.4 |

The flux addition is equivalent to 5.0 parts of CaO and 1 part of MgO added to the burden for Baie St. Paul and 6.0 parts CaO and 1 part MgO for MacIntyre.

It was a regular practice to heat the furnace first by arcing the electrodes on a carbon block for about $\frac{1}{2}$ hr prior to adding the charge. Approximately $\frac{1}{3}$ of the charge was dumped into the furnace after removing the carbon block and melted down. The balance of the charge was added gradually as the melting proceeded. The total time required for charging varied from 20–30 min. In order to establish the time required to obtain the necessary reduction, samples of slags were taken at various intervals for analyses. The total smelting time varied from 2–3 hr, depending upon the general operating procedure. The temperature of the slag as it flowed from the furnace, observed with an optical pyrometer, was normally about 1500°C. The slag was tapped into a ladle in which iron settled out in the bottom and the slag formed as a separate layer on top. The slags

which had proven most satisfactory in the induction furnace could be duplicated on a larger scale in the arc furnace.

The progressive reduction of the charge in several tests made from Baie St. Paul ilmenite is given in Fig 5. The reproducibility of the smelting was fairly consistent when the power input was maintained very carefully.

Observation of the mechanics of the reduction definitely indicated that the slag and carbon were reacting. The reduction was found to be affected by type of carbon used. Coke, because of its high surface area, was better suited for a reductant than anthracite. As a result of the high secondary voltage delivered by the transformer, the electrodes could not be maintained in the slag during the final period of reduction. The change in resistivity of the slag was quite apparent and appeared to be a function of the ferrous iron content.

Summary

1. The adaptation of melting point data to slag formation is shown.
2. Ilmenites having 38–44 pct TiO_2 were smelted in laboratory to produce fluid slags with 65–69 pct TiO_2 .
3. A high titanium slag can be produced in which the formation of appreciable amounts of Ti^{3+} may be avoided.
4. The final slag with 62–69 pct TiO_2 requires 5–11 pct MgO and 9–13 pct CaO in order to have desired fluidity from MacIntyre and Baie St.

Paul ilmenites.

5. High titanium slags can be produced in an arc furnace with slag temperatures of 1450–1550°C which were identical in behavior and properties to the induction furnace slags.

Petrology of High Titanium Slags

CHARLES H. MOORE, JR.,* Member AIME and H. SIGURDSON*

Introduction

Extensive studies have been carried out on electric furnace and blast furnace slags obtained in the winning of iron from its ores. These slags normally consist of elements of the gangue minerals present in the ores, as well as the added flux materials. In consequence, melts of CaO , MgO , Al_2O_3 and SiO_2 can be considered as representing typical slag compositions. When a slag of this composition cools, it usually crystallizes according to predictions possible from an equilibrium diagram of these constituents, providing the melt is not undercooled to form glass. The melt is either viscous or fluid, depending upon the ratio of binary cations to silica, and crystallizes easily or forms a glass for the same reasons. If the melt is not overheated so that carbides of the metal components of the slag are formed and if the composition of the slag is so adjusted that it has a high fluidity, liquid equilibrium is attained and the slag can be held in a liquid state for extended periods of time. Upon tapping, the slag crystallizes into minerals, the type and proportion of which are determined by the melt composition. Since equilibrium is attained, the holding period is not critical.

In melts containing a large increment of titanium, however, the normal slag procedures are not applicable. Titanium, as one of the atomic transition elements, is, at elevated temperatures, capable of being reduced to form metalloid compounds much more readily than the refractory oxides present in normal slags. In consequence, an oxide melt containing titanium never reaches equilibrium in a reducing environment, but continues to shift its composition until cooled. If melts of this nature are cooled and samples submitted to metallographic and X ray analysis the course

of reaction and crystallization in this type of slag can be determined.

Preparation of Slag

The slags investigated fell into the system $\text{CaO-MgO-TiO}_2\text{-Al}_2\text{O}_3\text{-SiO}_2$ and were produced from ilmenite ores reduced by carbon in an electric furnace. Since the equilibrium series¹ and the laboratory smelting of ilmenite² are described in two of the accompanying papers, detailed description of the smelting procedure is not required here. However, certain essentials must be mentioned.

Two types of melts were used to produce slags studied in this investigation. The first series of smelts made to determine proper flux addition were produced in a 4 lb Ajax induction furnace. The charge, consisting of ore with the proper flux addition, was heated in a graphite crucible until fluid, held fluid for a sufficient time period to obtain 1-5 pct FeO content, and poured. Because of the small size of the charge only the final sample of these melts could be examined. In the melts made in the 50 lb arc furnace, however, grab samples taken at 10 min. intervals between time of initial melting and final pouring were available for examination. These samples allowed a much clearer picture of the course of reaction and crystallization.

amounts of ferrous oxide and reduced titanium compounds is opaque to transmitted light. Therefore, all petrographic studies had to be made on polished slag sections. A representative sample of slag was cut or broken, mounted in a thermosetting plastic, ground flat using 400 grit silicon carbide, the coarse scratches removed with 600 grit silicon carbide and polished on billiard cloth using levigated alumina. Rouge was avoided because of the entrainment of the red particles in pores in the slag, causing a possible confusion with some of the mineral phases. In order to prevent sample projection above the plastic surface red bakelite was used to hold the sample, and backed up with clear lucite. In this manner sample labels could be permanently retained in the mounting. The polished samples were examined on a Bausch and Lomb metallograph at magnifications of 250 \times , 500 \times , 1000 \times and 1800 \times . The instrument was equipped for examination of specimens under bright field illumination and with crossed nicols. A magenta tint plate to aid in color tone differentiation was also used.

Petrology of Slags

In order to determine the composition and mineral relations of a previously unreported system petrologically, it is essential that the starting composition, reaction temperature and final composition be known. The chemical composition of the ilmenite ore used in these smelts is given in Table 1, and the complete analysis of a typical high titanium, low iron slag is given in Table 2.

In the winning of TiO_2 from ilmenite by a smelting process it is necessary to produce a slag which will melt at an economically feasible temperature, remain molten as the iron is removed by reduction, be fluid enough to be readily removed from the furnace, contain a high percentage of TiO_2 and a low percentage of reduced titanium com-

FIG 1—Micrograph of slag sample No. 1. X 500.

Slightly reduced in reproduction. The slag at this early stage of reduction contains 16.2 pct FeO and 58.8 pct TiO₂. The presence of this amount of ilmenite indicates that reduction of the slag has not progressed to the desired final composition. Mineralogical composition is as follows:

I—20 pct ilmenite
C—10–20 pct CaO·TiO₂
M—50–60 pct (Fe, Mg)O·2 TiO₂
G—10 pct silicate glass
S—Small amount Fe, FeS, etc.

pounds, and be amenable to digestion in sulphuric acid. In light of the melting data obtained in the accompanying paper on slag equilibria it is apparent that at least part of these requirements was fulfilled by the additions of lime and magnesia fluxes to ilmenite.

Course of Reduction

As ilmenite is heated with carbon, the iron begins to reduce to metal at

1000°C, by a solid state reaction, leaving a composition that appears to be FeO·2TiO₂. At 1150°C, and when the amount of FeO·2TiO₂ reaches 70 pct an apparent eutectic occurs in the system FeO·TiO₂–FeO·2TiO₂ and the charge becomes pasty.*

If reduction continues, the charge remains pasty until the temperature reaches 1450°C. Here a probable equilibrium between FeO·TiO₂, (Fe,Mg)O·2TiO₂ and calcium magnesium silicate makes the melt fluid. If frozen at this point, the slag consists of ilmenite, FeO·2TiO₂ (probably with some magnesium replacing the iron), minor amounts of CaTiO₃ and a glass. The FeO content of such a slag is 11–14 pct. If reduced further the last skeletal crystals of ilmenite disappear at 7–8 pct FeO and the slag consists of a (Fe,Mg)O·2TiO₂ structure and CaTiO₃ (near the 60–40 eutectic proportion)

* Grieve and White² indicate two eutectics and only pseudobrookite and ilmenite in the thermal equilibrium diagram FeO–TiO₂. However, they mention an undetermined amount of Fe₂O₃ in their system. We have found that if conditions are sufficiently oxidizing to transform FeO to Fe₂O₃, the compound FeO·2TiO₂ does not form, being replaced by ilmenite or pseudobrookite and rutile. If the compound FeO·2TiO₂ (with minor amounts of magnesium in solid solution) is heated to 500°C in air it dissociates to pseudobrookite and anatase. This indicates that the (Fe, Mg)O·2TiO₂ structure is stable only when deficient in oxygen.

FIG 2—Micrograph of slag sample No. 2. X 500.

Slightly reduced in reproduction. The slag at this stage of reduction contains 13.3 pct FeO and 60.3 pct TiO₂. Ilmenite still remains in sufficient quantity as acicular particles to indicate the reduction has not progressed to the optimum composition. The mineralogical composition is as follows:

I—10–15 pct ilmenite
C—10–20 pct CaO·TiO₂
M—50–60 pct (Fe, Mg)O·2TiO₂
G—10 pct silicate glass
S—Small amount of Fe, FeS, etc.

and glass. $(\text{Fe,Mg})\text{O}\cdot 2\text{TiO}_2$ is the primary phase, CaTiO_3 the secondary phase and finally, an interstitial glass, which may on slow cooling partially devitrify to poorly crystallized silicates. As reduction proceeds, the mineralogical relationship of the constituents remains essentially the same except that iron is isomorphously replaced by magnesium in the compound $(\text{Fe,Mg})\text{O}\cdot 2\text{TiO}_2$. However, as the iron content of the slag system falls below 3 pct the titanium begins to reduce. If frozen here the slag is still amenable to processing, but the compound is designated as MgTi_3O_8 . As the loss of oxygen from the system continues the $\text{MgO}\cdot 2\text{TiO}_2$ type structure is no longer stable and shifts to a structure designated as MgTi_2O_4 . When this occurs, the melt becomes more refractory and hence less fluid and is no longer amenable to standard sulphuric acid digestion procedure. The slag is then called "over-reduced." If reduction is allowed to continue $\text{Ti}(\text{O,C})$ and finally TiC , are formed and the melt freezes. As far as can be determined, the amount and composition of the CaTiO_3 remains constant, from its first crystallization in eutectic proportions, throughout the course of reduc-

FIG 4—Micrograph of slag sample No. 4. $\times 500$.

At this stage of reduction the slag contains 4.9 pct FeO and 67.8 pct TiO_2 . The presence of the MgTi_3O_8 phase indicates slight over-reduction of the $(\text{Fe,Mg})\text{O}\cdot 2\text{TiO}_2$ phase which apparently is not detrimental to optimum digestion of the slag. Mineralogical composition is as follows:

C—20–30 pct $\text{CaO}\cdot\text{TiO}_2$
M—60 pct $(\text{Fe,Mg})\text{O}\cdot 2\text{TiO}_2$
5 pct MgTi_3O_8 (not evident at $\times 500$)
G—10 pct silicate glass
S—Small amount Fe, FeS, etc.

FIG 3—Micrograph of slag sample No. 3. $\times 500$.

The slag now contains 8.7 pct FeO and 63.8 pct TiO_2 . It has now been reduced almost to the optimum composition since ilmenite remains only as small crystals surrounding the $(\text{Fe,Mg})\text{O}\cdot 2\text{TiO}_2$ phase and no over-reduction of the dititanate phase is evident. The mineralogical composition is as follows:

I—5 pct ilmenite
C—20–30 pct $\text{CaO}\cdot\text{TiO}_2$
M—50–60 pct $(\text{Fe,Mg})\text{O}\cdot 2\text{TiO}_2$
G—10 pct silicate glass
S—Small amount Fe, FeS, etc.

tion. The series of micrographs shown in Fig 1 through 5 illustrates the course of reduction but does not in all cases indicate the proportions of phases present in the melts. The representative phase proportions were determined from a large number of samples.

Mineral Phases

The isomorphous series $\text{FeO}\cdot 2\text{TiO}_2$ – $\text{MgO}\cdot 2\text{TiO}_2$ is by far the most interesting mineral phase in this type of slag. It not only is the primary crystallization phase in the slags, but incorporates the greatest amount of titanium in the system. The shift from $\text{FeO}\cdot 2\text{TiO}_2$ to $(\text{Fe,Mg})\text{O}\cdot 2\text{TiO}_2$ is continuous and occurs as iron is removed from the system. This composition shift is difficult to detect. It is distinguished microscopically only by a change in color of the laths from dark gray to light gray as the amount of iron is decreased. X ray powder patterns of $\text{FeO}\cdot 2\text{TiO}_2$ and $(\text{Fe,Mg})\text{O}\cdot 2\text{TiO}_2$ are apparently identical.

Under reducing conditions $\text{MgO}\cdot 2\text{TiO}_2$ is not stable and always contains vacant titanium equipoints. As

mentioned above, the formula MgTi_3O_6 is assumed and is used to indicate this. The structure and habits of this compound are identical with $\text{MgO} \cdot 2\text{TiO}_2$ and are not distinguishable by X ray powder patterns. Under reflected light the color is a very light gray with a pink tone.

The next reduction stage, however, is readily distinguished under the microscope. It is a dark red to purple in reflected light and assumes a quadratic habit. Although the structure has not been completely delineated it is apparently cubic and has been assigned the probable formula MgTi_2O_4 .

The flexibility of the structure which is called " $\text{MgO} \cdot 2\text{TiO}_2$ type" is indicated by its ability to lose iron, gain magnesium and lose oxygen, and still preserve its identity.

There are indications that it is capable of far more flexibility. It was shown early in the investigation that the amount of TiO_2 determined chemically to exist in these slags was not accounted for by the $(\text{Fe}, \text{Mg})\text{O} \cdot 2\text{TiO}_2$ and CaTiO_3 present. In consequence a series of synthetic slags was prepared under both reducing and oxidizing conditions in which the proportions MgO to TiO_2 were varied.

Under oxidizing conditions, no success has been obtained in attempts to form magnesium titanates higher in TiO_2 than $\text{MgO} \cdot 2\text{TiO}_2$. All attempts to form $\text{MgO} \cdot 3\text{TiO}_2$ have given $\text{MgO} \cdot 2\text{TiO}_2$ and rutile.

Under strongly reducing conditions, however, it has been found that the $(\text{Fe}, \text{Mg})\text{O} \cdot 2\text{TiO}_2$ structure will take TiO_2 into solid solution up to explored limits of the order of 12 mol of TiO_2 per mol of $(\text{Fe}, \text{Mg})\text{O}$, without a breakdown in structure. The solid solution compound with TiO_2 values of this order has been produced readily during smelting of low gangue ilmenite ores and also from mixtures of Fe_2O_3 , MgO and TiO_2 . X ray examination of the compound shows a shift in the structure to larger interplanar spacings (for example, $(\text{Fe}, \text{Mg})\text{O} \cdot 12\text{TiO}_2$ showed a strong line at 1.894\AA in contrast to the typical line at 1.876\AA in $\text{MgO} \cdot 2\text{TiO}_2$ and $(\text{Fe}, \text{Mg})\text{O} \cdot 2\text{TiO}_2$).

Oxidation of the $(\text{Fe}, \text{Mg})\text{O} \cdot 2\text{TiO}_2$ ($\text{Fe}, \text{Mg})\text{O} \cdot 12\text{TiO}_2$ series in air at 500°C for several hours causes a breakdown in the structure to the compounds which are stable under oxidizing conditions. These compounds are Fe_2O_3 , TiO_2 , $\text{MgO} \cdot 2\text{TiO}_2$, $\text{MgO} \cdot \text{TiO}_2$ and TiO_2 . At 500 – 800°C the TiO_2 is present as anatase. At temperatures higher than 800°C , the TiO_2 which is crys-

FIG 5—Micrograph of slag sample No. 5. $\times 500$.

At this stage of reduction the slag contains 1.0 pct FeO and 70.7 pct TiO_2 . The presence of the MgTi_2O_4 stage indicates serious over-reduction of the $(\text{Fe}, \text{Mg})\text{O} \cdot 2\text{TiO}_2$ phase and this phase is detrimental to optimum digestion. Mineralogical composition is as follows:

C—20 pct $\text{CaO} \cdot \text{TiO}_2$
M—20–30 pct $(\text{Fe}, \text{Mg})\text{O} \cdot 2\text{TiO}_2$
M-R—30–40 pct MgTi_2O_4
G—15 pct silicate glass
S—Small amount Fe, FeS, etc.

tallized from the $(\text{Fe}, \text{Mg})\text{O} \cdot 2\text{TiO}_2$ structure exists as rutile.

The fact that TiO_2 cannot be retained in the structure under oxidizing conditions indicates that the solid solution of TiO_2 in the dititanate struc-

ture is possible under reducing conditions because of an oxygen deficient lattice in the dititanate. Data on the degree of oxygen deficiencies in the lattice have not been completely determined.

Under oxidizing conditions there is a continuous solid solution series Al₂O₃-TiO₂-MgO.2TiO₂ as discussed in the accompanying melting equilibria paper. Under reducing conditions Al₂O₃ is taken into solid solution in the (Fe,Mg)O-2TiO₂ structure up to approximately 20 pct by weight, without the formation of Al₂O₃-TiO₂. This solid solution compound shows a considerable shift in the structure to smaller interplanar spacing (for example, the shift is from 1.876Å for normal MgO-2TiO₂ or (Fe,Mg)O-2TiO₂ to 1.854Å for (Fe,Mg)O-2TiO₂ with 20 pct Al₂O₃ (by weight) present in solid solution. Fig 6 shows X ray powder pattern comparisons of the effects of solid solution of TiO₂ and Al₂O₃ on the (Fe,Mg)O-2TiO₂ structure. Additions of over 20 pct Al₂O₃ gave the above solid solution compound and Al₂O₃-TiO₂. The line position for Al₂O₃-TiO₂ in this region of the X ray pattern is 1.792Å. Table 3 shows the d/n values for these compounds.

No change in the structure of the compound from the normal (Fe,Mg)O-2TiO₂ is discernible under the metallographic microscope when TiO₂ or

Al₂O₃ are present in solid solution even at the higher values of these oxides.

CaTiO₃ apparently always crystallizes as the secondary phase in the range of composition used in slag formation. These crystals are cubic in crystallization, quadratic in habit and usually the only colorless constituent of the slag. In slag samples which were quickly frozen the CaTiO₃ occurs as skeletal outlines in the glass. In slowly cooled slags the large cubic crystals are fully developed. No evidence of structural shift or solid solution in CaTiO₃ was observed at any reduction stage by either X ray diffraction patterns or petrographic character.

The role of the silicate glass in these melts is rather ambiguous. It apparently helps fluidization of the melt by incorporating at least part of the alumina to form a probable FeO-CaO-Al₂O₃-SiO₂ melt. The index of refraction of the glass preserved in the quickly frozen slags is ±1.55. The silicates which are observed in the slowly cooled slags are so poorly crystallized that their identity could not be determined.

Table 4 is a compilation of the opti-

cal properties in reflected light of the phases which occur in titanium bearing slags when fluxed with lime and magnesia.

Acknowledgment

The writers wish to express thanks to Dr. S. S. Cole, Assistant Research Manager, Titanium Division, National Lead Co., for technical suggestions and aid in preparation of the paper and to Mr. C. H. North of the Research Laboratory for the X ray data which have been of great value in this investigation.

Notes on the Electrolytic Isolation of Carbides in Steel

GUSTAF WRANGLÉN*

On account of the possibility of isolating carbides in steel it is generally assumed that the electrode potential of iron carbide is more noble than that of ferrite.^{1,2,3,4,5} Differences from 0.032 V¹ to 0.4 V⁴ have been recorded. However, it is important to realize that the more noble behavior of

cementite in relation to ferrite is not

Technical Note No. 28 E.

¹ References are at the end of the paper.

an issue of thermodynamics but of reaction kinetics. Theoretically, cementite is less noble than ferrite, which is a direct consequence of its thermodynamic instability. With the value ΔF^o₂₉₈ = +4700 cal per mol for the free energy of formation of cementite⁶ it is easily calculated that the electrode

potential of the reaction $\text{Fe}_3\text{C} = 3\text{Fe}^{2+} + \text{C} + 6\text{e}^-$, found to be the relevant one, particularly in neutral solution,⁵ is -0.47 V (cf. $e^\circ_{\text{Fe}} = 0.44\text{ V}$). There are great hindrances to this reaction, however, implying a slow reactivity, which has to be termed high chemical polarization in this case. Hence, the electrolytic isolation of iron carbide is *not* a parallel to the retention of noble metals as an anode slime in electrolytic refining.

It is evident, furthermore, that the reaction referred to cannot be even chemically reversible, the less so thermodynamically. An equilibrium corresponding to the computed figure will never be reached. On measurement more noble and varying values will be obtained. These static potentials are of minor interest. It would be more valuable to determine the actual dissolution potentials during electrolysis and then select those conditions for separation, under which the difference between the dissolution potentials of cementite and ferrite is the greatest.

Structure is the most important factor influencing the isolation. If the carbide is present as large spheroid particles it is fairly insensible to varying conditions of electrolysis. If the structure is unfavorable (lamellar pearlite, cementite network) the operating conditions become important. Current density has to be kept fairly high in order to bring down the time of electrolysis. Elevation of temperature greatly diminishes the chemical polarization of iron but the same applies to cementite. Chemical attack by the electrolyte also increases strongly with rising temperature. The latter has to be kept low, therefore, and the anodic polarization of iron has to be reduced by other means, such as presence of chloride ions stirring, frequent removal of carbide and possibly superimposed alternating current.^{7,8}

The most effective stirring is rotation of the anode, preferably cylindrical, but this is usually not enough to remove the carbide particles. The specimen has to be scraped or at least knocked now and then. A brush in contact with the rotating specimen often gives poorer results, presumably

due to disaggregation of carbide, increasing its reactivity. If hydrochloric acid is employed as electrolyte, evolution of hydrogen occurs even at the anode and aids in loosening the carbide. In this case the carbide ought to be better protected on the anode than out in the solution to begin with. In no case, however, must the carbide remain on the anode to form a thick layer since that causes the current density and anodic polarization to be greatly increased and then the carbide also will begin to dissolve.

Regarding the electrolyte there is a wide-spread erroneous theory for the choice of anion. Treje and Benedicks^{9,10} used sodium citrate as an electrolyte for isolation of both slag inclusions and carbide. With this electrolyte alone they expected to get oxygen evolution at the anode. They therefore wanted to add another anion that might be discharged instead of oxygen. They considered the electrode potentials SO_4 1.90, Cl 1.34, O 1.33, Br 0.99 and I 0.52 V and concluded from them that sulphates and chlorides could not be used as they would not exclude oxygen evolution. The only rational anions would be Br and I which are discharged more easily than oxygen.

As far as the author has been able to find there have been no objections to this theory but it has been widely spread in the literature^{3,11,12,13,14} and has exerted a great influence. Electrolytes containing bromides and iodides have been employed in a great many investigations, particularly by German workers.

In reality, however, the quoted anion potentials have nothing to do with the dissolution of iron. The electrode potential of significance is that of iron itself, -0.44 V . Discharge of hydroxyl ions or other anions will occur only at very high current densities if the iron salts formed at the anode are not removed quickly enough or if the anode becomes passivated. Chloride ions are a very good means for counteracting passivity and a chloride, such as hydrochloric acid or ammonium chloride, is therefore a very suitable electrolyte. There are no valid reasons for using

bromides or iodides. Furthermore, iodide solutions are easily decomposed under the formation of iodine which attacks the carbide.

To support their theory, Treje and Benedicks⁹ carried out some potential measurements. In a FeBr_2 -solution at $2\text{--}4\text{ A/dm}^2$ they normally found anode potentials as high as $0.70\text{--}0.79\text{ V}$, that is, somewhere between the electrode potentials of iodine and bromine. However, these values are erroneously calculated, since the authors failed to see that the anode potential was negative in relation to the calomel electrode and hence added 0.286 to the positive value of the bridge reading instead of to its negative value. Recalculated, the true values are -0.22 to -0.13 V . Similar results were obtained in a control measurement by the author. In German literature^{15,16} there is a precept that the anode potential should be kept below $+0.50\text{ V}$ in order to exclude oxygen evolution. Presumably, this high limit originates from the erroneous figures referred to. As shown above, the anode potential need not and should not be higher than -0.3 to -0.2 V .

Effect of Prestraining Temperatures on the Recovery of Cold Worked Aluminum

T. E. TIETZ,* R. A. ANDERSON* and J. E. DORN,* Member AIME

Introduction

Recent investigations^{1,2,3,4} have conclusively shown that the strain hardened state of metals depends upon the temperature and strain rate of prestraining as well as on the total plastic strain. A typical example of the effect of temperature of prestraining on the work hardening of metals is reproduced in Fig 1. When pure aluminum is strained at liquid nitrogen temperature the upper solid stress-strain curve (OFGH) is obtained. But when pure aluminum is prestrained to $\epsilon_2 = 0.153$ at atmospheric temperature and the test is then completed at liquid nitrogen temperature, the curve OBCD results. Thus a prestrain $\epsilon_2 = 0.153$ at atmospheric temperature gives a flow stress *C* when continued at liquid nitrogen temperature, whereas a higher flow stress *G* results when the specimen is strained exclusively at liquid nitrogen temperature to the same strain ϵ_2 . Consequently the metal strain hardens more rapidly at the lower temperature. Obviously the strain alone is not a measure of the strain hardened state in metals.

Inspection of Fig 1 reveals that the flow stress at *C* is identical with that at *F*. This fact suggests that a strain $\epsilon_2 = 0.153$ at atmospheric temperature induces the same work hardened state as a strain $\epsilon_1 = 0.058$ at liquid nitrogen temperature. But this concept of equivalent strains is also in error. If curve *CD* is shifted to the left so that point *C* falls on *F*, point *D* becomes *D'*. Inspection of the curves reveals that the rate of increase of stress with strain at *C* is greater than the rate of increase of stress with strain at *F* even though the flow stresses are identical. Consequently *C* and *F* do not represent

FIG 1—Effect of temperature of straining on the strain hardening of pure aluminum (99.987 pct).

identical work hardened states. It therefore becomes important to ascer-

tain how the strain hardened states at *C* and *F* might differ from each other.

In a more recent report⁴ it was shown that straining at higher rates of strain increases the amount of strain hardening in a manner quite analogous to straining at lower temperatures. These observations suggested that the flow stress is not only a function of the strain but also a function of the strain rate-temperature history of straining, perhaps in accord with the Zener-Hollomon parameter $p = \dot{\epsilon} e^{\frac{\Delta H}{RT}}$ (where

FIG 2—Method of evaluating the recovery.

e = base, natural logarithm, and $\frac{\Delta H}{RT}$ is an exponent of e). If then a specimen is strained ϵ_1 at ρ_1 and ϵ_2 at ρ_2 etc., the flow stress might be given by

$$\sigma = \sigma(\epsilon_1, \rho_1; \epsilon_2, \rho_2; \dots)$$

Such concepts have practical utility for correlation and analyses of data but they fail to identify the fundamental causes for the effect of strain rate and temperature histories on the strain hardening of metals.

The well known effect of the strain hardened states of metals on their recovery rates suggested that a more complete identification of the effect of strain rate and temperature histories on the strain hardening of metals might be obtained from recovery tests. Preliminary data from two recovery tests¹ appeared to confirm this thought. The tests described in the following pages of this report were made in order to obtain more conclusive evidence on the effect of temperature of prestraining on the recovery of the flow stress.

Materials and Testing Techniques

Pure aluminum (99.987 pct Al) was selected for these studies in order to minimize the effect of such factors as strain aging on the interpretation of

the data.

All of the tests were performed with equipment previously described in the literature.^{2,4} Strains were measured to 0.001 and stresses were determined to about ± 25 psi. All recorded data are given in terms of true stresses and true plastic strains.

Method of Evaluating the Recovery

The procedure used to determine the amount of recovery in this investigation is shown schematically in Fig 2. A specimen strained exclusively at liquid nitrogen temperature has the true stress-true plastic strain curve OFF' whereas a specimen strained to ϵ_2 at some higher temperature T_2 and then immediately tested at liquid nitrogen temperature gives the curve $OABB'$. Thus a prestrain ϵ_2 at T_2 gives the same flow stress (B) at liquid nitrogen temperature as is obtained by straining exclusively at liquid nitrogen temperature to ϵ_1 . If the strain hardened states at B and F are identical the recovery rates of the two specimens should also be identical. But if the recovery rates are dissimilar the strain hardened states must be different even though the flow stresses are approximately the same at liquid nitrogen temperature.

The recovery of specimens prestrained to ϵ_1 at liquid nitrogen temperature was obtained by aging the specimens at some appropriate temperature for various times and then testing again at liquid nitrogen temperature. In this way a series of curves GG' , HH' , etc. were obtained for the partially recovered material. For the data reported here these curves exhibited a sharp knee at the yield stress so that rather accurate determinations of the stresses G , H , I , etc. were obtainable by extrapolation to zero additional plastic strain upon restraining after recovery.

One complication arose in the analyses of the recovery data. Due to minor variations in properties from specimen to specimen, the flow stress F after prestraining to ϵ_1 at liquid nitrogen temperature was not quite the same for all specimens. The F value, however, was obtained for each specimen as well as the recovered stress, for example, G . The amount of recovery was then calculated as $F-G$ for each specimen. In this way the effect of minor variations from specimen to specimen on the calculated amount of recovery was reduced to a negligibly small value.

A somewhat similar procedure was used to determine the recovery after prestraining an amount ϵ_2 at a temperature T_2 . In order to evaluate the

FIG 3—Effect of prestraining at various temperatures on the flow stress at liquid nitrogen temperature.

amount of recovery on a comparable basis, all tests after a recovery treatment were conducted at liquid nitrogen temperature, providing in this way curves CC' , DD' , etc. The stress A differed slightly for each specimen strained to the same value ϵ_2 but stress B was found to vary in an analogous way so that $B-A$ was substantially constant. This value was then used as a basis for calculating the amount of recovery. A specimen to be treated for recovery was strained to ϵ_2 and the stress A for the specimen was measured. After recovery the stress-strain curve CC' was obtained at liquid nitrogen temperature. In this way $C-A$ was determined for the recovered specimen. The amount of recovery was then calculated as $(B-A) - (C-A)$.

Experimental Data

The question of prime interest in the present study concerns possible differences in the work hardened state as revealed by recovery experiments after the metal has been subjected to various prestraining histories of such extent that the instantaneous flow stress is

constant. If different recovery rates are obtained for specimens that have been so prestrained that their flow stress at liquid nitrogen temperature is about 12,500 psi, it follows that the instantaneous flow stress under constant conditions of temperature and strain rate is not a measure of the work hardened state. Under such conditions the relative rates of recovery for the various prestraining treatments will serve to qualify the existing differences in the work hardened states that were generated. In order to permit this evaluation the metal must be prestrained just that amount at various temperatures to give a constant flow stress (12,500 psi in the following tests) when the test is continued at liquid nitrogen temperature. The conditions of prestraining used to accomplish this are shown in Fig 3. Prestraining to 0.252 at 296°K, 0.203 at 273°K, 0.137 at 194°K and 0.081 at 78°K gave approximately the same flow stress of 12,500 psi when the temperature was changed rapidly from that for prestraining to liquid nitrogen. In all cases the transfer to liquid nitrogen temperature was accomplished in less than 15 sec in order to reduce the

amount of recovery that might have occurred during the transfer interval.

It is significant to note that the two specimens prestrained at atmospheric temperature (296°K) gave slightly different stress-strain curves, but that the differences between the flow stress at liquid nitrogen and room temperatures were $12,750 - 9,890 = 2,860$ psi, and $12,450 - 9,630 = 2,820$ psi respectively, which are identical within the limits of experimental error. Similarly the difference in flow stress at liquid nitrogen (78°K) and CO_2 -acetone (194°K) for the two specimens prestrained at CO_2 -acetone temperature $12,475 - 10,270 = 2,205$ psi and $12,250 - 10,060 = 2,190$ psi which is again within the limits of experimental error. These data suggest that the effects of sampling can be largely eliminated by the procedure previously described for calculating the amount of recovery.

The recovery data are recorded in Fig 4 and 5. The amount of recovery was determined by the decrease in the flow stress at liquid nitrogen temperature upon recovery as described previously. Although there is some scatter in the data, the results are nevertheless

FIG 4—Effect of prestrain temperature on recovery at 273°K.

less conclusive. At 273°K the rates of recovery were relatively slow whereas satisfactorily higher recovery rates were obtained at 305°K. At both of these temperatures the specimens prestrained at 273 and 296°K presented approximately identical recovery rates indicating thereby almost identical work hardened states. But for both of the recovery temperatures used here the specimens that were prestrained at liquid nitrogen temperature (78°K) recovered most rapidly. Fig 6 shows the recovery data at 305°K on a log-log plot. As shown in Fig 4 and 5 the specimens prestrained at CO₂-acetone temperature (194°K) recovered at an intermediate rate.

The data recorded in Fig 4 and 5 reveal that the high purity aluminum used in these tests recovers somewhat at atmospheric temperature after prestraining at atmospheric temperature. Such recovery must, therefore, also occur during the straining. It might, therefore, appear that the observed differences in the recovery rates after various prestrain histories is attributable to the possibility that recovery occurring during prestrain reduces the subsequent recovery for those specimens prestrained at the higher temperatures. In Fig 7 are shown recovery tests at the testing temperature for 273, 194, and 78°K. Although recovery does occur at 273°K in 1 hr, no recovery was detected in 4 hr at 194°K or in 1 hr at 78°K. Evidently the data obtained by prestraining at 78 and 194°K are not clouded by possible recovery during prestraining. Therefore, evidence is substantial that metal prestrained at the lower temperature recovers more rapidly than metal prestrained at a higher temperature even when the two conditions of prestrain-

ing result in the same instantaneous values of the flow stress at the lower temperature.

It is possible of course that greater rates of recovery are induced by the applied stresses during prestraining. In order to test this thought six recovery tests were made under stresses approximating the yield stress at the recovery temperature. No indication of a significant effect of stress on the rate of recovery was detected, thereby disqualifying this suggestion.

Discussion of Results

The preceding experimental data reveal that high purity (99.987 pct Al) aluminum work hardens more rapidly for lower temperatures of prestraining. By appropriate selection of the amount of prestraining for each prestrain temperature it is possible to induce a work

hardened state that gives the same flow stress when straining is continued at liquid nitrogen temperature. In order to accomplish this, the specimens must be prestrained a greater amount for the higher prestraining temperatures. Although the instantaneous flow stresses at liquid nitrogen temperature are adjusted to the same value by this procedure, the rates of strain hardening differ systematically for the various prestraining temperatures. Specimens prestrained at the higher temperatures have higher rates of strain hardening for identical flow stress when they are subsequently tested at liquid nitrogen temperature. This fact suggests that although the flow stresses are the same, the work hardened states nevertheless differ in some yet obscure way as a result of the previous prestrain temperature history.

Specimens prestrained at the higher temperatures to a strain that induces a fixed flow stress at liquid nitrogen temperatures exhibit much slower rates of recovery of the flow stress upon storage at the same recovery temperature than specimens prestrained at lower temperatures. This not only occurs under conditions where the prestraining temperature is high enough to cause some recovery during prestraining, but it also occurs for prestraining temperatures at which the amount of recovery during prestraining is so small that it cannot be detected. The evidence is thus unmistakable that lower temperatures of prestraining to a fixed flow stress yield a more rapidly recoverable work hardened state. Consequently specimens of a metal so treated by various histories that they have the same in-

FIG 5—Effect of prestrain temperature on recovery at 305°K.

FIG 6—Effect of prestrain temperature on recovery at 305°K.

FIG 7—Recovery at testing temperature.

stantaneous flow stress under specified conditions of testing do not necessarily exhibit the same work hardened state.

The differences in these work hardened states is somewhat elucidated by their relative rates of recovery. It appears justifiable to assume that the work hardened state induced in cold worked metals is essentially attributa-

ble to imperfections of a type that are perhaps analogous to dislocations. The work hardened state is then determined by the size, distribution and density of the dislocations. Prestraining under different conditions of temperature, strain-rate and strain induced unique sizes, distributions and densities of the dislocations. Thus it is pos-

sible to acquire the same flow stress in a metal by various strain histories and yet have differences in the size, distribution and density of the dislocations. Upon recovery the more mobile dislocations will be activated and might migrate out of the mosaic blocks or be otherwise annihilated. The rate with which such a recovery process

would occur at a stated recovery temperature would depend upon the relative activation energies for the various sizes, distributions and densities of dislocations. The new work hardened state and the new flow stress following recovery would depend on the resulting dislocation statistics. Inasmuch as those specimens which were prestrained to a stated flow stress at the lower temperatures recovered most rapidly it appears logical to conclude that they also contain a larger number of more easily activated dislocations. Perhaps they contain a greater number of more readily activated dislocations more propitiously distributed as a result of the lower prestrain temperature to give nevertheless the same flow stress as is obtained by an appropriately larger prestrain at a higher temperature. Perhaps the dislocations generated at the lower prestrain temperatures are smaller, (as has been suggested on the basis of other evidence by Taylor⁶ and Kauzmann⁶ and Dushman⁷) but more numerous so that the same flow stress is achieved as is obtained by more extensive prestraining at the higher temperatures. The latter suggestion is of interest and will constitute the subject for further investigations.

Conclusions

1. The mechanical properties of cold-worked metals depend not only on the instantaneous values of the

strain, strain rate and temperature but on the entire past history of temperature and strain rate during prestraining.

2. Neither the instantaneous value of the total strain nor the instantaneous value of the flow stress under stated conditions of strain rate and temperature are adequate for characterizing the strain hardened state.

3. Specimens of a metal can be so prestrained at various temperatures that the same flow stress is obtained when they are subsequently tested at the same instantaneous temperature and strain-rate. Those prestrained at the higher temperatures require greater amounts of prestrain.

4. Although such specimens have the same instantaneous flow stress, those prestrained at the higher temperatures have greater instantaneous rates of strain hardening.

5. The recovery rate of pure aluminum depends upon the temperature of prestrain; specimens prestrained at the lower temperatures exhibit much higher rates of recovery.

6. These observations appear to suggest that lower temperatures of prestraining induce the formation of smaller or otherwise more readily activated dislocations.

Acknowledgments

This investigation was sponsored by the Office of Naval Research as part of

a more extensive program of investigation on the plastic properties of aluminum alloys. The authors express their sincere gratitude to the O.N.R. for their sponsorship of these studies and their substantial contributions to the planning and execution of this program of study. In addition they wish to thank Messrs. C. Peters and E. Berliner for their aid in conducting the tests and Mrs. G. Pelatowski for the preparation of the figures in this report.

Flow and Fracture Characteristics of a Die Steel at High Hardness Levels*

L. J. KLINGLER,† C. C. CHOW,‡ and G. SACHS,§ Member AIME

Introduction

Most structural parts which are heat treated are designed using strength properties which have been determined in the principal direction of the wrought material. For example, for rolled or drawn materials, properties are given for the rolling or drawing direction. The structures, however, may be loaded so that the critical stress is in some direction other than that for which the properties of the material are known.

Investigations of forged products,^{1,2,3} have shown that while the yield strength and tensile strength of carbon steel billets and bars vary little with the direction of the test specimen in relation to the fiber, the contraction in area in tension tests and the impact strength in notched bar impact tests decrease in the transverse direction. The contraction in area and, consequently, the fracture stress of hard aluminum and magnesium alloy forgings have also been found to be lower in the transverse direction.

An investigation on aluminum alloy plate⁴ likewise has shown the dependence of the fracturing characteristics upon the direction* of the test specimens, the longitudinal direction being considerably stronger than the transverse direction and the normal direction, with the normal direction being the least strong.

The variation of properties with direction has been explained by a type of anisotropy called mechanical anisotropy. This anisotropy results from the elongation, in the direction of the principal strain, of certain phases, inclusions, and/or cavities in the metal

during working. A mechanical fibering is thus produced which seems to persist through annealing and heat treatment.

This investigation was initiated to determine the flow stress and fracture stress, at high hardness levels, at 90° to the rolling direction in a round steel bar. It is this direction which receives the critical stress in drawing dies machined from round bars. Preliminary tests showed a large difference in properties between the 0° and 90° directions. Consequently, it was felt that a more complete investigation, utilizing several types of tests, was warranted to determine the flow and fracture characteristics of a steel at various orientations, for a number of hardness levels. This investigation was conducted on an air hardening nondeforming die steel.

Material and Procedure

The distribution of properties was

made on a 3-in. round bar of annealed high-carbon, high chromium steel of the following analysis:

| | Pct |
|-----------------|-------|
| Carbon..... | 1.53 |
| Manganese..... | 0.39 |
| Silicon..... | 0.27 |
| Chromium..... | 11.76 |
| Vanadium..... | 0.25 |
| Molybdenum..... | 0.81 |

The 3-in. bar was produced from an 8-in. ingot, which was annealed and forged to a 4-in. square billet. The billet was annealed and rolled to a 3-in. round which was then annealed and straightened.

This steel is an air hardening die steel which has very good dimensional stability on hardening; therefore, the residual stresses resulting from hardening would be expected to be low. A hardness survey across the diameter of the annealed bar showed no difference in hardness from the center to the outside. However, the test sections of all the specimens were taken approximately half way between the center of the bar and the surface to avoid any surface effect or possible porosity at the center.

Tension, compression and bend tests were made on specimens hardened and tempered at six different temperatures.

The tension test specimens, Fig 1, were machined from the bar at orientations of 0, 22.5, 45, 67.5 and 90° from the axis of the steel bar. The specimens were rough machined, heat treated and then ground to size. The test section on each specimen was lapped in a direction parallel to the axis of the specimen to remove any transverse scratches which might act as stress raisers. The specimens were tested in fixtures which insured concentricity of loading of less than 0.001 in.⁵ The transverse strains were measured with a radial strain gauge,⁵ the least count of which was 0.0001 in. change in diam.

The compression specimens, Fig 1, were machined from the bar at ori-

New York Meeting, February 1950.

TP 2724 E. Discussion of this paper (2 copies) may be sent to *Transactions AIME* before April 1, 1950. Discussion is tentatively scheduled for publication in November 1950.

Manuscript received May 23, 1949; revision received Aug. 31, 1949.

* The direction of a test specimen can be defined as the relation of the axis of the specimen to a set of axes made up of the longitudinal, transverse, and normal directions in the material.

entations of 0° and 90° from the axis of the steel bar. The specimens were rough machined, heat-treated, and then ground to size. The specimens were tested between hardened ground steel blocks in a specially built ball-bearing die set, which assured pure compression. The ends of the specimen were lubricated with a drawing compound to minimize the friction. The transverse strain was measured with the same radial strain gauge which was used for the tension specimens. All the specimens were strained in excess of 4 pct (increase-in-area). No perceptible bending or barreling of the specimens was noted at these strains.

The bend test specimens, Fig 1, were machined from the bar at orientations of 0° and 90° from the axis of the bar. The specimens were rough machined, heat treated, and then ground to size. A photogrid, 100 lines per in.⁶ was applied on the tension surface of the bend bar. Readings were made from this grid after fracture to give the strain at the middle of the tension surface. The strains were measured with a Filar eyepiece, using a gauge length of 0.01 in. Five gauge-lengths were meas-

FIG 1—Test specimens.

c. Bend specimen.

ured on each side of the fracture and the strain at the fracture was extra-

polated from these measurements. The specimens were bent in a "Wrap Former" around a 1.25 in. radius die.⁶ All of the specimens fractured during testing at relatively small angles of bend. The bend angle was measured after fracture on a microprojector.

All of the test specimens for each tempering temperature were heat treated together, the specimens being held 40 min. at 1820°F, in a Vapo Carb Atmosphere furnace and cooled in still air. The specimens were tempered in a forced air convection furnace at 1000, 1025, 1050, 1100, 1150 and 1200°F for one hour.

The corresponding hardness values for the various tempering temperatures were as follows:

| Tempering Temperature °F | Hardness Rockwell C |
|--------------------------|---------------------|
| 1000 | 62.5 |
| 1025 | 62.5 |
| 1050 | 59. |
| 1100 | 54.5 |
| 1150 | 50. |
| 1200 | 45. |

Results

STRUCTURE

the carbides, micrographs were made in the longitudinal and transverse directions of the bar in specimens which had been quenched and tempered at 1200°F. These micrographs are shown in Fig 2 at both 100 and 500 magnifications. It can be seen that the undissolved carbides have been strung out in the longitudinal direction of the bar by the fabricating operations.

TENSION TESTS

The results of the tension tests are shown in Fig 3, 4, 5, and 6. In Fig 3 a few typical tension curves are shown for the longitudinal and transverse directions at three different tempering temperatures. The fracture stress, ductility, and yield stress are shown in Fig 4, 5, and 6 as functions of tempering temperature and of specimen direction for three selected temperatures.

The fracture stress, Fig 4, for every orientation reached a maximum at a tempering temperature between 1025 and 1050°F. At 1000°F the fracture stress fell off for all of the orientations. The fracture stress at each tempering temperature decreased from a maxi-

mum at the 0° direction to a minimum at the 90° direction.

The reduction in area, Fig 5, was small for all of the tests but showed an increase with tempering temperature for all orientations. The increase in ductility was greater at each tempering temperature as the orientation changed from 90 to 0°. The yield stress, 0.2 pct offset, Fig 6, was the same for all orientations at each tempering temperature. The yield stress increased as the tempering temperature was lowered until a maximum was reached at 1025°F and then the yield fell off at 1000°F in a manner similar to the fracture stress.

COMPRESSION TESTS

Typical stress strain curves in compression are shown in Fig 7 for the longitudinal direction at three different tempering temperatures. The stresses in compression for 0.1, 0.2, 0.5, 1.0 and 2.0 pct plastic flow are shown in Fig 8. A small but consistent difference was noted between the orientations of 0° and 90°, the values for 0° always being higher. The values of yield stress in-

creased with decreasing tempering temperature and unlike the yield stress in tension, did not have a maximum at 1025°F.

BEND TESTS

The strains measured at the center of the tension surfaces and the angles of bend after fracture are given in Fig 9 and 10. Considerable difference is shown between the 0° and 90° orientations for both the bend strain and bend angle, this difference becoming larger with increasing tempering temperature. Both the strain and the angle increased with increasing tempering temperature for both 0° and 90° orientations.

Discussion of Results

A high degree of directionality was shown in the fracture stress and ductility for this material. At 1200°F tempering temperature the strength in the transverse direction was 18 pct less than the longitudinal direction and this difference increased at lower tempering temperatures. An even greater

FIG 4—Dependence of fracture stress on tempering temperature and orientation.

FIG 5—Dependence of ductility in tension on tempering temperature and orientation.

difference was shown by the ductility over the whole range of tempering temperatures used.

The decrease in fracture stress expressed as a percentage of the fracture stress at 0°, is shown in Fig 11 for the different orientations at three tempering temperatures. This decrement appears to be a function of the specimen direction and is also dependent upon the structure, particularly at 90°. This behavior is of the type which would be expected if discontinuities or cavities existed parallel to the axis of the bar. The yield stress in tension, however, showed no such directionality (the yield stress in compression showed a slight degree of directionality). This further supports the belief that mechanical anisotropy is the cause of the differences in fracture stress and ductility since a crystallographic preferred orientation normally causes differences in yield strength in various directions. Cubically aligned copper is

one exception, in that it shows little dependence of yield stress upon the direction of testing.⁷

The decrease in yield stress in the vicinity of 1000° tempering temperature may be due to the retention of residual stresses which lower the apparent yield strength. The sharp drop in yield stress was not observed in compression. A comparison of the yield stress in tension with the yield stress in compression (0.2 pct), Fig 12, shows that between 1200 and 1100°F the yield stress in compression was slightly higher than that in tension. This is the usual case. However, below 1100°F, the tension yield stress decreased, whereas the compressive yield stress continued to increase.

The ductility of this steel is extremely low in the range of tempering temperatures used. On hardening, the steel retains a high percentage of

austenite (30 to 40 pct) which transforms on tempering.⁸ A secondary hardening range is observed at tempering temperatures about 1000°F, Fig 2, where additional chromium carbides are formed. Consequently a mixed structure is obtained which is composed of variously tempered marten-sites, carbides, retained austenite, and possibly other transformation products. Small amounts of carbides, retained austenite or other transformation products would all cause a lowering of the ductility.

In the range of tempering temperature from 1000 to 1050°F the ductility is reduced to less than one per cent. Consequently, the fracture stress is lowered in this range.

The bend tests showed considerable difference between the 0° and 90° orientations when measured either by the strain or the bend angle. A comparison

FIG 6 (Upper left)—Dependence of yield stress in tension on tempering temperature and orientation.

FIG 7 (Above)—Typical stress strain curves in compression for a die steel tempered at various temperatures and tested in the rolling direction.

FIG 8 (Lower left)—Dependence of yield stress in compression on tempering temperature and orientation for various amounts of strain.

of the strains measured in the bend tests with those in tension shows that the strains were greater for the bend tests although a slight degree of biaxiality* exists at the center of the tension surface of a square bar.

Conclusion

As a result of this investigation, the

* On bending a square bar, a small transverse stress results at the center of the tension surface due to lateral restraint.⁶

FIG 9—Dependence of bending strain on tempering temperature and orientation.

FIG 10—Dependence of bend angle on tempering temperature and orientation.

following conclusions can be drawn:

1. The fracture stress and ductility in tension and the ductility in the bend test exhibited pronounced directionality, properties always being higher in the longitudinal direction for every tempering temperature chosen.

2. The yield stress in tension did not vary with direction. The yield stress in compression varied only slightly with direction.

3. The directionality can be attributed to mechanical anisotropy caused by the carbide stringers developed in the fabrication of the material.

The Effect of Working and Heating Eutectic Structures

J. S. BROWN* and A. G. GUY*

With the exception of the work of Tammann and Hartmann,¹ no published information has been found on the structural changes produced in eutectic structures as the result of heating following plastic deformation. In part this lack of information may be due to the fact that many eutectic structures contain an intermetallic compound as a prominent phase, and as a consequence have been considered to be unworkable. For example, Tammann and Hartmann were able to obtain useful data only on those alloys that they could greatly reduce in thickness

cooling in the mold from about the eutectic temperature. The fairly coarse eutectic structure thus obtained was too brittle to work at room temperature without cracking. Fig 1b shows the worked structure obtained by compressing a $\frac{1}{2}$ -in. cube 70 pct in about 15 sec at 550°F and then water quenching. The pronounced changes in the distribution of the two phases produced by heating the worked alloy at 850°F for 1 hr are shown in Fig 1c. Recrystallization of both phases appears to have taken place, and the mechanical properties of the cast alloy

tion, to have a granular structure after heat treatment: Sn-9 pct Zn (98 pct); Cd-82.5 pct Pb (60 pct); and Bi-43.5 pct Pb (90 pct). On the other hand the alloy Al-11.7 pct Si (60 pct) showed no change after heating. Tammann and Hartmann observed a distinct shrinking of the needles in unworked eutectics subjected to heat-treatment. In the present work inappreciable change in the eutectic structure was found on heating undeformed alloys.

In summary, it appears that eutectic structures can be recrystallized into a "spheroidized" condition by heating

FIG 1a—The cast structure of the Pb-33.2 pct Mg alloy; the Mg_2Pb intermetallic compound appears dark and the Mg solid solution light.

FIG 1c—The 70 pct reduced Pb-33.2 pct Mg alloy after heating for one hour at 850°F.

Unetched. 1500 \times .

by cold rolling. This restriction placed on the investigation of alloys containing intermetallic compounds has been largely removed by the work of Savitskii² which showed that large deformations of such alloys can be produced by relatively slow compression at temperatures near the melting range. It was possible, therefore, to carry out the present work on a range of binary eutectics including one composed of two intermetallic compounds.

The essential results obtained on the alloy systems studied are illustrated by the Pb-Mg eutectic containing 33.2 pct Mg, Fig 1. The cast structure, Fig 1a, was obtained by melting together magnesium of 99.8 pct purity and chemically pure test lead, casting into a heated, small steel mold, and furnace

must have been significantly changed by the working and heat treatment.

Similar results were obtained with the Mg-59.5 pct Bi, Mg-36.4 pct Sn, Mg-65.4 pct Cu, and Bi-40 pct Cd eutectics, only the last of which could be worked at room temperature. Tammann and Hartmann reported a thickening and shortening of the needles of the eutectics which they heated about 10°C below the melting range for 1 hr after drastic cold rolling. They found the following eutectics, given the indicated amounts of reduc-

near the eutectic temperature after severe deformation. If the eutectic contains one or more brittle phases the necessary deformation can be accomplished by pressing at high temperatures. It is reasonable to expect that this tendency towards equiaxed grains from the plate- or needle-like eutectic structure should be general since the energy relations and mode of growth in recrystallization are so different from those that hold for eutectic crystallization.

The Fume and Dust Problem in Industry

HARRY V. WELCH,* Member AIME

Introduction

In this paper, as prepared for delivery at the Southern California regional meeting on Oct. 14, 1948, it was thought best to interpret the term "economics" in a rather broad manner and to include, in addition to the material losses and recoveries and associated monetary values (Part I), a limited discussion of the increased difficulties or the particular problem and the special requirements, as the particle sizes of the suspended particles range down from the relatively coarse to 100, to 10, to 1 micron or even to a fraction of one micron (Part II). Further, it is not quite in order to overlook entirely the community and individual health problems, although space requires the economics of this to be considered only very incompletely. Therefore, Part III, covering this phase of the subject, is very limited.

This paper, then, is divided into 5 parts or headings as follows: I Losses and/or values in suspended solids. II Particle size. III Dust and fumes in community and individual living. IV Means and Procedures for dust and fume collection. V Description or examples of specific equipment in service and of the several types used for dust and fume collection. Because of the wide extent and wealth of subject material available and the space and time limitation imposed, presentation and discussion are less than originally planned.

I—Losses and/or Values in Suspended Solids

The weight involved in moving streams of industrial plant gases is commonly not appreciated, neither is their carrying power in the weight of solids maintained in suspension and

moved with the gas stream from a point of origin or pick-up to a point of dissipation or settlement. These, however, are major weight figures; for example, in a modern iron blast furnace there may be five tons of gas for every ton of iron produced and by the time this blast furnace gas has been burned in stoves or under boilers the weight of gas discharged to atmosphere is on the order of eight times the weight of iron produced. Similarly for nonferrous metallurgy there may readily be from 10 to 20 times the weight of gases discharged to atmosphere as there is metal produced.

A cement kiln in operation or a kiln in service to produce metallurgical lime may have on the order of 5 to 6 times the weight of stack gases as of clinker or lime produced, and at least the cement kiln, because of the very fine nature of its feed, is a very heavy dust producer.

It may be noted that there have been two developments in progress for nearly three decades. Both are extraordinary in the industrial economics effected and in their ready availability to ever larger units of operation and their ever widening importance in industry, and both are productive of great quantities of finely divided material in furnacing. The first of these is the flotation process for ores, especially the metallics such as copper, lead, and zinc; and the second, powdered fuel combustion for power plant, industrial plants and metallurgical operations. Today, new developments, for

example, flotation for the nonmetallics such as higher grade limestone for cement manufacture which requires still finer grinding and the powdered-coal-fired boilers with production ratings of over 1,000,000 lb of steam per hr, bring still more concentrated and hugely increased quantities of stack emission.

Perhaps the honors for the greatest interest in the quantities and values escaping in waste furnace and equipment gases belong to the nonferrous metallurgical operations. Their record of achievement in the installation of dust and fume collection equipment, largely baghouses or Cottrell electrical precipitators, is exceeded by no other industry.

Something of the magnitude and variety of equipment utilized in such recovery systems was covered by the writer in two papers presented to the Institute some 10 years ago.^{1,2} It is not intended to repeat the material of those articles, but it is thought that they complement this offering and should be noted.

COPPER ROASTERS

As the copper roasters are the first of the series of furnaces handling the copper-bearing concentrates in the usual copper smelter of today, it is in order to make them the first consideration.

Multiple hearth sulphide roasters, not hard driven, often maintain their dust loss through exit gases at 3 pct or below of feed to furnace; in hard-driven or maximum-driven furnaces, exit gas losses often approximate 7 pct of charge with a ± 2 pct variation for special conditions prevailing at some plants. A 5 pct loss of feed in a roaster gas exit, unless reclaimed, often makes the difference between a profit and loss operation, and in many cases substantial recovery is the very basis of dividend payments. As there is available very practical and successful equipment for the collection of the

¹ References are at the end of the paper.

suspended solids in the acid-bearing copper roaster gases, all plants handling good tonnages of through-put material are equipped with some form of collection equipment; the most common and quite the most successful collection equipment makes use of high potential electrical discharge—the process of *Electrical Precipitation*, more commonly referred to as the Cottrell process. In general, the values in copper roaster feed are not confined to the copper only but include both gold and silver. Copper and gold show no appreciable fume production and their recovery in a normal roaster precipitator may be on the order of 10 pct higher than that of total solids (commonly there are present in the precipitate minor amounts of fumes and dust—as oxides and/or sulphates of lead, zinc, arsenic, antimony and the like) and 5 pct better than the silver recovery efficiency. Silver has a greater volatility than copper and gold, and particularly so in the presence of volatilized lead compounds.

No two copper smelters are alike as to losses with their flue gases, the variation being surprisingly large and usually excessive in hard-driven plants or older plants, or with poor maintenance as indicated by leaky flues and general large air infiltration conditions. It is, however, worthwhile to go through a sample set of figures of furnace losses and collections for a copper smelter and while the figures are not those of any one smelter they are more or less representative of all. Consider a custom smelter, as an example, with a charge of 1000 tons per day of crushed ore averaging 7 pct copper, and 1000 tons per day of concentrates averaging, say, 35 pct copper. The crushed ore which may be considered coarse in comparison with concentrates, is fine when considering only run-of-mine ore. However, even on their crushed ore, say, $\frac{1}{8}$ to $\frac{1}{4}$ in. dimensions, there is much decrepitation and production of fines in the actual furnacing operation, so that it will be productive of finely divided particles readily carried off by the furnace-exit gas stream. Nevertheless, the major dust will be derived from the concentrate fraction of furnace feed, and the collection in a precipitator will approximate 15 to 20 pct copper, say, $17\frac{1}{2}$ pct as an average. On flotation concentrates alone the dust loss may reach 10 pct of feed. On crushed ore with appreciable decrepitation taking place, dust loss is often 5 pct and if we say $7\frac{1}{2}$ pct as an average dust loss and a precipitator

recovery of 98 pct on the copper, the distribution of copper may be placed as follows: In new feed to roaster 420 tons copper, in Cottrell collection 73.5 tons, in stack gases 1.5 tons. The latter, the stack loss, is 0.36 pct of the copper in furnace feed and it is very evident that there is the desirability of high efficiency of recovery. With copper at a market of 23¢ per lb (1948) even the recovery of 98 pct and the accompanying loss of $1\frac{1}{2}$ tons of metallic copper, or roughly $\frac{1}{8}$ of 1 pct, is an item of some interest and will bear further consideration.

REVERBERATORY FURNACES

In the past, the operation of reverberatory furnaces has varied so widely from plant to plant and from time to time in the same plant, that the majority of operators have considered their waste-heat boiler installation as a good enough collector and have disregarded further dust and fume-collecting equipment.

Reverberatory practice, however, is divided into two types, first with all feed passing through the multiple-hearth roaster, and second, that type in which the wet concentrate is directly fed to the reverberatory furnace. As is to be expected, the latter type of operation uses more fuel and has a greatly increased gas volume. Both these conditions are normally productive of a higher dust loss from furnace. In addition, however, the wet feed, although preventing dusting at charge time, is often after an interval of time productive of disruptive surface conditions due to the very rapid change of water particles to steam vapor, and this effect is productive of dusting.

A reverberatory, with roasters pre-treating its feed and working on a mixture of crushed ore and fine concentrates, is considered operating as well as may be reasonably expected if its stack loss is on the order of $\frac{1}{2}$ to $\frac{1}{4}$ of 1 pct of furnace feed in copper—about the same fraction of a percent loss in gold, and 1 to 1+ pct in silver—the latter increasing with the presence of lead fume in the gases. On the basis of a smelter operation with new copper-bearing feed of 1000 tons per day, 20 pct copper, 0.3 oz gold and 2 oz silver and present-day market (1948) of 23¢ per lb for copper, such reverberatory loss is considerable, amounting to approximately \$250.00 per day. However, 85 pct of the total value is in the copper and since the present price is nearly twice that of war-time fixed

price, it does not follow that such losses would warrant the immediate construction of high efficiency and relatively expensive recovery equipment. Perhaps it is in order to consider means for a relatively lower-efficiency mechanical recovery.

Where the reverberatories are directly fed with undried and unroasted concentrates the losses in the exit gases after boilers are appreciably greater (commonly double or even more) than stated above for calcine-fed reverberatories, and the dust collection is justified. Commonly such investment where the copper content in the feed is high, is returned within a very few years of service of collecting equipment by the value of recovery.

COPPER CONVERTERS

Generally, modern and large converters will lose from the furnace, with their exit gases, on the order of 1 to 2 tons copper per day and this may be 1 to 3 pct of the copper produced. It varies widely from plant to plant due to grade of matte, type of flux and procedure of operation.

The actual solids lost, both dust and fume, may be several times the copper loss and in lead and zinc-bearing mattes the elimination of these two constituents as oxides or sulphate compounds is almost 100 pct with the gases.

Because of the necessities of operation there is always a tremendous infiltration of outside air at the converter hoods, and thus a volume in the flue just back of the converter stands may be on the order of 100,000 to 150,000 cfm for a present-day large converter. Such excessively large gas volume, in proportion to air supplied to converter at tuyeres or to tonnage of material treated, or to weight and nature of suspended solids in the exit flue gases, makes the economic handling of converter losses a rather uncertain problem. A portion, approximately one half the total suspended solids, is relatively coarse particles, being essentially the material expelled mechanically by the effects of converter blast, and this is substantially collected in a flue or settling chamber. The remaining fraction, however, is normally very fine and it may justify only a mechanical collector, say, with 80 to 90 pct (on copper) efficiency or it may justify an electrical precipitator of about 98 pct efficiency and perhaps, with the latter, at least twice as expensive to build.

Roughly, one can say the North

American capacity for production of copper (in copper reduction works) and in some 30 plants, approximates 1,000,000 tons per year, or at \$400.00 per ton copper, \$400,000,000.00. Certainly this is a primary sizable, and for the security and good of the country, a most important industry! On the basis of a furnace loss of 7 pct of the copper content and a recovery from the furnace gases of 96½ pct of the furnace loss there is a copper recovery in flue dust of around 67,550 tons copper, or expressed in dollars at \$400.00 per ton a total of approximately \$27,000,000.00 with a final loss from stack of about ¼ of 1 pct of original plant input of new copper-bearing material. These are, of course, quite generalized figures but show the magnitude and ability of our copper smelter metallurgists to confine their stack losses to an exceedingly small minimum through the installation and skilled use of a large variety of dust collecting equipment. The main dependence, however, is on electrical precipitation for the collection in acid-carrying gases and of the exceedingly large amount of fines which the modern flotation milling plant provides.

DIFFERENTIATION OF DUSTS, FUMES, AGGLOMERATES, ETC.

As a distinction between recoveries of copper values and those of lead and zinc in exit furnace gases, it is to be noted the copper is recovered almost entirely as a "dust," while in the lead and zinc suspensions both dust and fume are present, with the fume often the largest fraction. We define a dust particle as substantially a fragmental particle derived by percussion or crushing as the ore and fuel and flux are processed and handled through mines, mills and furnaces. It commonly has a chemical and mineralogical composition approaching that of the furnace feed. In practice the major fraction of the dust is said to average 5 to 50 microns, but blasting and crushing operations always produce a minor fraction below the 3 or 5 micron range and a minute portion may be not over or even less than 1 micron.

A very special suspension product results from solid carbonaceous fuel combustion. This runs in composition from the raw coal and partly burned particles of fuel to tar fogs, soot, soot agglomerates, fragmented ash particles and the fused, rounded and commonly hollow particles, the so-called "fly ash" of powdered-fuel suspension combustion. The fly ash particles cover a fair

range in size but a goodly portion are on the order of 1 micron, and broken sphere fragments less than a micron. Other than the tar fogs they are all solids and do not represent a volatilized product but no doubt some of the finer carbon or soot particles, before agglomeration has taken place, are products of decomposition, probably carrying with them traces of actual tar, and may be looked upon for size and function, too, as "fume"-like or "fog" particles.

Fumes, as compared to dust, are constituents or compounds as of or from the charge, vaporized in the hottest areas of the furnaces and chilled to a solid form out of contact with walls. These fumes bear no physical resemblance to the new materials of furnace feed, often existing in the flue gas suspensions as an "igneous concentration" product. They are generally assumed to be of rounded form and of exceedingly small diameter, from a few hundredths of a micron to one micron in diameter or occasionally somewhat larger. There is always an appreciable agglomeration present, probably due to the effects of electrical charges on the solid particles occurring in fume-laden gases. Similar agglomeration effects are to be noted in liquid suspended particles, that is, in mists and fogs. Examples of the latter are tar and acid fog. The effect of agglomeration or of agglomeration and coalescence is to produce fewer and larger particles and thus increase the settlement rate.

LEAD AND ZINC FURNACING UNITS

Lead and zinc reduction works, in the roasting and reduction departments, produce both dust and fume, perhaps to the gross amount of 5 to 10 pct of the new metal-bearing material to reduction works, but thanks to modern development in dust and fume-collecting equipment, including both baghouses and electrical precipitators, actual stack losses in modern lead smelters and zinc works of the electrolytic type, including the roasting or sintering operations essential thereto, may be on the order of a small fraction of 1 pct of new metal input. In fact these enterprises today rarely are in trouble from dust-fall, but doubtless some who do not convert their SO₂ production into acid, or liquid SO₂ or elemental sulphur, do have what is termed an SO₂ problem.

IRON AND STEEL WORKS

Our main mineral wealth producers here in the West have, in the past,

been our lead, zinc and copper enterprises and therefore we have been particularly interested in their dust problems. However, we have, within recent years, developed several plants in ferrous or iron metallurgy and these plants have dust problems, quite as great in volume and weight as copper and lead smelter enterprises, but with values in the collected products for which most iron smelter men are entirely unwilling to set any worthwhile figure. Nevertheless, modern iron and steel plants are eager to clean their combustible gases from blast furnaces and coke ovens and public officials look with concern at open hearth stacks and sintering machine stacks with large and objectionable "plumes."

There are three main sources of dust-bearing furnace gases passing to atmosphere in an iron and steel works, first the iron blast furnace, second the sintering machine and third, the open hearth reverberatories. In plants of a generation ago, there were only the crudest, if any, dust and fume-collecting devices on blast furnace equipment. From the stack discharge gases from the blast furnaces, the stoves and adjacent boiler plants burning the blast furnace gas, there was almost a rain of reddish colored dust, giving the blast furnace a most undesirable reputation. Today, however, all modern plants realize the savings and benefits of clean gas in stoves and boilers, and even greater economic advantages are secured in plant operation by burning the low Btu blast furnace gas under coke ovens, and the high Btu gas from coke ovens in domestic or steel plant operation. For by-product coke oven service the blast furnace gas must be practically as clean as outside air, the usual specification calling for not over 0.002 grains of solids per cf of gas calculated at N.T.P. Almost equally important is clean gas for modern closely spaced checkerwork of the blast furnace stoves, but here a specification not quite as rigid as considered necessary for use in coke oven combustion, is permissible and the usual figure is stated as not over 0.007 grain per cf as calculated to N.T.P. conditions. To accomplish the degree of cleaning, the usual current design calls for (1) a dry dust settler adjacent to the blast furnace providing a 180° turn for the gases, in other words, an impingement type dry cleaner; (2) such dry dust collector to be followed by an efficient wet scrubber, usually counter-current type in baffle or tile packed chamber; (3) the scrubber to be followed by a

wet or film-type electrical precipitator. The dry dust collector may have an inlet concentration of 10 to 15 grains per cf, an outlet of 3 to 5 grains per cf, the scrubber with an inlet which is the outlet of the dry dust catcher and an outlet of 0.25 to 0.3 grains per cf and lastly an electrical precipitator with an inlet concentration of the scrubber outlet and precipitator outlet concentration of 0.007 grains per cf. These correspond to average efficiency for each piece of series-operating equipment and as developed only on its own average inlet and outlet concentration, of approximately 70 pct for the dry dust collector, 94 pct for the scrubber and 97 pct for the precipitator. The precipitator collection is substantially all fumes, largely those of the alkali or alkali-earth compounds but occasionally fumes of zinc are present.

The economic results of this train of dust and fume collection equipment are very considerable indeed. Clean gases to stoves mean nearly theoretical combustion, with high heat; no suspended solids in gases permits close packing of brick work and greatly increases the storage and release of heat, and the absence of any fine deposits upon the checker work permits rapid accumulation of heat and its equally ready release. Thus the furnace is better served and responds by greatly increased uniformity of operation, by increased daily production or greater capacity and by simplicity and ease of handling. These are not readily-figured benefits over one day's operation, but over several years provide noteworthy economics of operation and the maximum of production.

The numerous reheating and soaking pits of a steel works do not commonly discharge visible or appreciable quantities of suspended solids but the sintering plants and open hearth furnaces are at times producers of considerable clouds of dust with some fume. These pieces of plant equipment, in their stack discharge, reflect the nature of the dry feed to the furnace; where there is much fines there is corresponding furnace loss, where there is fume-making material (for instance, galvanized iron scrap) a fume discharge will be evident.

The open hearth reverberatories, in particular the newer and larger units, say 100 to 150 tons of steel production per charge and above, are now very generally being equipped with waste heat boilers. Such boiler installations in themselves are fair dust collectors and provide the very decided additional

advantage of cooling the furnace exit gas volume and thereby correspondingly decreasing the gas volume to be handled, so that additional collection means after the boilers are relatively easily supplied and installed. In reverberatory furnaces where blast furnace pig iron is a major constituent of the feed it is also common practice to add iron ore as a means of effecting the combustion of the carbon of the pig iron. At the time of feeding that charge to the reverberatory and perhaps for an hour or more thereafter, there will be heavy reddish stack discharge. This is not a serious loss as regards weight of materials or of values at the furnace but it is certainly one of the items that give the steel works an evil name as a maker of community dust. Reverberatory furnaces, depending upon their size, condition of feed or of fineness and fuming characteristics, and degree of "hard driving," range in dust loss from around 2 tons per day in a small hearth to around 10 tons of furnace dust loss per day in a very large furnace. As in a great many cement plants, it has been the practice to provide one chimney for each furnace, and this practice adds to the cost and inconvenience of any form of dust collecting devices. Once the procedure is adopted of installing waste heat boilers on each reverberatory and bringing all the boiler exit gases to a central point for treatment, the cost and feasibility of dust and fume collection installation will be greatly simplified, which makes for the minimum of expense. It is evident that one central recovery plant will cost less and be easier to handle than several individual dust recovery units.

The sintering machines in use at iron works are of comparatively recent introduction. The usual type is commonly provided with a large diameter, horizontal type of cyclone which serves to collect a coarse constituent of suspended material passing the grates; but in general, when fine ore or flue dust constitutes a major element of the sinter feed, there is a nuisance stack loss if not an important material loss. This equipment will receive due attention for dust collection along with the reverberatory department if and when the collection question is not one of plant economy but one of community betterment as regards appearance, cleanliness, saving in wear and tear, and the like. The installation of collecting equipment is neither more nor less pressing than in many other industrial operations or plants, such as cement plants, modern powdered-fuel-

fired power plants, railroad yards, handling equipment and the like.

CEMENT PLANTS

Cement plants are large producers of dusts and fumes in their furnace gases, as would readily be expected from the nature of their operation. This operation includes preparation of a furnace feed of exceedingly finely ground limestone and clay or shale, 86 to 90 pct or above of minus 200 mesh (a 74 micron particle size just passes a 200 mesh screen), and the furnacing of this mixture to a point and temperature sufficient to produce a sinter. Commonly the prevailing temperature in the clinkering zone of the kiln is in the range of 2500 to 2700°F. On the basis of 600 lb of raw mix to 1 bbl finished cement, dust losses in stack discharges have been reported all the way from 10 to 120 lb per bbl. Needless to say the latter is abnormal, and good plant operation will not long permit such a loss. However, 30 to 40 lb per bbl kiln loss is quite ordinary and at 40 lb per bbl and 5,000 bbl per day the kiln dust loss (not stack loss) per day is 100 tons.

In former days of cement plant operation, before government regulations became the dominating and costly practice they are today for all of us, manufacturers were disposed to figure the value of their clinker so low that they were reluctant to give worthwhile values to the recovered kiln discharge dust. Today, however, with high labor and operation costs and still higher prices for cement, the dust becomes of considerable value to the producer—such figures of \$1.00 to \$2.00 per ton, occasionally more, being the practical basis of consideration. Since the U. S. production of Portland cement for 1947 is given as 185 million bbls it is evident we are talking of a kiln dust loss of over 3 million tons per year. It is to be understood that not all this dust reaches the atmosphere and is distributed around the surrounding community as a rain of dust, for the great majority of cement plants have some provision for collection. Their dust-collecting equipment runs all the way from an enlarged kiln-end housing or a boiler setting to an electrical precipitator, and includes baghouses or settling chambers, scrubbing systems, or one large or several small cyclones. On the whole, good collection service is provided by the industry. Possibly over half the total dust produced is collected—between one and two million tons per year.

POWER PLANTS

A field somewhat similar to that of cement manufacture as far as large gas volumes and dust loadings are concerned, is that of the new powdered fuel-fired-boiler power plants. Units in this field are ever growing larger and boilers producing 1,000,000 lb of steam per hr, are being built with corresponding gas volumes of around one half million cfm at the average prevailing temperature of about 300°F. In the earlier powdered-fuel power plants and even in some modern ones upwards of 90 pct of the ash in the coal is discharged with the stack gases. The practice of burning coal in suspension has permitted the use of coal, without combustion difficulties, much higher in ash content than formerly was permissible. This, no doubt, along with the tremendous size of the modern power plant, has led to the very general complaint of the discharge of chimney solids (fly ash). As an example, take a power plant of a million kw capacity burning 12,000 tons of coal per day of possibly 12 pct ash, and assume 75 pct of ash in chimney discharge and not the 90 pct which has been occasionally reported. There results a stack loss of fly ash, so named, of approximately 1000 tons per day. Part of such stack loss is excessively fine, with many 1 micron particles, and usually 1/3 of the total dust particles are less than 10 microns in diameter. While American practice has favored the dry collection and predominantly that by the Cottrell process of electrical precipitation, the English have leaned toward the scrubber types with neutralization of the acidity resulting from sulphur dioxide collection.

In a British power plant³ which has been reported in successful operation with better than 95 pct removal of dust and sulphurous acid from plant gases, the neutralization has been effected by use of a mixture of lime and limestone so that the active neutralization agent is reported as the bicarbonate of lime. This operation of neutralization, they state, is accomplished without the building of caked material, or scale (which we assume is a bisulphite salt) of the usual and very serious insoluble and voluminous calcium deposits so commonly encountered in non-precisely controlled scrubbing of waste gases containing SO₂ with suspended lime or limestone in the scrubbing liquor. Past experience in attempts to scrub the dust and sulphur-bearing compounds from cement plant gases does, indeed, make one most hesitant to accept with-

out thorough proof any scrubbing scheme for sulphur-bearing dust-carrying gases in which the neutralization is to be accomplished with a lime compound, and where the assumption or the assurance is given that no serious build-up of lime-carrying deposits will occur.

All indications point to more severe restrictions as to stack emanations from power plants and city factories for the future, and it is well if it is so understood by technical staff and plant management and plans and equipment are provided to accomplish the desired end. A statement was made some years ago by an English investigator that the damage resulting to structures, furnishings, clothing and health of the people was not less than 3/4 shillings for every ton of raw coal burned. Since at that time 3/4 shillings probably equalled about 55¢ of our money, it is easy to figure raw coal combustion without treatment of discharge combustion gases as running to hundreds of millions of dollars. The damage and nuisance and unpleasant results of raw untreated coal combustion are, of course, open to a wide range of interpretation, evaluation and even argument and one whose interests are normally technical is well advised to be cautious and conservative in his figures and remarks.

GENERAL

In the preceding account there has been covered in a brief and general discussion the losses of wastes from stacks and chimneys of metallurgical operation of industrial and power plants. Stack losses for the entire United States, without the incorporation of present-day quality and recovery equipment of industry, smelting and power plants, would easily reach a billion dollars or more per year in values. With suitable equipment installed to collect suspended solids from furnace and industry exit gases, community savings of the above amount may be effected. Nevertheless, for health, for community, for good house-keeping and for the acceptance of the responsibility to be a credit to the community, which every industrial plant really plans to provide, there are required still further effort, expansion and investment for suppression or collection of vent or stack emission.

II—Particle Size

If one would understand the problem of handling, controlling and collecting suspended particles in gases,—aerosols

as they have been termed—it is necessary to have a mental picture of the relative sizes and the special characteristics that go with such range of particle sizes. Over the years various relationships have been developed by one observer after another and these scattered data have been gathered into a very useful chart (Fig 1) by C. E. Miller and published in *Chemical and Metallurgical Engineering* in March, 1938 (p. 113). Due to the large amount of convenient and related information, this is reproduced here for convenience and by the courtesy of the publisher, McGraw-Hill Co.

It is of interest to point out several of the interesting features of this chart compilation. Reference to the lower left hand corner shows the relationship of standard screen size as compared to micron sizes. The particles just passing a 325 mesh screen are approximately 44 microns in diameter and while this is about as fine as one cares to go with screen sizes it is to be noted that 44 micron is still in the first third of size range given and such 325 screen, passing a 44 micron particle, is just about midway point or the sizes of many industrial operations, for example, sulphide ore, flotation pulps, pulverized coal, combustion ash (flyash) cement, and others. It will be noted few dusts go as low as 1 micron but many fumes and mists (including fogs) go down to about 0.02 micron, for instance, zinc oxide fume, tobacco smoke, and oil smoke. A half micron particle is nearing the edge of visibility with the most powerful optical microscopes and at 0.1 micron diameter particles show Browning movement and thereby display no tendency to settle.

To place the respective diameters and rates of fall in figures more common to our experience, Table 1 taken from Gibbs⁴ and here somewhat extended to express the rate of fall both in foot per second and miles per hour is presented.

Table 1 . . . Particle Diameter vs. Rate of Fall (Spherical and Still Air)

| Diameter of Particles | | Mi-crons | Rate of Settling | | |
|-----------------------|------------------|----------|------------------|---------|--------------|
| | | | Cm per Sec | Fpm | Miles per hr |
| Screen Size* | Cm | | | | |
| | 10 ⁻² | 100 | 30 | 59.0 | 6.711 |
| | 10 ⁻³ | 10 | 0.3 | 0.6 | 0.06711 |
| | 10 ⁻⁴ | 1 | 0.003 | 0.006 | 0.00067 |
| | 10 ⁻⁵ | 0.1 | 0.00003 | 0.00006 | 0.0000007 |

* Tyler Standard screen size, 200 mesh = 74 micron; 325 mesh = 44 micron.
† Approximate, size of opening in mesh to pass 100 micron (spherical) particle.

It is obvious from Table 1 that a mild breeze, of about 5 miles per hr, would permit settlement of only 100 micron particles or those rounded particles passing a 150 mesh screen; and for 10 microns diam and below, no settlement should be expected in the ordinary always-moving air currents about us. It is therefore a welcome and well-known phenomenon that atmospheric particles below settlement size are continually agglomerating into larger particles and in due course of time do settle. Observing the ordinary Tyndall beam and the huge mass of floating particles observable therein it is a satisfaction to realize that there is not a continuously increasing density of particles and that normally the Tyndall beam reflects an equilibrium condition wherein about as many old particles are agglomerated and removed by settlement as there are new particles entering the beam. The dust particles usually seen in a Tyndall beam are from 1 micron downward and that fraction from about 1/2 micron downward is invisible individually. However, when sufficiently concentrated into masses, the appearance is that of a cloud.

Two types of suspended particles are of particular interest to those whose activities in mining and smelting operations are in the West, and in the non-ferrous field. The first of these is silica dust, which in a certain size range has a health hazard. On the Miller chart the range is given as from 10 microns with a lower limit somewhat indefinite, as there is a question mark showing at 0.25 micron; others give the danger size range as from 5 micron to 1/2 micron. More particular mention will be made of this under a later division of this paper. The second type of suspended particle is white SO₃, (or SO₃ · xH₂O) a so-called "fumé," but in actuality a fog or mist that escapes in such tremendous volumes particularly from our copper plant stacks. On Miller's chart the diameters of these SO₃ particles are given for the range of approximately 3 microns down to 1/2 micron. One series of interesting investigations of size of fumes for a number of products such as ammonium chloride, sulphur trioxide, phosphorus pentoxide, sodium peroxide and the like, were carried out about 25 years ago by H. Remy⁵ in Germany. He followed the size change from formation until it was "aged," that is, agglomeration took place. He found these fume products aged very slowly after formation about 1/2 micron in size and that on "aging," that is agglomerating and

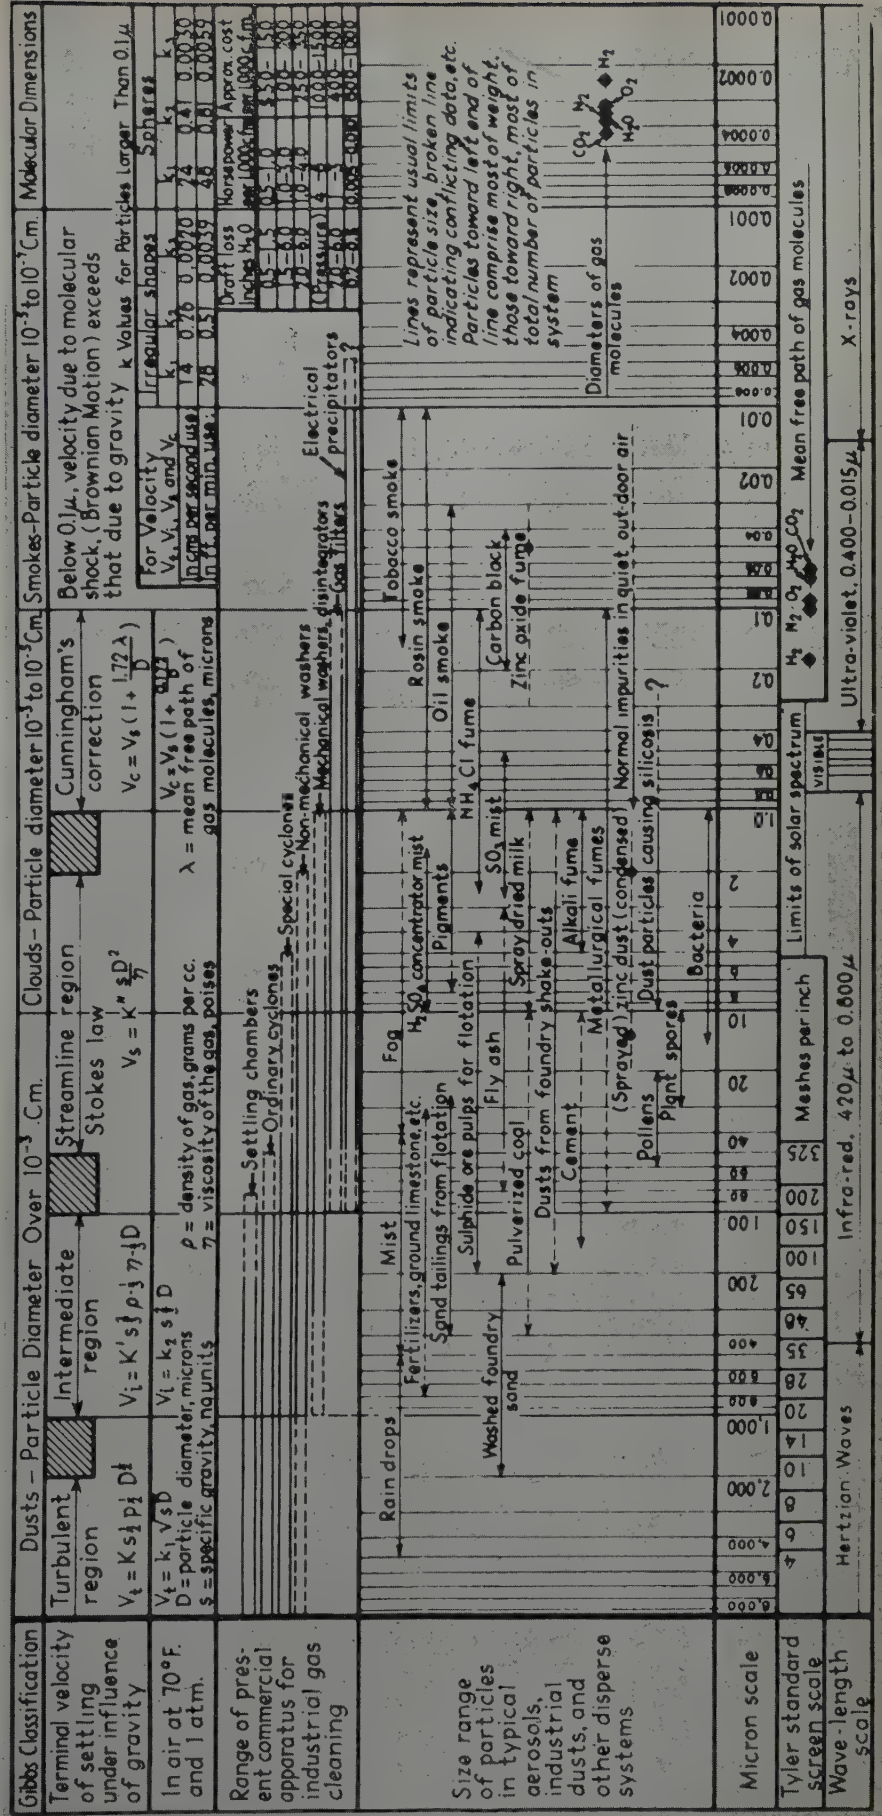

FIG 1—Summary of properties of some typical aerols. Size relationship to physical characteristics.
Compiled by C. E. Miller, *Chem. and Met. Eng.* (1938) 45, 133. (Courtesy Chemical and Metallurgical Engineering.)

settling, they were somewhat over 1 micron in size. It is to be interpreted that if the settling distance had been that of many feet instead of the inches of his glass vessel, the agglomerates would have still further increased in size to the upper limits we often detect on a slide of settled fume, that is, to 3 microns or more.

III—Dust and Fumes in Community and Individual Living

One who worked around our Western mines and lead smelters about 40 years ago noted a general indifference to possible health dangers. There were cases of silicosis on the one hand and lead poisoning on the other, occasionally both in one individual. Similar plant visits today make one realize the great advances that have been made in today's practice. Nevertheless, we still have a long way to go to reach desirable working conditions that are free of health hazards. Much of the betterment has come from understanding the necessity of proper ventilation and the installation and operation of proper equipment plus the equally vital understanding that cleanliness is an important consideration. Particularly around lead mines and smelting enterprises it is essential that simple health measures be enforced; such as the washing of hands before eating, the shower bath at the end of a shift, and changing and washing of underwear and work clothing. The reduction of incidence of lead poisoning by such measures is striking, and one has only to remember the poorly-kept plant of earlier years and compare it with an intelligently operated mine or plant of today to realize the change.

The average productivity per man hour in a well-run lead smelter or lead mine or in the handling and treatment of relatively high silica carrying ores, is more than sufficient to cover the costs of good working conditions, and in not a few places makes the difference between a profitable and nonprofitable operation.

Where it is a matter of health hazard there is the greatest anxiety to be certain and precise on the atmospheric content and character and state of subdivision of the suspended solids. In spite of a vast amount of endeavor, the development of many types of equipment and practices and procedures for particle counting and particle-collection weighing, there has resulted no one

method of procedure or equipment which may be called standard. Dust and fumes differ enormously in their collection characteristics, and while one type of equipment may give the most consistent and most accurate analysis of dust content in a given gas, it by no means follows that it will serve with equal fidelity on another type of suspended solid, or in a greatly changed set of conditions even with the original suspended solids. Therefore it may be said that there are some uncertainties still existing in reporting suspended solid concentration by any of the half dozen or more widely used types of apparatus.

Added to the problem of equipment is that of whether the basis should be expressed as the number of particles in a given gas volume or the weight of the suspended solids. The problem may be visualized by considering 1 cm cube of quartz and subdividing it into cubes of 1 micron edge length. The original 1 cm cube has 6 sq cm of total area while the equivalent mass in 1 micron cube has 6 sq meters and the number of micron particles becomes 10^{12} or a million million. On the basis of 100 million particles per cf of air the 1 cc of the original quartz would be dispersed in an air volume of 10,000 cf.

Health authorities in investigating the hazards of occupation have leaned to the consideration of a count of number of particles rather than weight on the basis that the relatively coarse particles and that portion of the fines below about $\frac{1}{2}$ micron are not relatively reactive to lung tissue; the coarse, because the moist and hair-like lining of the air passages collects and removes them, and the very fine ($\frac{1}{2}$ micron and below) because they substantially conform to the characteristics of gases and move in and out of the lungs without chemical action with the tissues.

In a practical sort of understanding the particle counters and the weight followers have agreed that 1 mg of crushed quartz material contains about 300 million particles.⁸

The count-the-particle investigators are largely responsible for our laws on permissible concentrations of dust particles per cubic foot of air and such specifications are for particles which are less than 10 microns in diam as counted on microscopic fields. For example, the State of Illinois⁶ through its health department specified permissible limits of dust by count as follows:

Total dust—50 million particles per

cf of air.

Free silica—5 million particles per cf of air.

Asbestos—5 million particles per cf of air.

Silicates—5 million particles per cf of air.

Alundum—15 million particles per cf of air.

Carborundum—15 million particles per cf of air.

Particles counted in microscopic field are limited to the all minus 10 micron sizes. Immediately after firing a blast to break rock in almost any hard rock mine a dust count will show about 50 million particles per 1 cf and it is usually necessary to reduce this to around 10 million particles in order to keep to 5 million or under of silica. Such a specification as this involves extended studies in mine ventilation. Allowable settling periods, use of sprays, bags, filters and the like all help to reduce the particle concentration to an acceptable figure. It seems the old days of one shift a day at a mine, blasting at end of shift and allowing 8 to 16 hr for workings to clear of dust particles resulting from the use of high explosives, are passing, and in our large low grade underground operations it is customary to work around the clock. Whereas in the old days a full shift was required to move the broken rock, substantially all by hand power, nowadays with a modern mucking machine the broken rock is removed in a couple of hours. Equally reduced is the drilling cycle and thus the opportunity for natural settling of rock particles is greatly lessened in comparison with the old days, and an acute problem in maintenance of limited dust concentration confronts the modern operator of larger tonnage in the lower grade ore mines.

IV—Means or Procedures for Dust and Fume Collection. Both Test or Laboratory Equipment and Commercial Installation in Mine, Smelter, Power-house and Factories

The type of equipment effective for collection in commercial operations varies with the fineness of the suspended particles as will be noted by reference again to the Miller chart. That chart indicates 5 fundamental types of equipment, *viz*, (1) settling chambers (including wire-hung dust chambers), (2) Inertial or cyclonic

equipment (including baffled chambers and many types and kinds of cyclone collectors), (3) Spray chambers and/or scrubbers, (4) Filters (baghouses), (5) Electrical precipitators. A 6th, however, is on its way, industrially, and that is supersonic precipitation. For test work, little use is made of cyclone equipment if very high or complete collection is the end object, but the other four procedures mentioned are all used in test and laboratory work and in a large number of modifications. Two additional procedures have had considerable study: (1) thermal precipitation, and (2) impingement on a prepared surface with the particular object of counting the particles as they appear on a glass slide under suitable magnification. Impingement on liquid wet wall surfaces in a bath is also used for weight samples by health authorities.

Due to the protracted discussion required for any worthwhile review of the test methods proposed and used, which would unduly lengthen this paper, it is felt those particularly interested in this field should consult the extensive literature available.^{7,8,9,10}

However, it is worth our while to consider some cost figures in commercial operations and respective efficiencies of the several types of collection equipment. You will note on the Miller chart several small tables on the right giving draft loss, power requirements and cost per 1000 cf of gas treated and, except for the cost item which needs to be doubled or more for today's installation, the data are quite in line.

It is cheapest to collect only the coarsest dust and here, if we can afford to pass everything on the order of 100 micrograms and finer, a settling chamber is the most economic type of equipment. However, you will note from the Miller chart that 100 microns or 150 mesh is less than halfway along the range of usually suspended dusts in the majority of industries. Note, for example, sulphide ore pulps from flotation, foundry dusts, cement, fly ash and the like. Of course such settling chambers have low draft losses and corresponding requirements for power are small (commonly a stack is sufficient) but, if a fan is required, it may be for ½ in. or less of draft loss and require ½ hp or less per 1000 cf of gas treated. As far as the writer knows, no enterprise having a modern dust problem has attempted to solve it by settling chambers during the last 25 years or thereabouts. Such settling chambers as are used today are inci-

dental—for example, a particularly large flue originally constructed and in anticipation of greatly increased plant size. One device, making use of the fact that decreasing the distance of fall increases collection, proposes a chamber with large number of superimposed shelves spaced a few inches apart—the Howard collector. At one time it was of particular interest to acid manufacturers using pyrites to prevent pyrites cinder from reaching the Glover tower. However, the restricted spacing between plates resulted in much trouble from choking of passageways so that gradually their use was abandoned.

Quite the contrary development has taken place with regard to inertial or cyclonic type of equipment. Special designs and modifications, almost without limit, have appeared during the last 15 to 20 years and many of these have added to the efficiency and range of fineness susceptible to collection by centrifugal equipment. Probably the most notable advance has been the recognition of the importance of decreasing the diameter for increasing efficiency and offsetting the capacity loss per item of equipment by using a multiplicity of cyclone units instead of one on a given gas volume. A number of investigators have reported such studies in various technical society proceedings or in the technical press, to which those desiring more details should refer.^{11,12,13} Some of these special cyclones do good work on particle sizes appreciably below 10 microns, although there is also an escape of 10 microns and minus 10 micron particles. The basis of these newer studies on effect on recovery are well illustrated by a table prepared by Evald Anderson¹⁴ which sets up the increased gravitational pull as the radius of collector is decreased from a 10 ft radius to a 1.5 in. radius while maintaining, through all changes in radius, a 60 fps tangential velocity (Table 2).

Table 2 . . . The Centrifugal Separating Force in a Circular Gas Stream with a 60 fps Tangential Velocity for Different Radii, Expressed in Terms of Gravity, that is, Gravity = 1 in.

| Radius of Curvature of Gas Path | Separation Force |
|---------------------------------|------------------|
| Gravity..... | 1 |
| 10 ft..... | 11 × gravity |
| 5 ft..... | 22 × gravity |
| 2.5 ft..... | 45 × gravity |
| 1.0 ft..... | 112 × gravity |
| 6 in..... | 224 × gravity |
| 4 in..... | 336 × gravity |
| 2.5 in..... | 548 × gravity |
| 1.5 in..... | 896 × gravity |

The above appears almost too good, but as a practical consideration there

must be taken into consideration the turbulence existing at the interface of the stationary cylindrical wall and the high-velocity centrifugally-moving gas stream. This is of considerable magnitude and lowers the collection or separating efficiency. Pressure drop is an important consideration on all centrifugal equipment and in general, at least up to 6 or 8 in., efficiency is improved by increasing pressure drop. Commonly such equipment runs at pressure drops of 1½ to 6 in., and doubling the cost figure given by Miller for 1000 cf of capacity is in order, viz., \$200.00 to \$400.00 per M. of gas treated.

SCRUBBERS

Of extraordinary extent of field of application, varying from simple to complex design, and from small to extraordinary large power requirements are *spray chambers* and *scrubbers*.

Their service is, of course, limited to materials or products which it is permissible to wet and collect as a sludge, and if ordinary steel is to be the structural material, then only to that type of gases with their suspended solids which are not acid, or if acid then with a continuous addition of neutralization agent as a protection against corrosion. The simplest of these starts with a spray in a flue or a stream of water running over grid or lattice work and ends at the combined cyclone-scrubber construction of Theisen,¹⁵ the Pease-Anthony¹⁶ and the very recent Venturi scrubber.¹⁷ Both the Theisen and the Venturi scrubber perform excellent service on very fine materials such as the fines present with the dusts and fumes from black liquor furnace combustion of kraft paper mills, the fumes and fine dusts of open hearth steel manufacture, iron blast furnace gas and the like. Their handicap is the large power requirement to drive the special-bladed Theisen scrubber runner, or the power required to provide the pressure drop and high gas velocity in the throat of the Venturi scrubber.

It will be noted in the Miller chart that the "Mechanical Washer, Disintegrators" cover the Theisen, and the latter is often known as a "disintegrator." The Theisen has an efficiency of recovery practically to the 1 micron size and it will also be noted the power requirements are on the order of 4-6 hp hr per 1000 cf. Many of the old Theisen washer-disintegrators handling iron blast furnace gas required power on the order of 500 to 1000 hp

and the gas leaving the Theisen disintegrator was clean enough for use in gas engine operation.

This Theisen scrubber was developed about a generation ago and, disregarding its heavy power requirement, has not been equalled by a scrubber of any other type up to very recently. However, within the last few years the Venturi scrubber followed by a Pease-Anthony scrubber has shown a capacity equal to the Theisen to collect fine particles, for example, soda fume from paper mill recovery furnaces, and fumes from reverberatory steel furnaces, with an overall efficiency of around 98 pct. The equipment, however, is about on a par with the Theisen as to power requirements and pressure drops—for example, on a paper mill, the combined Venturi-Pease-Anthony scrubber gas collecting sodium compounds, largely as fumes, and for a gas volume of some 45,000 cfm, required an induced-fan motor unit of between 225 and 250 hp.¹⁸ The velocity of gases in the narrow section of the Venturi was about 300 fps and the pressure drop across the Venturi section something over 12 in. of water gauge. Its good efficiency is proportional to the power consumed, since the latter expresses the energy necessary to break up the water into independent small particles and it has been stated that, for good collection, the water particles should be reduced in size so that the diameter ratio between water particles and suspended dust or fume particle is not greater than 10 diam for the water to 1 diam of solid particle. It is evident if one is trying to collect particles of 1 micron and less a very fine subdivision of the wash waters is required and both the Theisen and the Venturi do that very thing but at a corresponding expense for power.

Packed towers (with coke or tile) have always given a good account of themselves but their efficiency is quite largely dependent on the pressure drop which again represents a power consumption to subdivide the water or increase its total surface, and the weakness of these packed towers is their tendency to choke with deposited solids.

The simplest design of scrubber, a coarse spray in a tower, is a good gas cooler but, except for the coarser particles of dust, is a poor collector. It uses relatively little power.

FILTERS OR FILTRATION

Filters or filtration, as a means of dust and fume recovery, are very widely

used throughout industry, largely as baghouses. The temperature limit is quite low—for cotton bags it should not exceed 200°F and for woolen bags 250°F. Acid gases or corrosive compounds, of course, greatly shorten the life of bags but in very low concentrations or after partial neutralization, are encountered in many gases going to bag houses, for example, lead smelter gases.

A newer material for bag manufacture has become available during the last 10 years and gives promise, indeed, of great future service. This is glass fiber cloth, and while the earlier material tended to plug, new methods of weaving and new physical types of thread appear to offer fabrics having the filtering characteristics of wool, that is, filtering on the surface rather than through the pores of the medium. Present price and delivery are perhaps drawbacks but undoubtedly the future use of material such as woven glass fibers for baghouse service will become much more general, both for large and small units.

Bag house operation is generally on a basis of about 2 in. of draft loss but some are made to operate on 6 to 8 in. One difficulty is the passing of fume-like material through the bag weave at high pressure loss, while the same material may be satisfactorily collected at lower pressure drops, say 1 to 2 in. Cost of good baghouses or filter chambers are commonly less than electrical precipitators but still on the order of two to three times that of the best designs in centrifugal equipment. Filtration with a nearly new bag properly coated with a filter layer of particles removed from the gas stream and at a reasonable pressure drop is nearly perfect, that is, nearly 100 pct. The efficiency varies downward from this as the bags get old and worn, or as pressure drop is increased and as rapping or shaking of bags must be done to prevent buildup of flow resistance across the bag wall. In bag house operation, where the bags are being shaken or rapped at regular intervals of time, there is usually to be noted a good "puff" to atmosphere as the rapping period starts. Some test work would indicate as very good practice a 95 pct collection efficiency, considered over a period of baghouse operation.

ELECTRICAL PRECIPITATION

The last of the commercial types of equipment to be discussed is the *Electrical Precipitation* of suspended

particles in gases, perhaps as well known by the name of its inventor, the Cottrell process, after Dr. Frederick G. Cottrell, former professor of physical chemistry of the University of California, Berkeley.

You will observe from Miller's chart that its limit in degree of fineness of the material which it can collect far exceeds any other device or method of collection considered. Tobacco smoke, which is a tar fog, plus some carbon particles, is given a particle size of from 0.15 down to 0.01 micron, individually far too small to be seen under the highest magnification of a microscope. It has been stated that in the visible cloud exhaled from a cigarette there are some 5 million particles of tar fog per cc. In a laboratory apparatus the instantaneous precipitation of such tobacco smoke is quite a striking demonstration of electrical precipitation.

Strange as it may seem, the electrical phenomenon of precipitation as the result of a high potential direct current discharge and field, was a very early discovery. Hohlfield, in 1824, noted that a bottle filled with smoke and with a wire led into the bottle through the cork, could be almost instantly cleared when the knob of a charged Leyden jar was made to contact the wire into the bottle. That was at a date in history in which electricity was truly still a mystery and the only known way to generate it was the rubbing of a glass or wax rod with a silk or wool cloth.

As an industrial process it did not become of interest or successful until Cottrell, in the early years of this century,¹⁹ applied our modern electromagnetic means of producing abundant high potential electricity. It is true a first effort was made at industrial application by Sir Oliver Lodge and associates in 1884-5, in attempting the precipitation of lead fumes in a lead smelter flue in Wales. His source of electrical power was a Wimshurst machine (developed in 1881) of two 5-ft glass plates driven by a 1 hp steam engine. We know now that such a Wimshurst machine could energize only a few inches of a pipe electrode and that to handle successfully the gases from an average lead smelter requires thousands of feet of electrode pipe and perhaps 50 to 100 kw of installed high potential electrical equipment for service therewith. The conversion of high potential alternating current readily obtained from modern power plant equipment into direct current (true, of an intermittent or pulsating type) by

means of a synchronous rotating make-and-break switch, was a major contribution by Cottrell and by this means he was enabled to pass to his electrically insulated high potential discharge electrode the necessary power to provide the electron or corona glow essential for dust charging and static precipitation.

While electrical precipitators for dust, fumes, mists and fogs have been built in a great variety of size, shape and outline designs, in essence they conform closely and are commonly either of plate or pipe design. The spacing between plates or the diameter of electrode pipes varies generally from 6 to 12 in., is tied directly to the available or desirable high voltage, and the latter, for general working conditions, is specified in the range of 50,000 to 100,000 volts. Always the high potential or discharging electrode possesses elements of small diameter, that is, from a No. 16 wire up to $\frac{1}{4}$ in. rod from which there is obtained an electron discharge, commonly visible as a corona glow. Such electron emission produces a rupture stress upon the electrical neutral gas molecules immediately adjacent to the discharge electrode, and while the positive charge must fall into the negative discharge electrode, the negative charge, i.e., the electron charge attaches itself to a gas molecule and such charged gas particle under the strong electrical field between the discharge and collecting electrodes starts to migrate to the collecting electrode. As it encounters dust or fume particles it either gives up its charge thereto or the charged gas particle is adsorbed or attached to the dust particle and thereby the suspended dust or fume particle is moved toward the positive or collecting electrode. Upon reaching the collecting electrode such charged dust particle should give up its charge and become grounded and form one particle of a cake which may later be rapped or shaken down into a hopper beneath the plate electrode. The readiness of suspended particles to receive a charge, to release such charge upon reaching the electrode of opposite polarity and the mechanical adherence of deposited particles, all are modified and are increased or decreased by conditions within the gas stream. Therefore for "poorly conducting dusts" it is common to "condition" the gases and particles, that is, improve their collectability by adding to the gas stream such agents as moisture, acids, bases, salts, oils, and others. In general

each installation and the operations to which it is attached provide a special problem and require specific handling.

With the provisions as outlined above, the field of collection of industrial dusts and fumes is broad indeed and the actual application and plant installation are ever widening and the units in service always increasing in numbers.

Since its cost of installation is several times that of cyclonic equipment or a settling chamber, its use is justified only where the amount and value of recovered products are large or where the degree of gas cleaning is of the highest importance. Good examples of the latter are to be found in the gas cleaning necessary for contact acid manufacture from gas produced in the roasting of mineral sulphides, and the cleaning of iron blast furnace gas for use as a dust and fume-free fuel in stoves and coke oven retorts.

One phase of electrical precipitation not covered in the preceding discussion, is its use in the purification of air for human habitations. Here the recovery in the precipitator may be bacteria, pollen and the like, as well as minute floating particles of solids and mists. Its construction and operation vary from those of the usual commercial plant by the use of very much reduced spacing and corresponding voltage reduction and the use of very fine wires for ionization and of a double plate field for the static collection of the charged particles. It is essential in this field that ozone and oxides of nitrogen be reduced below detectable amounts, which is accomplished by the relative low voltage and the use of a static field following upon a gas and dust-charging field.

V—Description of Equipment of the Several Types Discussed Previously for Dust and Fume Collection

SETTLING CHAMBERS

In 1902 the Anaconda Copper Mining Co. completed a new copper smelter which, at that time, was the largest and the best equipped of any such type of plant in the world. In design and provision for the possibilities of the future, no plant built had had better engineering or more skill of design. Each unit of operation such as roaster, blast furnace, and converter department had its own stack and its own dust collection settling chamber. These

chambers, approximately 40 ft wide, 40 ft high and 260 ft long had a net height for dust settling of 30 ft, since about 10 ft from ground level a chamber floor was installed and below this was a system of tracks and means of dust removal and transport. Since the furnace feed, as compared with today's, was relatively coarse, comprising crude ore and the output of the best of gravity mills of the day, the settling chambers gave a very good account of themselves on the basis of copper recovery, but still there was a stack discharge which reached the valley areas well below the smelter level and several miles away, which brought on complaints of harm to livestock and growing crops. To secure still more provision for settlement, for cooling and condensing of certain constituents and to discharge the smelter gases at a greatly increased height above the valley, a combined settling chamber and flue for the combined smelter gases was carried up a hillside, the lower section being 60 ft wide, 20 ft on its side walls, both sides sloping to the middle with an underground cleanout tunnel on the middle line with 36 ft from top of flue to top of tunnel. This lower section was built approximately 1000 ft long and with a brick jack arch roof. The upper 1000 ft was made just twice as wide and twice the cross-section and with a steel top to promote condensation, particularly of the arsenic trioxide, the constituent of the stack gases to which most objection had been raised. This entire system of settling chambers and extended flues comprised about 6,000,000 cf of settling space and represented a heavy investment even for those days. Due to the acid character of the gases, the only other competing equipment of that date, the baghouse, was entirely out of consideration, and the system installed did represent the best of engineering and scientific application.

Nevertheless the complaints continued and the evidence of operation indicated the inability of a settling chamber to collect satisfactorily the "fumes" or volatilized and condensed metallic compounds such as the oxides of arsenic, lead and antimony. Years later, to bring the collection of all products up to a high degree of recovery, an extended Cottrell or electrical precipitation installation was built to operate in series with and after the settling chamber system. Its collection, largely fumes, brought the overall recovery of both dust and fume from

furnace to stack to the present highly efficient operation.

An interesting modification or improvement of the simple settling chamber is the wire-hung dust chamber of which the largest was that installed at the Boston and Montana Company's Smelter plant at Great Falls, Montana, in 1908 or 1909.²⁰ As a matter of fact a wire-hung dust chamber is really a combination of a settling and an inertial type of recovery equipment, since the gas stream in striking the wire must sharply turn while the dust particles move forward and strike the wire surface, yielding their energy thereto and falling. This wire-hung dust chamber was 177 ft wide, 367 ft long, 21 ft high. It had a completely hoppers bottom (over 1000 hoppers) with wires attached to and guided by heavy screens of about 2 in. mesh. Over one million wires in two banks were hung in this chamber. A mechanical rapping device was provided for the suspended system of vertical wires. Its collection efficiency, on total solids, was about $3\frac{1}{2}$ times that of the simple open dust chamber and it undoubtedly collected more efficiently on the finer fractions; but in course of time, due partly to shutdown periods and consequent corrosion, it was found too expensive to maintain the wire hung feature of construction and the wires were removed. This settling chamber, without its wires, operated for a number of years but eventually was replaced by a Cottrell, the latter making use of hoppers and supporting steel work of a portion of the old chamber.

INERTIAL OR CENTRIFUGAL

For the inertial or centrifugal type of collectors it is proposed to discuss briefly three installations, two on boiler plant gases and one on converter dust recovery.

Modern combustion of coal in a power house required the coal to be finely ground and then burned in suspension. This results in most of the ash appearing in suspension in the gases as finely divided small spheres, some hollow, and of which a fair proportion—say a third—may be in the size range of 1 to 10 microns. The percentage of the ash leaving the boiler as so-called "fly ash" is usually better than 80 pct of the total ash and occasionally some plants get into the 90 pct class of ash to stack gases. While the huge central station plants with their requirement of overload for limited periods have generally, in the past, used electrical precipitators, some of

the new plants today are choosing a combination of cyclonic tubes followed by an electrical precipitator. This mechanical collector between the boiler and the precipitator, for a 1,000,000 lb per hr boiler with over 400,000 cfm of flue gas, comprises a series of Multiclone units all operating in parallel from a common flue of boiler width, there being 5 units of Multiclones, each unit with 156 tubes in parallel position, the tubes being of a uniform inside diameter of 9 in. and each tube provided with a stationary cyclonic vane at its top and inlet heading.

Plants of an industrial nature are not usually so severely restricted as to amount of emission and an example without the auxiliary electrical precipitator, in series, is a sugar mill at Vancouver, B.C. It is an excellent example of a reasonable efficiency utilizing a small-diameter type of cyclonic collector with a multiplicity of tubes. The gases derived from three boilers at this Vancouver plant and totaling approximately 70,000 to 80,000 cfm, pass to a battery of Multiclone units, each unit of 30 tubes and each tube 9 in. in diam. A system of dampers is provided for the Multiclone units so that as a boiler is taken off or put on the line the number of Multiclone units in service can be proportionately varied. Normally the pressure drop across the Multiclone is maintained at 2 to 3 in. of water column. The pulverized coal is of local supply of relatively high ash and usual efficiency is on the order of 85 pct.

Multiclones with a larger diameter of tube, that is, 16 in. diam tubes have found service at several copper smelter converter installations in the West. As an example, there may be taken the installations at the McGill, Nevada, Smelter of the Kennecott Copper Corp. Here 4 units of Multiclones, each of 45 tubes 16 in. in diam are installed to serve three converters. The gas volume approximates 273,000 cfm at 600°F. For movement of the gases through the flue system and to supply the approximately 3 in. pressure drop across the Multiclones, a large induced draft fan is located on the exit flue from the Multiclone units and is driven by a 150 hp motor. Due to the corrosive nature of converter gases at lowered temperature, ample heat insulation has been provided, mainly in the form of a rock wool blanket 4 in. in thickness. On the copper content only of the converter dust and fine discharge, the Multiclone collects 90 pct or better but on the overall of dust and fume the

collection is considerably below the copper collection.

FILTRATION

The third method of dust collection to be illustrated by plant example is that of baghouse and we have selected two baghouse installations; one at a copper smelter and one at a lead plant.

While present-day practice does not favor a baghouse on copper plant gases but does favor its use at lead reduction works, it is of interest to note an example of a baghouse installation on a copper plant works which for its day and time was a signal success. Early in this century the Mammoth Smelting Co. at Kennett, California, operated a copper smelter of 4 blast furnaces and 2 converters. The copper ore, a sulfide, also carried enough zinc so that the gases were approximately free of SO_3 or H_2SO_4 and, by lowering the temperature by radiation-cooler pipes, plus further cooling by dilution with outside air, successful operation on the baghouse was obtained. The installation of the baghouse was not necessitated by plant requirements as the collected product was not returned to furnaces, and unless it has been washed away or dissolved by the rains since the plant was shut down about 30 years ago, it is still on hand at the smelter site. Its construction was due to a desire of the smelter company to meet the objections to smelter dust fall from communities in the upper end of the Sacramento Valley.

The gases from the furnaces averaged about 600°F and were passed to a radiation cooler consisting of a number of 2-ft pipes operating in parallel, which discharged to the inlet flue of the baghouse. Into this same header flue a fan forced outside air and the resulting air-smelter gas mixture was maintained at about 200°F. The baghouse discharged to atmosphere through the 5 large square stacks. Approximately 3000 woolen bags, 18 in. diam by 35 ft high were installed in the baghouse and the gas volume, as cooled and diluted to approximately 200°F, amounted to 350,000 cfm. The tonnage of ore smelted amounted to approximately 1000 tons per day, and the baghouse collection to 18 to 20 tons per day.

Typical baghouses for lead smelter service have been described by several authors and the one in service at Murray Smelter²¹ in the Salt Lake area is representative of good design and good construction. The housing for the bag sections is of heavy brick construc-

tion and has outside dimensions of 216.5 ft long, 90.5 ft wide and a height to roof trusses of 51.5 ft. The lower 16 ft of wall is 21 in. thick, the next 18 ft 17 in. thick and the remaining height 13 in. wall. Forty-eight brick buttresses are spaced along the walls and add stiffness and rigidity to construction. There are four bag compartments separated by brick partition walls from floor line to roof trusses. Each compartment below the chamber floor is separated into 4 divisions by brick walls, each with its own cleanout door. Installed in the four compartments is a total of 4032 bags, each bag 18 in. diam and 30 ft long and these bags are made of wool to very careful specifications. As originally built there was provided 570,012 sq ft of filtering area to handle 165,000 cfm of gas or at the rate of 3.45 sq ft of bag surface to 1 cf of gas per min. Mechanical rapping or shaking of the bags was provided at their top ends.

Some later and smaller baghouses at lead smelters have been able to increase greatly the ratio of cfm per square foot of area by means of fully automatic operation of damper and bag shaking, some reporting a ratio of 1 to 1. In the case of a true fume such as arsenic or lead, however, increasing velocity through the filter cloth openings tends to cause increased escape of unagglomerated particles, and so increased economy of investment is offset by somewhat lower efficiencies. However, it is to be recollected that baghouses at lead smelters are as much a consideration for employee and community health as they are an investment in equipment to provide an economic return, and therefore are always planned for relatively ample capacity and high efficiency.

SCRUBBERS

The fourth means of collection, that is, scrubbers, "disintegrators," and the like, making use of water as a medium to collect fume and dusts, have rarely found practical use at lead and copper works except for the small volumes encountered in silver and gold refining, and this, no doubt, has been largely due to the corrosion hazard. More than half a century ago, around iron blast furnaces, they received much attention and many units were installed. The combined inertial and wetting procedures used, for example, the Theisen disintegrator gas washer, were the most efficient collectors on the market and

collected not only the dust, but also the zinc and alkali fumes which often appear in the iron blast furnace gases. In principle, this Theisen scrubber is a fan with the usually solid blades replaced by perforated plates or a heavy screen mesh. Water is introduced with the inlet gases near the center of the fan runner and is broken up into fine particles in passing through or from center to periphery of runner. To collect particles of dust and fume, the water particles must be on the order of not over 10 times the diameter of the dust or fume particles and where particles of around 1 micron or less are to be collected, an enormous subdivision of water particles is required and this subdivision requires extraordinary high power consumption. In the older steel works of continental Europe, often the largest power unit of the works was attached to the Theisen washer and from 2 to 10 hp per 1000 cf of gas treated was the rule. The Theisen disintegrator, however, did prepare iron blast furnace gas for combustion in gas engines with a content in solid suspended particles not far from that of outside air. Today their use has greatly decreased, the same degree of cleaning being secured by a film type of electrical precipitator with a power consumption only a few percent of that of the Theisen. Nevertheless, it should be noted that at the time of its first introduction, 50 years or more ago, it was an outstanding success and for the service it rendered over a generation or more, no other equipment of that period was in its class.

However, within the last few years a new scrubber has been brought on the market, known as the Venturi¹⁷ which, combined with the Pease-Anthony scrubber¹⁶ shows reported efficiencies on the order of 98 pct on paper mill fume. On reverberatory open hearth waste gases containing fumes and the like, equally good efficiencies have been reported. In the Venturi scrubber a high velocity of gas stream is maintained at the throat, about 250 to 300 fps with a corresponding pressure drop across the throat section approximating 12 in. of water column. A series of water connections surround the throat of the Venturi, and in the throat conditions are such that an extraordinarily violent turbulence is set up, sufficient to provide for the wetting and collection into the moving water gas mixture, of the dust and fume particles suspended in the gas stream. From the Venturi the gases

either pass to a simple cyclone for separation of water particles and gas, or to a Pease-Anthony scrubber, which is a cyclone with tangential gas entrance near the bottom and a central column with an array of spray heads discharging in such a manner that the longest possible path in the cylindrical shell is obtained for spray discharge and passing the gas stream. On paper mill (soda) fume, the Venturi alone has been reported as collecting approximately 90 pct and the combined Venturi and Pease-Anthony 98 pct of the suspended fumes in the gases. The latter figure and also that for the combined Venturi-Pease Anthony have been reported on an open hearth reverberatory with oxygen in the bath, the latter to speed the refining operation at top temperatures. The drawback of the Venturi scrubber, like that of the Theisen, is the high power consumption required for induced fan and to provide the throat velocity or the pressure drop across the Venturi and the Pease-Anthony. About 220 hp was used on the reverberatory tests handling approximately 45,000 cfm. Should it prove practical to reduce the power consumption without decreasing the efficiency appreciably, this type of scrubber should have most excellent industrial possibilities.

Excepting these two types of Theisen and Venturi which do collect fume, the general run of scrubbers is used on dust particles (say, 100 to 1000 times the weight of a fume particle) and there they do acceptable work with relative low power consumption. Probably best in practice are the countercurrent tile-packed towers, although commonly these require periods of special flushing or cleaning to prevent choking and buildup. They are generally planned for a 1 to 3 in. pressure drop across the tile sections but with only a small buildup of mud or caked material will promptly double or triple their pressure drop.

On hot gases and series operation of two or more spray chambers, the first at a higher temperature, the second cooling the gases below dew point, it is practical to vaporize more moisture into the first chamber than the gases can retain in the cooler conditions of the second spray chamber with the result of the condensing out of a proportion of the water vapor produced in the first chamber. Such condensed precipitates make use of fine particles of dust and fume as nuclei for their condensation and thus permit of high effi-

ciencies. On a calcining kiln, where only a fine dust escaped, a reported 97 pct removal of suspended solids in gases was reported in this manner of operation.

The great objection to scrubbing in general is the need to care for large volumes of water containing a relatively small amount of solids. Thickeners, filters, storage tanks and extensive pumping and piping are commonly required to complete a properly operating plant.

ELECTRICAL PRECIPITATION

We now come to the fifth and last method under discussion for dust and fume collection, *viz.* *Electrical Precipitation*. So many plants have been described in the literature that it seems questionable if anything new may be offered here. However, we propose to describe briefly two types of precipitators: (1) that aimed at collection of large quantities of dust or dust and fume, and (2) that aimed at the final cleanup of a gas so that such cleaned gas may be advantageously used in further processes or equipment.

For the first classification above, it is proposed to describe an electrical precipitator recently installed at a cement plant in the South, and a power plant precipitator going into service in the near future. For the second classification above or purification of gases it is proposed to describe a plant installed to "fine"-clean iron blast furnace gas and a plant to clean roaster gas for contact acid manufacture.

The cement plant of the Universal Atlas Cement Co. at Leeds,²² Alabama, is not far from the center of the town and while producing only at a minimum or average capacity did not discharge from its stack an objectionable quantity of dust. Along with the war and the aftermath of war, with its huge demand for cement, came the necessity to increase to the limit the plant's capacity to produce and, with this increase, came immediate evidence of greatly increased dust discharge from the stacks. To meet the desired reduction in stack emission of solids a three-unit precipitator was installed, each unit to handle 100,000 cfm at the prevailing temperature of approximately 700°F. The actual efficiency for slightly less than the rated gas volume was 94 pct or better. Each of the three units of precipitator are provided with three sections or electrode banks in series, the first two sections being of 15 gas passageways or ducts on 8 in.

centers and the last section of a V or pocket type with 12 gas passageways or ducts on 10 in. centers. Each collecting electrode approximates a dimension of 8 by 18 ft, the discharge electrodes being square twisted rods $\frac{1}{8}$ in. in diam in a supporting frame. Six special electrical units each with a 75,000 volt transformer and mechanical rectifier serve the installation. Automatic or push button controls are provided for all operating equipment including rapping both discharge and collecting electrodes, dampers, screw conveying equipment and the like. The return of the dry dust to a wet process plant is always a difficult problem and here 55 pct of the collected dust is returned as a dry feed to the center of a vortex of slurry just as it enters the feed pipe to kiln.

Power plants and boiler sizes are ever growing larger and in some of the newer power plants gas volumes exceed anything but those of our very largest copper smelters. The boilers of huge size now being installed are possible because of powdered fuel combustion developments and since, in powdered fuel plants, the major portion of the ash is suspended in the spent gases from boiler and normally passing to stack, collection equipment for ash particles has become an essential requirement. Electrical precipitation is generally favored because of the degree of fineness, (20 to 50 pct minus 10 microns) of the ash and the fact that its collection is dry, thus avoiding a corrosion problem.

At the present time there is under construction a power plant involving three boilers each of one million lb steam evaporation per hour and each producing somewhat under $\frac{1}{2}$ million cf of gas as measured at exit of air heater at approximately 300°F. Each boiler gas discharge has its own collection installation and a brief description follows: The collector is a combined inertial and electrical precipitator in which the electrical precipitator for each boiler is preceded by a Multiclone installation as described under the heading of inertial or centrifugal equipment. The precipitator for each boiler is divided into five units, each with an outlet damper and each precipitator unit consists of 15 gas passageways or ducts, and while only one section long, each duct carries three collecting plates, each plate 3 ft wide by 16 ft high with 2 ft of settling and agglomerating space between each two plates in the direction of gas flow. The duct width,

or from center to center of two collecting plates, is 9 in. Discharge electrodes consist of the usual square twisted $\frac{1}{8}$ in. bars. The gas volume per boiler is 400,000 cfm at prevailing temperature of 325°F and the total for three boilers is 1,200,000 cfm at 325°F. For the three-boiler plant there is a total of 2340 Multiclone tubes preceding the precipitator and a total of 225 gas passageways or ducts in the electrical precipitator. This gas volume is larger than the usual nonferrous metallurgical plant except for several of the very largest copper smelters. Eventually the power plant will have a fourth and a fifth boiler, each of one million lb per hour production of steam or perhaps even larger—a million and a quarter is even under discussion.

From collection of the major portion of a nuisance waste at a power plant with a huge gas volume, we turn now to a plant handling a much more limited gas volume, a mere 100,000 cfm, but which is required to clean the gas almost to the equal of outside air, that is, to 0.007 grain per cf or better. This is entirely an operation of purification of the gases and the recovered material, mostly fume, is of no value or use.

Modern steel works find it profitable to have the cleanest obtainable fuel gas from iron blast furnace operation in order (1) to prevent slagging of the checker work in the stoves, (2) to permit closer packing of refractory brick in stoves, (3) to permit satisfactory operation of automatic air and gas regulators on blast furnace stoves and of fuel at coke oven plants without danger of slagging the brick work. All this they obtain with a train of collection equipment on the gases coming from the iron blast furnace top. The train consists of (1) a dry dust catcher or chamber where the very coarse dust is caught and where dust concentration is reduced from around 12 grains per cf to around 3 or 4 grains per cf. (2) The gases then enter a scrubber provided either with a checker work of wooden strips or a series of sections of tile packing with heavy coarse sprays at top and commonly at two or three intermediate points with gases passing upward and water downward, that is, countercurrent operation. The gas entering the scrubber has a concentration of 3 to 4 grains and the gas leaving the scrubber has a concentration in solid suspension of 0.25 to 0.3 grain. From the scrubber the gases enter the precipitator and are cleaned in the

precipitator down to a concentration of approximately 0.007 grain per cf. This reduction in suspended solids of 0.3 to 0.007 corresponds to an efficiency of 97.7 pct. From the precipitator the clean gases go to the receiver and to special services where extreme cleanliness is desired. The gas volume at precipitator approximates 100,000 cfm and 4 units of precipitator are placed in two circular shells, each with a division wall down its center. Each unit has 126 pipe electrodes 8 in. in diam by 15 ft long or a total for the 4 units of 504 tubes. Three electrical sets, each 25 kva, with 75,000 volt transformers supply the special direct current required for precipitator operation.

A second field where electrical precipitators are used in the purification of gases is in the manufacture of sulphuric acid by the contact process with the SO_2 derived by combustion of the usual run of sulphide ores or sulphide concentrates—commonly zinc, iron, or copper sulphides or mixtures usually with minor amounts of arsenic, antimony, lead and the like.

Arsenic oxide, and some of the other constituents, poison the platinum catalyst and others merely coat over the active mass, so it is necessary to have the gas, before going to the SO_2 to SO_3 converters, cleaned down to a few parts in 100,000 of arsenic figured as As_2O_3 and as grains per cf. This is accomplished by a thorough wetting and cooling of the roaster gas in towers and scrubbers of various design, occasionally a packed tower is required, and the passage of the gas at 80 to 100°F to a lead type precipitator. The gases reaching the precipitator are fully saturated with water vapor and contain in addition mist particles of very weak acid. These latter usually contain the minute particles of arsenic probably as the nuclei of mist particle formation. In one acid plant with a gas volume of about 7500 cfm at the prevailing temperature of 80 to 100°F, a precipitator was used consisting of 72 pipes, 70 of these 10 in. in diam by 12 ft long and two pipes carrying stiff rods to lower grid, 13 in. diam by 12½ ft high.

The actual precipitate was a very light liquid sludge which drips from pipes and eventually finds its way to a waste sump. One electrical set with a 75,000 volt transformer and two mechanical rectifiers (one a spare) serves the pipe section. The discharge electrodes are lead-covered iron wires in a star cross-sectional design and held straight and true by lead weights. Many lead pipe units of the same general design are used at acid-concentrating plants such as are to be found at munitions works and occasionally at chemical and oil works. Both material savings and improvement in health conditions are derived benefits from the precipitator operation on waste acid gases.

Conclusion

It may be true we have tried to cover too much, too sketchily in this paper. However, it is thought the object in view, *viz*, to acquaint our member engineers both with a birds-eye view of the problems of collection of suspended dusts and fumes as a whole and also to offer enough of the practical in description of types of equipment and specific installation as will permit of fair engineering visualization, has been reasonably well accomplished. It is recognized that books have been written and more are in prospect on particular phases of the subject matter here handled and that is as it should be, for truly to meet the modern requirements in dust and fume control in mines and mills, in industrial plants and smelters, will require some technical knowledge of the problem by nearly all engineers and a great deal on the part of those directly involved in collection. Also this latter class in industry will constitute a staff many times that of today and the expenditure for equipment will approximate hundreds of millions and this is limited to the near continental area of our United States.

Some Observations on the Recovery of Cold Worked Aluminum

T. V. CHERIAN,* P. PIETROKOWSKY* and J. E. DORN,* Member AIME

Introduction

The phenomenon of recovery of cold-worked metals is interesting not only because of its practical importance but also because of its fundamental significance in solid state reactions. Although extensive investigations^{1,2} have already been made in an attempt to discover the mechanics of the recovery process, many of the observations have not yet been satisfactorily correlated to provide a completely consistent model for the process. The wide differences in the recovery rates of various properties can be cited as a typical example of one of the difficulties that are encountered. Frequently, for example, the electrical resistance will have almost completely recovered before any recovery in tensile strength can be detected. Of course, such differences in the recovery rates of different properties might be explained by assuming that each property is a unique function of the work-hardened state, and consequently each property exhibits its own unique recovery rate. The assumption that different properties are uniquely related to the work-hardened state cannot be denied. On the other hand, the properties that recover at different rates often exhibit more or less parallel changes upon work-hardening. This suggests that the microstructural changes attending recovery are not exactly the reverse of the changes attending work-hardening. Several types of imperfections must be postulated in order to account for this apparent anomaly. The different recovery rates for various properties, then, are due to the different recovery rates of the type of imperfection to which each property is most sensitive as well as the unique dependence of each property on the cold-

worked state. This concept assumes that a simple model of the work-hardened state consisting only of one type of imperfection, such as Taylor's type of dislocation patterns, is inadequate to cope with the diversified phenomena attending work-hardening and recovery.

Although current models for the work-hardened state are not useful for describing all aspects of the recovery process, the general trends of the recovery of each postulated type of imperfection as a function of time and temperature should be at least qualitatively deducible from the rather well developed laws of kinetics of reactions in the solid state. Consequently, recovery data might prove useful for elucidating some aspects of the complexities of the work-hardened state of metals. A preliminary attempt to study work-hardening by investigating recovery rates of cold-worked metals is outlined in the following pages of this report.

Experimental Procedure

Many properties recover when cold-worked metals are annealed below their recrystallization temperature. Therefore, electrical resistivity, thermal electromotive force, X ray diffraction line

widths, X ray diffraction line intensities, elastic spring back, density and other physical and chemical properties have been used to study the recovery process. Major interest, however, has generally been directed toward the recovery of the mechanical properties such as hardness, yield strength, and tensile strength. But a search of the literature suggests that the effect of recovery on the true stress-true strain curve has been neglected, in spite of the current recognition of the fundamental importance of such an investigation. An investigation on the effect of recovery treatment on the true stress-true strain curves in tension, therefore, was undertaken in the present study.

Commercially pure aluminum (99. + pct Al) in the form of 0.100 in. thick rolled sheet of 2S-O aluminum alloy was selected as the material for this investigation because rather extensive correlatable data are already available on the recovery of some of its properties. Tensile specimens having a 6 in. long gauge section and a uniform reduced section width of 0.500 in. were machined from the sheet in accordance with a design that has previously been reported.³ All specimens were selected with their axes aligned in the rolling direction. In order to eliminate the effects of previous work-hardening and the effects of machining, the specimens were annealed for 15 min. at 750°F before testing.

During tensile testing the loads were measured by means of a proving ring (sensitive to $\frac{1}{2}$ lb) in series with the specimen.⁴ Strains were determined from the extension of a rack and pinion strain gauge sensitive to a strain of ± 0.0001 . The stress was recorded as the true stress, namely

FIG 1—Recovery of 2S-O alloy at 90°F after a prestrain of 0.092.

FIG 2—Recovery of 2S-O alloy at 212°F after a prestrain of 0.092.

$$\text{Stress} = \frac{\text{Load}}{\text{Instantaneous Area}}$$

and the total true strain was evaluated by

$$\text{Strain} = \log_e \frac{\text{Instantaneous Length}}{\text{Initial Length}}$$

The true plastic strain was then calculated by subtracting the known elastic component from the total true strain.

Experimental Results

Several typical experimental results are given in Fig 1 to 4 in the form of true stress-true plastic strain curves. The upper curve of each figure is the work-hardening curve for the annealed specimens. The remaining curves were obtained from specimens that had been strained to $\epsilon = 0.092$ at atmospheric temperature, recovered for the recorded time and temperature, and then re-tested at atmospheric temperature. Only a few representative data are shown in Fig 1 to 4. Other prestrains

(0.048 and 0.125) and intermediate times of annealing yielded analogous results.

Discussion of Results

The data recorded in Fig 1 reveal that cold-worked aluminum recovers upon annealing at 90°F. The recovery rate is quite rapid initially, but it ceases before complete recovery of the initial flow stress is achieved. It is significant to note, however, that upon restraining only the initial flow stress appears to have recovered, and after an additional strain of about 0.04 the stress-strain curve of the recovered material coincides with that of the virgin annealed specimen at the same total strain. Consequently those imperfections that are readily activated at this low recovery temperature are readily reintroduced upon restraining. The exact coincidence of the latter portion of the stress-strain curve of recovered specimens with the curve for the virgin

annealed material at the same total strain suggests that the work-hardened states in the two cases are substantially identical.

As shown in Fig 2 the phenomenon of recovery at 212°F is qualitatively analogous to that which occurs at 90°F. The only significant difference is that a greater amount of recovery of the initial flow stress results at the higher annealing temperature. Nevertheless the constant value of the initial flow stress is yet above that for complete recovery.

The term metarecovery will be used to describe the type of recovery experienced by cold-worked aluminum 2S-O alloy upon annealing at 90 and 212°F. Metarecovery, then, consists of the removal of readily activated imperfections at low recovery temperatures. The removal of these imperfections causes an appreciable decrease in the initial flow stress; they are again readily restored upon restraining. After small additional strains (about 0.04) have been imposed on the recovered

FIG 3—Recovery of 2S-O alloy at 300°F after a prestrain of 0.092.

FIG 5—A method of evaluating the amount of orthorecovery.

specimen it responds plastically in a manner identical with that of a virgin specimen which has been deformed to the same total strain. Metarecovery takes place at a high initial rate but the specimen soon acquires constant plastic properties before complete recovery occurs. The amount of metarecovery, as dictated by the reduction in the initial flow stress below the value in the work-hardened specimen, is greater the higher the annealing temperature. Two possible interpretations can be ascribed to this observation. If the type of imperfections that are removed upon metarecovery do not interact with each other, they must individually have activation energies for recovery over a broad band of values. The imperfections having the lower values of activation energies are then removed at the lower annealing temperatures, whereas higher annealing temperatures are required to remove those imperfections that have higher activation energies. In this way it is

possible to account for the early termination of metarecovery before complete recovery is achieved. On the other hand, the imperfections might exhibit interactions such that the activation energy for metarecovery is a function of the density of the imperfections. In order to account for the observations it must be assumed that the activation energy for recovery increases rapidly with a decrease in the density of imperfections. The present evidence does not permit identification of which of the two alternate mechanisms of metarecovery is correct; it is interesting to note, however, that only the second mechanism is compatible with recovery of Taylor's stable patterns of edge type dislocations.⁵⁻¹⁰

The stress-strain curves given in Fig 3 and 4, for specimens annealed at 300 and 400°F, appear to be slightly different from those shown in Fig 1 and 2. They not only exhibit the previously described metarecovery, as indicated by the decrease in the initial flow stress after annealing, but they also show permanent effects of the annealing treatment. The flow stress after recovery at these higher temperatures never acquires the same value as the flow stress of the virgin material at the same total strain. Beyond an additional strain of about 0.05 after recovery treatment at these higher temperatures, the stress-strain curves for the recovered specimens fall below but parallel to that for a virgin annealed specimen at the same total strain. It will be convenient to describe this type of recovery as orthorecovery. Two important characteristics serve to distinguish orthorecovery from metarecovery. First the true stress-true strain curve of a material which has been subject to orthorecovery is below that for the virgin material at the same total plastic strain for all strains. And secondly, whereas orthorecovery appears to continue until complete restoration of the annealed properties is achieved, metarecovery practically ceases far short of complete recovery. This conclusion is immediately apparent when it is noted that even after annealing 2466 hr at 300°F or after 664 hr at 400°F additional orthorecovery is yet occurring.

It is not immediately apparent as to how a quantitative measure of orthorecovery might be obtained. It might be thought that shifting the stress-strain curve of a partially recovered specimen to the left would bring the latter portion of the stress-strain curve

FIG 6—The reduction in flow stress upon recovery as a function of total strain.

of the recovered specimen into coincidence with that for a virgin specimen. Then $\epsilon_r - \epsilon_u$ shown in Fig 5, would serve as a measure of the strain-recovery. This method should work if only one kind of an imperfection is present. But, as shown in Fig 5, coincidence of the stress-strain curves for the virgin and annealed materials is obtained at only one point, a fact that not only disqualifies the proposed procedure, but also implies that several types of imperfections responsible for work-hardening are induced by cold-work.

In order to obtain a method of measuring the amount of orthorecovery, consider evaluation $\sigma_u - \sigma_r$ (illustrated in Fig 5) as a function of the total strain. Several typical curves for various recovery treatments are shown in Fig 6. It is immediately apparent that the various curves are substantially parallel. After annealing for 2588 hr at 212°F the lowest curve representing the effect of almost complete metarecovery is obtained. The remaining curves represent the effect of both meta- and orthorecovery for various recovered states. The parallel trends of these curves suggest that metarecovery is almost complete after annealing at 212°F for 2588 hr and that orthorecovery results in a uniform decrease in the flow stress below that for the virgin unrecovered specimen independent of the subsequent strain.

In order to test this concept consider now the data of Fig 7 obtained by prestraining about 0.048 and annealing at 400°F for recovery. If after annealing for 1.5 hr at 400°F all of the metarecovery has taken place as well as some orthorecovery, the difference between the stress-strain curve after 1.5 hr of annealing and that following 1578 hr of annealing is attributable to orthorecovery. Furthermore, if orthorecovery causes a uniform decrease in the flow stress for all strains a vertical shift of the stress-strain curve after annealing 1.5 hr should yield a curve that coincides exactly with that obtained after annealing 1578 hr. Upon shifting the stress-strain curve after 1.5 hr of annealing to lower stress values, the broken curve of Fig 7 is obtained. The excellent agreement between the experimental data and the broken curve support the concept that orthorecovery consists of a uniform lowering of the flow stress for all strains, whereas metarecovery consists in decreasing only the initial flow stress. Consequently, $\sigma_u - \sigma_r$ at high total strains might be taken as a measure of

orthorecovery.

This concept was also checked and found to give equally good agreement for values of prestrain equal to 0.092 and 0.125. The results of this correla-

tion after a prestrain of 0.125 are shown in Fig 8.

No justification has been presented in the previous discussion in favor of the use of the term orthorecovery. It is

FIG 12—Back reflection X ray patterns. W radiation.

FIG 13—Schematic representation of distribution of imperfections induced by cold work as a function of activation energy for recovery.

quite possible, of course, that the specific phenomena peculiar to what has been called orthorecovery is actually due to recrystallization. Therefore, this possibility was explored.

Mehl et al.¹¹⁻¹⁴ have demonstrated that the fraction recrystallized-time curve is sigmoidal as illustrated in Fig 9. Although the mechanical properties need not vary linearly with the fraction recrystallized, nevertheless, some sigmoidal relationship would again be expected between the change in flow stress and time of annealing at temperatures of annealing if recrystallization takes place. In order to check this concept, the data for orthorecovery were plotted as a function of time as shown in Fig 9. The value $\Delta\sigma$ was obtained by taking $\sigma_u - \sigma_r$ (see Fig 5) at a large total strain ($\epsilon = 0.24$) where metarecovery no longer affects the flow stress. The $\Delta\sigma$ -time curve of Fig 10 illustrates that the process termed orthorecovery has its greatest rate at $t = 0$ in sharp contrast to phenomena that depend upon nucleation and growth. This evidence, then, suggests that what has been called orthorecovery is not a true recrystallization process. Furthermore, no detectable difference in microstructure was discernable upon careful comparison of the structures of a specimen strained 0.13 and another strained the same amount and then annealed at 400°F for 1577 hr.

The most conclusive evidence that recrystallization was absent in the annealing treatments leading to ortho-

recovery, however, is shown in Fig 11. It is well known that when the logarithm of the reciprocal of the time to achieve a certain percentage of recrystallization is plotted as a function of the reciprocal of the absolute temperature, a linear relationship, dictated by the laws of kinetics of reaction rates, is obtained. The data recorded by the solid lines of Fig 11 were taken from the excellent investigation of Anderson and Mehl¹⁴ on the recrystallization of high purity aluminum (99.95 pct Al). Thus the linear relationship that is obtained when recrystallization data are plotted in this manner is well established. Now 2S-O alloy is less pure than the material investigated by Anderson and Mehl and, therefore, longer times or higher temperatures of annealing would be required to cause equivalent recrystallization of 2S-O alloy.

A complete investigation of the recrystallization of 2S-O was not attempted, but only an estimate of its recrystallization temperatures and times was made in this study. Specimens of 2S-O alloy were strained 0.09 at atmospheric temperature and annealed for 15 min. and 24 hr respectively at a series of temperatures. Back reflection Laue patterns, using W radiation, were then taken to establish whether or not recrystallization was obtained. Three typical radiographs are shown in Fig 12a, 12b and 12c after annealing for 24 hr at a series of temperatures. Fig 12a exhibits the continuous rings (due to the L radiation)

of the fine grained cold-worked 2S-O. Fig 12c illustrates a coarse grained structure after complete recrystallization, whereas Fig 12b shows some rings attributable to the initial fine grain size as well as some spots resulting from the larger recrystallized grains. These data and analogous results for the recrystallization in 15 min. are recorded in Fig 11. Of course, the location of the line representing a given small amount of recrystallization cannot be ascertained accurately from these data. But the approximate curve shown by the broken line is not seriously in error. It is interesting to note that this line is practically parallel to that obtained in the more thorough microscopic investigation on the recrystallization of higher purity aluminum by Anderson and Mehl.

Assuming that the linear relationship of this plot is admissible, the calculated time for incidence of recrystallization of 2S-O alloy prestrained 0.09 and annealed at 400°F is of the order of magnitude of 10^{10} hr. Since the phenomenon described as orthorecovery is already clearly discernable in less than 18 hr after annealing the cold-worked 2S-O alloy, orthorecovery is distinctly separate from a recrystallization process. Orthorecovery appears to be a true recovery process.

Burgers¹⁵ has already discussed the mechanics of the recovery process in terms of dislocations but it will nevertheless be interesting to deduce what kinds of models of work-hardening are consistent with the preceding observa-

FIG 14—Schematic representation of distribution of imperfections induced by cold work as a function of activation energy for recovery.

tions on the recovery of the flow stress of cold-worked aluminum. It will be convenient to designate those imperfections that are removed by meta-recovery as metaimperfections and those that are removed by pure orthorecovery as orthoimperfections.

The activation energies for the removal of orthoimperfections by recovery must be higher but may overlap the activation energies for annihilation of metaimperfections. The rather uniformly continuing process of orthorecovery suggests that orthoimperfections do not have strong interaction energies and consequently the activation energy for orthorecovery appears to be independent of the density of orthoimperfections.

The process of metarecovery is more complex than that for orthorecovery. First two alternate models appear to be possible. One is shown in Fig 13 based on the assumption that the activation energies for recovery of the metaimperfections consist of a broad band of values and that there is no interaction between the metaimperfections so that their activation energies are independent of their densities. The broken curves marked 90 and 212°F give a schematic representation of the distribution of metaimperfections following several hours recovery at these temperatures. After annealing at 300 and 400°F for a few hours all of the

metaimperfections will have been removed and some of the orthoimperfections will have been eliminated. Since the orthoimperfections exist over a narrow band of activation energies, the process of orthorecovery will continue (but at an ever decreasing rate because of the decrease in the density of orthoimperfections) until complete recovery is achieved.

An alternate model is shown in Fig 14. Here it is assumed that the metaimperfections have an activation energy for recovery that is a function of their density. As they are removed by metarecovery their activation energy increases as shown by the broken curves which represent the metastable states achieved after annealing a few hours at 90 and 212°F respectively. At temperatures of 300 and 400°F recovery of all of the metaimperfections occurs in a very short period of time and thereafter pure orthorecovery continues, the orthoimperfections being eliminated without major changes in the activation energies of those that remain.

It is helpful now to define more precisely the kinetics of the recovery process. To a first approximation the process might be considered analogous to a unimolecular reaction wherein the rate of recovery is proportional to the number of imperfections per unit volume, namely

$$-\frac{dN}{dt} = kN$$

where N is the density of dislocation, t is the time and k is the rate constant. For metarecovery the rate constant k is probably given by

$$k = k_0 e^{-\{E-f(N)\}/RT}$$

where $f(N)$ is some function of the density of imperfections, E is the activation energy, R the gas constant and T the absolute temperature.

Thus, as recovery takes place $E - f(N)$ increases and the process substantially ceases before complete recovery is achieved. Unfortunately the present evidence on metarecovery rates is too incomplete to evaluate $f(N)$.

For orthorecovery, however, no interaction energy is assumed and k is simply given by

$$k = k_0 e^{-E/RT}$$

Consequently

$$\ln \left(\frac{Ni}{N} \right) = kt = tk_0 e^{-E/RT}$$

where Ni is the number of orthoimperfections at $t = 0$. Then

$$\ln \ln \left(\frac{Ni}{N} \right) = \ln k_0 - \frac{E}{RT} + \ln t$$

Assuming that when $\sigma_u - \sigma_r$ reaches some value upon orthorecovery, Ni/N is constant, the activation energy E is obtainable by plotting $\ln t$ vs. $1/T$ for constant values of $\sigma_u - \sigma_r$. The data for orthorecovery reported here for 2S-O alloy reveal that E is a constant

independent of the time of recovery. Furthermore, E is about 33,000 cal per mol. It is scarcely accidental that this value agrees well with the activation energies in Table 1 quoted by Zener.¹⁶

According to either of the postulated mechanisms, orthorecovery is not compatible with the recovery of Taylor's patterns of dislocations, whereas meta-recovery of the kind illustrated in Fig 13 is not inconsistent with Taylor's concept of the work-hardened state.

The assumption that work-hardening introduced two distinctly different types of imperfections, namely the meta- and the orthoimperfections, not only facilitates the analysis of the recovery data reported here, but it also clarifies several issues of long standing regarding the recovery process. First, the models for recovery based on the presence of meta- and orthoimperfections demand that the work-hardened state, after partial recovery, be dissimilar from any state achieved by work-hardening alone. This conclusion is necessary for at the lower annealing temperatures only the metaimperfections are eliminated whereas both imperfections are introduced simultaneously upon strain-hardening. Consequently, recovery is not exactly the reverse of strain-hardening. Secondly, it now becomes clearer why properties exhibit unique recovery rates upon annealing. Some properties, such as the yield strength, (and perhaps the electrical resistivity) are sensitive to recovery of metaimperfection whereas other properties, such as tensile strength, are rather insensitive to the metaimperfections and respond most effectively to the recovery of the orthoimperfections. Consequently, some properties may exhibit almost complete recovery before any appreciable recovery is detectable in other properties.

Conclusions

1. After recovery at low tempera-

Table 1 . . . Activation Energies for

| Aluminum | |
|---|--------|
| Process | |
| Volume Diffusion ¹⁶ | 37,500 |
| Grain Boundary Slip ¹⁶ | 34,500 |
| Creep ¹⁶ | 37,000 |
| Orthorecovery..... | 33,000 |

tures (90 and 212°F) cold-worked aluminum exhibits a low initial flow stress upon restraining. But after an additional strain of about 0.04 the flow stress is restored to essentially that value which would have been obtained if the specimen had not been recovered. This is called metarecovery.

2. At higher temperatures (300 and 400°F) not only is metarecovery observed, but a permanent decrease in the flow stress is obtained such that the stress-strain curve for the recovered metal is below that for the virgin metal at the same total strain for all strains. This is called orthorecovery.

3. The kinetics of meta- and orthorecovery appear to be distinctly different. This suggests that during work-hardening at least two kinds of imperfections are introduced, one which is rapidly recoverable, and a second which is more slowly recoverable. This assumption rationalizes the observed differences in recovery rates of different properties.

4. These observations strongly suggest that the work-hardened state is characterized by at least two essentially distinct types of imperfections.

Acknowledgment

This investigation was partly supported by the Office of Naval Research as part of a more extensive project on the plastic properties of aluminum alloys. The authors express their sincere appreciation to the O.N.R. and its personnel for support of this investigation. In addition they wish to thank Messrs. T. Tietz, R. Anderson and E. Berliner for their aid in conducting some of the tests, and Mrs. G. Pel-

towski for the preparation of the figures.

Carbides in Isothermally Transformed Chromium Steels

WALTER CRAFTS,* Member AIME, and JOHN L. LAMONT*

Electrolytic extraction of carbides from quenched and tempered steel and their examination under the electron microscope were found to be helpful in understanding the mechanism of secondary hardening in alloy steels¹ and the same technique has been applied to isothermally transformed steels. A preliminary survey of the utility of the method has indicated that it has promising possibilities for investigating the characteristics of pearlite and bainite. The examination of a few carbon and chromium steels has suggested that pearlite is formed with carbides of two varieties representing the lamellar and nonlamellar forms and that bainite appears to form with a structure analogous to, but significantly different from, martensite.

Procedure

The method used for examining the carbides was similar to that described previously.¹ The chromium steels used in the investigation were made from an Armco iron base in an induction furnace and were not treated with grain-refining deoxidizers. The composition of the steels is given in Table 1.

Three-inch square ingots were forged and rolled to $\frac{1}{8}$ -in. thick sheet for use in the isothermal studies. After rolling, the sheets were sandblasted to remove the rolling scale.

Specimens approximately $\frac{3}{4}$ -in. wide and $1\frac{1}{2}$ -in. long were prepared from the $\frac{1}{8}$ -in. sheet. They were heated in a salt bath at 2100°F (1150°C) for $\frac{1}{2}$ hour, transferred to other salt baths at 1300°F (704°C), 1000°F (538°C), 800°F (426°C), or 600°F (315°C), held

for various periods up to 100 hr and finally quenched in water. After quenching, the specimens were cut in half, one half being submitted to microscopic examination and the other half being used for the electrolytic extraction. The isothermally transformed specimens were submitted to examination under the light microscope to determine the degree of transformation and type of structure and were photographed at 2000 \times .

Carbide residues were obtained by electrolyzing in 10 pct hydrochloric acid and collecting the residue in glycerine to minimize attack by the acid. As pointed out in the earlier paper, the carbides are attacked to some degree during electrolysis. This attack is relatively minor on the coarser carbides but may be quite severe on the fine bainitic carbides. The residues were washed free of the

glycerine with water and alcohol. The alcohol was removed by repeated washings of amyl acetate, and the amyl acetate suspensions were transferred to stoppered vials. Debye-Sherrer X ray diffraction patterns of the residues were prepared using a chromium target. A selection based on the microstructure and X ray data was then made of samples considered most illustrative of the progress of transformation. Electrolytically extracted residues from these samples were submitted to examination by W. D. Forgeng and A. C. Jenkins on the electron microscope at the Research Laboratories of The Linde Air Products Co. and electron micrographs were made at $\times 5000$ and enlarged to 25,000 \times . The micrographs obtained with both the light and the electron microscopes are mounted side by side in the accompanying figures.

Although no effort was made to establish the T-T-T diagram for the chromium steels, the times for holding in the salt bath were adjusted with the intention of making the samples represent different stages in the transformation at temperatures of 600, 800, 1000, and 1300°F. The degrees of transformation and results of X ray examination are shown in Tables 2-4. The carbide designations refer to orthorhombic or trigonal carbide types and are not meant to imply that the compositions are exactly as indicated.

X ray Diffraction Data

The occurrence of Fe_3C and Cr_7C_3 in these steels was found to be consistent with published data on comparable chromium steels. Steels A and B with relatively low ratios of carbon to chromium contained Cr_7C_3 in the pearlitic structures and Fe_3C in the

bainitic range. A pattern of the Cr₂N type was also found in steels A and B transformed at 1300°F. In general, the patterns of Fe C, Cr₇C₃, and Cr₂N increased in definition and intensity with the length of time the specimens were held at temperature.

Undissolved carbide was present after austenitizing steel C and X ray diffraction revealed a corresponding Cr₇C₃ pattern in all specimens. The carbide formed as the initial product of transformation at all temperatures appeared to be Fe₃C, but this pattern tended to disappear from pearlitic structures, leaving only Cr₇C₃ after long holding at temperature. As shown in Table 5, the dimensions of the

Cr₇C₃ pattern found in the 1.17 pct carbon steel C were different from those in the Cr₇C₃ pattern found in the lower carbon steels A and B. The Cr₇C₃ pattern of a steel containing 0.70 pct carbon and 5 pct chromium was also of the same dimensions as that found in the lower carbon steels, so that the change would seem to be discontinuous and probably represents a decided difference in composition.

In addition to the normally expected phases, the residues of specimens held for intermediate periods at temperatures producing pearlitic structures also contained a phase that gave a pattern with "d" values as given in Table 5. The pattern of this phase tended to appear only after the transformation was well advanced and to disappear on holding after completion of transformation. The nature of the phase has not been identified.

Microscopic Examination of Carbides in Pearlite

A limited number of carbon steels, transformed isothermally and by continuous cooling, as well as the chromium steels, have been studied by electrolytic extraction and examination of the carbide residue on both the light and electron microscopes. Only the coarser structures permit a direct comparison at comparable magnification between the structure found in the metal and the appearance of extracted carbides as revealed by transmitted light and the electron beam. However, the structures are sufficiently similar to make the higher magnification electron micrographs of finer structures quite convincing.

The pearlitic structures found in the 5 pct chromium steels were quite fine,

only partly lamellar, and generally of a confused and granular appearance rather than the well defined lamellar structure of slowly cooled carbon steel. The carbides extracted from well developed lamellar pearlite in a slowly cooled eutectoid carbon steel are illustrated by light and electron micrographs in Fig 1. The typical carbide is a thin, very irregularly shaped, and often curled plate. It may contain holes and usually has deeply indented bays. There are thickened knobs and fingers at the edges and sometimes within the body of the plate. The thickened edges appear to correspond with the clubby ends of pearlite lamellae seen in polished cross-sections of steel. This type of carbide was illustrated by Koch² using a similar procedure.

The predominant carbides extracted

from the fine pearlite of carbon steels transformed at relatively low temperatures are thicker skeletal or rod-like shapes of very irregular appearance. This type of carbide is illustrated in many of the micrographs of chromium steel residues where it will be seen that it is too thick to be penetrated by the electron beam. Because the thin plate type is predominant in specimens with well developed lamellar pearlite and the more massive skeletal type occurs mainly in specimens with little of the lamellar structure, it would appear that confused pearlite structures are actually not lamellar, but are composed mainly of carbides of the massive skeletal type. Both types of carbide are specific to pearlitic structures and may be readily distinguished from the residues of bainitic or tempered martensitic structures.

FIG 4—Steel A—0.20 pct C, 5.06 pct Cr. Transformed 100 pct after 100 hr at 1300°F.
A—Steel structure. $\times 2000$. B—Extracted residue. Electron micrograph. $\times 25,000$.

The carbides extracted from the pearlitic chromium steels, as well as micrographs of the corresponding steel structures are shown in Fig 2-5, 8-12, 14-19, and 21-22.

The carbides found in steel A transformed at 1300°F, as shown in Fig 2, show an initially fine structure composed mainly of the massive type of carbide in a complex irregular pattern. After 1 hr at 1300°F, as shown in Fig 3, the transformation was virtually complete, and the carbide particles are much coarser than in Fig 2. Both thin and thick carbides are present in a much more well developed form. The thin plate is seen to be corrugated or ribbed to a degree that was not observed in carbon steels, and the massive types are more crystalline in shape than at earlier stages in the transformation. After 100 hr at 1300°F, as shown in Fig 4, the light microscope revealed a spheroidized structure with virtually no lamellae, and the extracted residue

contained only massive, more or less idiomorphic, crystals. The thin plates were absent and had either been absorbed or had coalesced into the idiomorphic carbides. Similar carbide particles were shown by Koch and Wiester³ after an extended tempering of pearlite.

Both thin and massive carbides in steel B transformed at 1300°F, as shown in Fig 8-10, tend to be very long and relatively narrow, but are qualitatively similar to those found in steel A. The tendency toward thickening at the edges of the thin plates is particularly well illustrated in Fig 8. Some of the thin carbides are still present after 100 hr, although the predominant type is the well developed crystals. The appearance of the thin carbide shown in Fig 10 is somewhat more dense than is typical of specimens held for a shorter time at temperature, and there is a tendency toward local thickening. It is presumed that this represents a

typical mechanism by which the thin particles are converted to a more massive form, although the time involved is so great that a good deal of absorption and reprecipitation could occur. It is probable that the growth of the massive particles also progresses by a diffusion reaction.

The carbides found in steels A and B after 100 hr at 1000°F, Fig 5 and 11, are appreciably smaller than the carbides found after a comparable degree of transformation at 1300°F. However, they are quite similar in character even though the structure as seen in the light microscope is too fine to be resolved satisfactorily.

The carbides produced at 1300°F in steel C, as shown in Fig 14-16, are quite similar to those found in steel A. Although some undissolved carbide was present in these samples, it was not observed in the extracted residues. Ordinarily large carbide particles are too heavy to be supported by the suspend-

ing film used for electron microscope examination, so that they may not be observed in the examination of extracted residues. Transformation of steel C at 1000°F produced “arborescent” pearlite structures as shown in the light micrographs of Fig 17–18. Although the extracted carbides are quite small in the initial stages of transformation, they do not appear to be significantly different from those formed at 1300°F. In the same manner as at higher temperatures, the carbides become progressively larger as the specimens are held longer at temperature.

In general, it would appear that the carbide particles in pearlite are of a similar character regardless of the specific composition of the steel or temperature of transformation. There are two well defined types of carbide shape. The difference in character between the thin plates and the more massive carbide particles is shown in Fig 21. The extracted residue was

shadowed with gold before examination on the electron microscope, and the resulting electron micrographs clearly show the relative thickness of the carbide particles. One is a thin plate of very irregular shape tending toward heavier knobs and fingers at the edges. The other is a more massive type that occurs in an irregular skeletal or rod-like form. Both types eventually grow into the idiomorphic form illustrated in Fig 22. The thin type occurs more commonly in well organized lamellar structures and the more massive skeletal type tends to be formed in the more confused sublamellar structures. It would seem reasonable to believe that the plates represent the carbides of strictly lamellar pearlite. Pearlite in which it is difficult to see lamellae is presumably composed principally of the more massive skeletal type of carbides. It would appear that those nonlamellar areas of pearlite that are sometimes considered to be oriented

unfavorably to visualize lamellae are actually nonlamellar.

A tempering process with growth of the carbide particles seems to start immediately after transformation and to progress continuously before and after transformation is completed. It was not possible to isolate small carbide particles in the later stages of transformation and identify them as having been formed more recently than the larger carbides. Because of the time involved in the later stages of transformation, it is considered probable that even the freshly formed carbides would be tempered appreciably before examination. It is doubted, therefore, whether it would be reasonable to expect that this method of examination will readily reveal whether the size of carbides transformed late are affected by the growth of previously formed carbides. The progress of tempering of both the thin plates and the skeletal carbides to larger massive and ultimately

idiomorphic particles seems to be accomplished in part by coagulation of the more extended shapes as well as by normal diffusion and growth.

Microscopic Examination

of Residues from Bainitic Structures

The structures formed in chromium steel specimens treated to produce bainite are illustrated in Fig 6-7, 12-13,

20 and 23. The structures of the extracted residues appear to consist of a nebulous cloud of very fine particles in which there is a concentration of many or larger particles on certain planes as well as a number of well defined par-

ticles of a larger order of size. The "graininess" or size of the particles seems to increase as time at temperature and degree of transformation increase, but the structure never becomes sufficiently well defined to give

much assurance that the structures are adequately resolved.

Each group or cloud that appears to be a cluster of a myriad of particles has been shown by gold shadowing in Fig 23 to have a considerable thickness,

so that the electron beam has partially penetrated a great volume of fairly low density. The velvety black zones in Fig 6 and 20 are typical of residues extracted from martensite in which it is probable that the residue itself is only

amorphous carbon. No analytical work has been done on these bainite residues, so that it is possible that the residue is not carbide but a metamorphosed representation. The granular structure of the "clouds" is quite different from

that previously found¹ in tempered martensite residues in which indications of individual particles were not observed. As time at temperature and degree of transformation increase, the structure becomes even more granular,

probably reflecting an increase in the size of the individual particles. It has also been observed that residues of bainitic carbon steels transformed in shorter periods are intermediate in appearance between the bainitic chro-

mium steel residues and martensitic residues, and it is inferred that the growth of the fine particles to dimensions visible at this magnification results from a tempering process.

In a similar manner the thickened

planes that are seen in the cloudy matrix are significantly different from similar planes in martensite residues. The character of these planes is best shown in Fig 13 where three small zones are separated from the main

cluster. These are believed to be the fragments of the thickened planes that appear to contain larger particles than the matrix. The size of the particles and possibly their number increase with time at temperature. Such structures

have not been observed in tempered martensite where the density of the matrix is lessened by precipitation along many planes in the form of continuous two-dimensional plates rather than a number of fine particles. The well defined larger particles, shown best in Fig 7 and 20, seem to be of a different character and may have been formed by a different mechanism than that by which the main structure was formed.

Although it is not presumed that these structures are adequate to answer the question of whether bainite forms initially as a single phase or as an aggregate, the structures are quite suggestive. With respect to these steels it is evident that, if it be assumed that the bainite formed initially by a martensite-like reaction and that it was tempered immediately, the resulting structure is significantly different from that formed when a truly martensitic structure is tempered by reheating.

Thus, if bainite in these steels were formed by the decomposition of a martensite-like constituent, either the transitional structure or the manner of its tempering is significantly different from martensite. However, the structure is so closely related to that of martensite that it is not possible to infer, as an obvious corollary, that bainite forms as an aggregate. An examination of bainite residues at much higher magnification would be desirable to obtain a better understanding of the structure.

Summary

Examination of carbide residues extracted electrolytically from chromium steels has been shown by X ray diffraction to be consistent with the normally expected constituents of these steels, except for observation of two forms, differing in lattice dimensions, of Cr_7C_3 and of an unidentified transi-

tional constituent in pearlitic specimens. Electron micrographs of the residues have shown characteristic forms of carbide for pearlite and bainite.

The carbides associated with pearlite are of two shapes. One is a thin irregularly shaped plate with thickened edges that is considered to be the lamellar carbide of regular pearlite and the other is a skeletal, rod-like or massive type that is considered to be the nonlamellar carbide in confused pearlite. The more extended forms of both types tend to coagulate locally, and the resulting massive particles, as well as the initially formed massive type carbides, grow by diffusion until they assume idiomorphic shapes in spheroidized pearlite structures. The tendency toward either type is controlled by the conditions of transformation rather than by specific effects of composition, and similar appearing carbides may be produced regardless of whether the carbide is of

the Fe_3C or Cr_7C_3 type.

Residues from bainitic structures are closely analogous to those of martensite, but are significantly different. In bainite the residues have a nebulous, but granular, matrix, and discrete particles are found in the planes on which carbide tends to concentrate, rather than the unresolvable matrix and the continuous plates of tempered martensite residues. The bainite residues also contain fairly large particles not found in martensite residues. These characteristics suggest that although bainite may be formed in a manner analogous to martensite, the differences in structure are sufficiently great to indicate a significant difference in the mechanism. Further examination at much higher magnification should be helpful in understanding bainite formation.

Although this study of extracted carbides has been limited to the cursory examination of a few steels, it would appear that this use of the electron microscope is capable of adding considerably to our understanding of the structures of steel.

The Properties of Sand Cast Magnesium-Rare Earth Alloys

THOMAS E. LEONTIS,* Junior Member AIME

Introduction

Several publications¹⁻⁷ during the past few years have demonstrated the markedly greater effect of cerium, as compared to all other alloying elements, in enhancing the strength and creep resistance of magnesium at elevated temperature either with or without the presence of other elements. In the work reported in Ref. 1-6, the cerium was added in the form of Mischmetal, which contains all the rare earth elements in essentially the same proportions as they occur in monazite sand, the principal ore of these metals. Mellor and Ridley⁷ have presented the creep characteristics at 200°C of magnesium alloys prepared both with pure cerium and with Mischmetal. Up to the present time, however, no comprehensive study of the effect of the various component elements of Mischmetal on the properties of sand-cast magnesium has been made. This hiatus in magnesium technology undoubtedly is associated with the difficulty in obtaining the rare earth metals separately.

This investigation provides such a survey, the object of which was to determine which of the elements present in Mischmetal contributes the greatest effect in developing high strength and high resistance to creep at elevated temperatures. Toward this end the compositional variation of these properties has been determined as a function of temperature in the following alloy systems:

- 1. Magnesium-Mischmetal
- 2. Magnesium-cerium-free Mischmetal
- 3. Magnesium-didymium
- 4. Magnesium-praseodymium-lanthanum
- 5. Magnesium-cerium

Table 1 . . . Chemical Analyses of Rare Earth Metals

6. Magnesium-lanthanum
This designation, based on the names of the metals as furnished by the producer, is used throughout the paper in order to avoid the complicated system of listing all the elements present in the more complex alloys. The composition of the metals and the alloys is discussed in detail below.

Preparation of Alloys

ALLOYING INGREDIENTS

The chemical composition of each of

the six alloying ingredients used to prepare the alloys reported in this paper is given in Table 1. In each case, the percent total rare earths, percent cerium, percent neodymium, percent praseodymium, and percent thorium were determined in addition to the listed impurities. The percent lanthanum was determined by difference from the total rare earth content and consequently includes the other elements (samarium, terbium, yttrium, etc.) present in Mischmetal. These additional elements, however, seldom amount to more than 1 to 2 pct of the total rare earth content of Mischmetal. The iron content of the Mischmetal is considerably lower than that of the other metals. This grade of Mischmetal is now readily available.

The metals are listed in the order of decreasing complexity. Elimination of the cerium from Mischmetal results in what the trade calls "Cerium-free Mischmetal." Carrying the separation a step further by eliminating the lantha-

num yields what is commonly called "didymium" and should consist essentially of neodymium and praseodymium. Unfortunately, the material obtained for this work also contains 8 pct lanthanum (10 pct of the total rare earths) and the praseodymium content is rather low compared to that of Ce-free Mischmetal. The cerium and the lanthanum metals are both practically free of other rare earth metals. The praseodymium, however, contains a large proportion of lanthanum; consequently, the alloys made with it are called magnesium-praseodymium-lanthanum alloys.

MELTING AND CASTING OF ALLOYS

All the alloys used in this study were prepared in small laboratory melts according to the melting practice described by Nelson⁸ as the "Crucible Method." The special precautions necessary in the alloying of Mischmetal with magnesium have been described in detail by Marande.⁹ The same procedure was followed in introducing the other rare earth metals into magnesium.

A 50- to 100-lb melt of each alloy was prepared except for the didymium alloys and the praseodymium-lanthanum alloys, in which case smaller melts were necessitated by the smaller amounts of alloying ingredients available. Test bars of 6½ in. length with a 2½ in. long reduced section of ½ in. diam were cast in sand molds using a four-bar pattern. Electrolytic magnesium was used as the starting material; a typical analysis of this grade of magnesium is shown in Table 2.

In order to conserve the rare-earth metals, the alloy containing the highest percentage of the added element in each group was made first. Alloys of lower content were then prepared by remelting the scrap from the preceding melt and adding magnesium to obtain the desired composition of the next alloy in the series. All the melts were poured at 1300-1325°F in an attempt to obtain as fine a grain size as possible.

ANALYSIS

Chemical analysis to determine the rare earth content of each alloy was made on a sample taken from a test bar, whereas the spectrographic analysis of impurities was performed on separately cast specimens poured immediately before filling the test bar molds. The results of both analyses are given in Table 3; only the impurities which are present in major proportions

or those which differ markedly from the amounts present in electrolytic magnesium (Table 2) are tabulated.

As indicated in Table 3, two alloys from each series were analyzed for cerium, neodymium, praseodymium, and total rare earths; in all the other alloys, only the total rare earth content was determined. The lanthanum values represent the difference between cerium + neodymium + praseodymium and the total rare earths as mentioned

above. The method of analysis of cerium and of total rare earths is given in another publication.¹⁰ These analyses are accurate to ±0.10 pct rare earth. The neodymium and the praseodymium were determined by the spectrophotometric method described by Rodden.¹¹ The accuracy of the analyses by this method is believed to be ±5 pct for neodymium and ±10 pct for praseodymium. The same analytical methods were used in determining the composi-

tion of the rare earth metals given in Table I.

In the alloys analyzed for the separate rare earth metals, the proportion of each of the four elements agrees reasonably well with that of the same element in the corresponding alloying ingredient. This observation, together with the good agreement between the two alloys analyzed in each group, indicates that there is no preferential loss of any of these elements either in alloying with magnesium or in remelting. With these findings on hand,

it was deemed justifiable to apportion the total rare earth content of all the other alloys among the four elements. For each series of alloys, the proportioning factors used were based on the average of the two complete analytical determinations in the series.

HEAT TREATMENT

A preliminary study was conducted to determine the maximum possible solution heat treating temperature for each type of alloy. This was done by

heat treating small specimens of alloys containing 6 pct and 3 pct rare earths in the as-cast condition at a series of temperatures followed by quenching in cold water. Metallographic examination of these specimens has established the following minimum temperatures of liquation:

| | °F |
|--|----------|
| Magnesium-Mischmetal alloys..... | 1095 ± 5 |
| Magnesium-Ce-free Mischmetal alloys..... | 1100 ± 5 |
| Magnesium didymium..... | 1000 ± 5 |
| Magnesium-praseodymium-lanthanum alloys..... | 1100 ± 5 |
| Magnesium-cerium alloys..... | 1095 ± 5 |
| Magnesium-lanthanum alloys..... | 1125 ± 5 |

These temperatures are in good agree-

ment with the eutectic temperatures of the published magnesium-rare earth diagrams;^{12,13,14,15} no information is available on the principal constituent of didymium, that is, the magnesium-neodymium system.

With these determinations as a guide, the following heat treating temperatures were selected and used throughout this investigation:

Magnesium-didymium alloys.....

All other alloys.....

°F9751070

The higher temperature possible with magnesium-lanthanum alloys was not used in order to avoid the dangers of oxidation and sagging of the test bars. All heat treatments were of 24-hr duration followed by cooling on a thick iron

plate under a fan blast. The aging treatment consisted of heating for 16 hr at 400°F.

All the heat treatments were conducted in circulating air furnaces, electrically heated and controlled to $\pm 5^\circ\text{F}$. The atmosphere of the furnace was rendered protective by the maintenance of a concentration of 0.5 to 1.0 pct sulphur dioxide.

GRAIN SIZE

The grain size of each alloy (Table 3) was determined on a sample from the reduced section of every test bar after being tested either in tension or in creep. The measurements were made

by the comparison method described by P. F. George.¹⁶ A range of grain size is given for each alloy. This represents the variation from bar to bar. The figures given for columnar structure represent the percent of the area covered by columnar grains. It may be stated that, in general, the grain size decreases with increasing alloy content. The suppression of a columnar structure in the lower alloy contents is very erratic. No evidence of grain coarsening upon heat treatment was observed.

Testing Methods

Detailed descriptions of the methods of tension and creep testing have been given in earlier publications.^{4,17} All the properties were determined on cast test bars without machining the surface. Tensile properties are the average of two tests. All creep data are from tests of 100 to 160 hr duration. Space does not permit the presentation of detailed creep data. The creep characteristics of each alloy are defined in this paper by three parameters:

1. Limiting stress to give 0.1 pct creep extension in 100 hr

2. Limiting stress to give 0.2 pct total extension in 100 hr

3. Limiting stress to give 0.5 pct total extension in 100 hr.

These values were determined by interpolation of log-log plots of stress vs. extension as described previously.^{4,17} A minimum of 3 and as many as 8 stress levels were used to establish the log stress vs. log extension relationship for each alloy at each temperature. The total extension figures include the elongation obtained during loading as well as the creep extension. No significance has been attached to creep rates in this investigation because during the 100-hr test the secondary stage of creep, which gives the minimum creep rate, is not established in many tests.

The method of determining electrical conductivity has been described earlier.¹⁸

The density of each alloy in the heat treated plus aged condition was determined on a $\frac{5}{8}$ in. diam by 1 in. long specimen machined from the shoulder of a test bar. Each sample was weighed on an analytical balance under two conditions: (1) in air, and (2) in kerosene of known density. The density of the alloy was calculated from these two weighings.

Discussion of Results

TENSILE PROPERTIES

The room temperature tensile properties of all the alloys in the as-cast, solution heat treated (HT), and heat treated and aged (HTA) conditions are presented in Table 4. The yield and tensile strengths in the HTA condition are plotted as a function of composition for all temperatures investigated in Fig 1 through 13. The total rare earth content of all the alloys is used to represent the composition in these as well as all subsequent plots. Graphs of elongation vs. composition have been omitted in order to conserve space; furthermore, the scatter in these data renders them rather inconvenient for graphical representation. Elongation values at all temperatures are given in Table 5.

Marked differences exist in the degree to which the strength of magnesium is enhanced by the various rare earth elements. The highest properties at all temperatures over the entire composition range investigated are developed by the addition of didymium, whereas the lowest properties are found in magnesium-lanthanum alloys. Intermediate to these lie the alloys containing cerium-free Mischmetal, praseodymium + lanthanum, Mischmetal, and cerium in that order of decreasing properties for alloys containing 3 to 6 pct total rare earths. Among these four types of alloys there is little difference in strength in compositions of less than 2 to 2.5 pct alloying elements. In general, the elongation decreases with increasing amounts of rare earth elements; the slight increase in this property in alloys containing 0.18 and 0.40 pct Mischmetal is undoubtedly associated with the unusually fine grain size of these alloys as compared to that of electrolytic magnesium which is 100 pct columnar.

It can readily be seen from the data in Table 4 that all the alloys, with the exception of the magnesium-lanthanum alloys, exhibit a certain degree of age hardening. The alloys may be rated in the following order of decreasing age hardening: magnesium-didymium, magnesium-cerium-free Mischmetal, magnesium-Mischmetal, magnesium-cerium, magnesium-lanthanum. From these observations it may be concluded that of the four principal elements in Mischmetal, neodymium contributes the most to age hardening. Quenching from the heat treating temperature into water at 180°F instead of air cooling effects no increase in the properties or in the degree of age hardening of any of these alloys. The

properties of magnesium-lanthanum alloys after heat treating at 1100°F are the same as those reported here after the 1070°F heat treatment.

The specific effect of each rare earth metal is more clearly illustrated by the property vs. temperature plots shown in Fig 14, 15, 16 and 17. These graphs have been derived from the property-composition curves for two levels of alloy content, 3 and 6 pct total rare earths; below 3 pct alloy content the properties decrease quite rapidly to the values for electrolytic magnesium. The curves in these figures do not necessarily pass through all the points read

from the property-composition plots, but deviations from them are no greater than 1000 psi.

EFFECT OF EXPOSURE AT 600°F

Table 6 shows the tensile properties of two compositions of magnesium-Mischmetal, magnesium-cerium-free Mischmetal, magnesium-didymium, magnesium-cerium, and magnesium-lanthanum alloys at room temperature and 600°F after holding the test bars at 600°F for 5000 hr. This long-time exposure treatment was conducted in an atmosphere containing ½ to 1 pct sulphur dioxide in order to prevent any

FIG 5—Tensile yield strength at 500°F.

FIG 6—Tensile yield strength at 600°F.

FIG 7—Tensile strength at room temperature.

FIG 8—Tensile strength at 200°F.

preferential oxidation of the rare earth intermetallic compounds.

Compared to their properties in the HTA condition, the alloys containing Mischmetal, cerium-free Mischmetal, didymium, and cerium suffer a much greater loss in strength at room temperature and 600°F from this exposure than do the magnesium-lanthanum alloys. In fact, there is no change in the room temperature properties of magnesium-lanthanum alloys. However, the best combination of strength

at room temperature and 600°F after the prolonged exposure is exhibited by the magnesium + 5.74 pct cerium-free Mischmetal alloy.

Similar data have been reported by McDonald⁶ for an alloy containing 6 pct Mischmetal plus 1.5–2.0 pct manganese. His results showed that the strength of this alloy decreases within 16 to 24 hr exposure at 600°F to a value that is maintained out to 1000 hr exposure. Subsequent experiments on the same material have been extended

to 5000 hr without any further change in the properties.

CREEP RESISTANCE

The creep characteristics of all six alloy systems at 400 and 600°F are depicted as a function of composition in Fig 18 through 21. Only a limited number of alloys, other than magnesium-Mischmetal alloys, have been investigated at 500°F; the results of these tests together with the data at

300°F for magnesium-Mischmetal alloys are summarized in Table 7.

The pronounced differences among the various rare earth metals in their respective effect on the creep resistance of magnesium at 400°F is demonstrated clearly by all three indices of creep resistance used to represent the data. All the rare earth elements, with the exception of lanthanum, effect a marked increase in this property in the composition range between 0 and 2 pct. In general, the alloys may be listed in the same order with respect to creep resistance as was found in their relative tensile properties. This listing applies specifically in the range of 3 to 6 pct rare earth content; in lower compositions some of the curves cross one another. The decrease in creep strength in magnesium-cerium alloys between 3 and 7 pct cerium content is difficult to explain. The reason does not lie in grain size variation inasmuch as of the two alloys containing 5.70 and 6.73 pct cerium, the former has a grain size of 0.050-0.080 in. and the latter 0.014-0.16 in. Furthermore, alloys of lower cerium content having higher creep resistance than either of the two high cerium compositions have grain size values which fall at both ends of the range covered by the high cerium alloys.

The results of tests at 500°F show much the same trends as indicated at 400°F. It will be noted that again there is a drop in creep resistance between 3 and 6 pct cerium. Alloys containing 1.15, 1.62, 2.50 and 2.85 pct Mischmetal exhibit anomalously low creep resistance at 300°F and high creep resistance at 500°F. These effects appear to correlate with the abnormally large grain size of these alloys.

The situation at 600°F is a little more confused; many anomalies exist in the data rendering them difficult to evaluate on a comparative basis. To illustrate these effects, Table 7a has been prepared from Fig 21 for three levels of alloy content:

These results may be summarized by saying that the relative merits of the various magnesium-rare earth alloys depend upon the temperature. Furthermore, there definitely appears to be a grain size effect, but it is not the same for all alloy systems. This effect is most pronounced in magnesium-cerium-free Mischmetal and magnesium-didymium alloys at 600°F, and in magnesium-Mischmetal alloys at 300 and 500°F. The selection of an alloy for applications demanding high creep resistance at elevated temperatures must, there-

fore, take into consideration the temperature range as well as the stress level. In order to illustrate the range in properties that exists in magnesium alloys, the tensile properties and creep limits of three rare earth alloys are compared with those of two commercial casting alloys and magnesium-6 pct zinc-zirconium alloy¹⁸ in Table 8. The superiority of the alloys containing rare earth metals over the other alloys at 400°F is clearly demonstrated. In addition, this table illustrates in a concise form the quantitative differences among the rare earth alloys.

ELECTRICAL CONDUCTIVITY

The results of electrical conductivity measurements are given in Fig 22 for various conditions of heat treatment. The experimental points have been omitted from these plots in order to render the curves more clearly discernible. It can be said that the curves

as drawn follow faithfully the experimental data. The zero point of each series of curves is the conductivity of cast electrolytic magnesium in the same condition of heat treatment as the alloys in the series. The conductivity of this grade of magnesium is naturally a little lower than the value of 0.23 reciprocal microhm-cm reported for pure magnesium.

The decrease in conductivity with composition in each of the alloy sys-

tems is well illustrated by the curves. Considering the conductivity changes that take place upon aging, it may be predicted that the solid solubility of neodymium in magnesium is greater than that of any of the other rare earth elements. On the other hand, the relative insensitivity of the conductivity of magnesium-lanthanum alloys to heat treatment and to aging leads one to the conclusion that the solubility of lanthanum in magnesium is very low, cer-

tainly lower than that of cerium. This is in contradiction of the findings of Weibke and Schmidt¹³ and of Haughton and Schofield¹² both of whom have reported essentially equivalent solid solubilities of cerium and of lanthanum in magnesium. The measurements on magnesium-lanthanum alloys were repeated after heat treating the alloys at 1100°F; no change was recorded in the conductivity after this heat treatment nor did any change occur upon

aging at 400°F for 16 hr subsequent to the same heat treatment.

DENSITY

The density of magnesium-Mischmetal, magnesium-didymium, magnesium-cerium and magnesium-lanthanum alloys, all in the HTA condition, is shown as a function of composition in Fig 23. There is no significant difference in the density of these four types

of alloys. With this information on hand, it can be predicted that the density of magnesium-cerium-free Mischmetal alloys and that of magnesium-praseodymium-lanthanum will fall in the same range.

METALLOGRAPHY

Considerable attention was given to the microstructure of the alloys throughout this investigation; a few

micrographs (Fig 24 through 30) are presented to illustrate some of the most important features of the structures. The etchants used have been described by P. F. George.¹⁶

The as-cast structure of the 6 pct composition of each of the six alloy systems is shown in Fig 24 at a magnification of 100 × and in Fig 25 at 250 ×. The general distribution of second phase is clearly illustrated in Fig 24.

FIG 17—Tensile strength of magnesium—6 pct rare earth alloys as a function of temperature. HTA condition.

FIG 18—Limiting stress for 0.1 pct creep extension in 100 hr at 400°F.

All the alloys have a dendritic structure. There is a distinct difference in the nature of the eutectic in alloys containing more than one rare earth element from that in the magnesium-cerium alloy and in the magnesium-lanthanum alloy. Both the magnesium-cerium and the magnesium-lanthanum alloys have a very fine eutectic which can be resolved only with difficulty at

250 \times . However, in all the other alloys, there is a very strong tendency for the eutectic to become divorced, in fact in magnesium-didymium alloys it is completely divorced, and what eutectic is present is in the form of massive compound areas with particles of magnesium solid solution imbedded in them. The magnesium-cerium and the magnesium-lanthanum eutectics are

shown more clearly at higher magnification in Fig 26 and 27 and for still better resolution of their structure the electron microscope was used with the results shown in Fig 28 and 29. That these two eutectics differ in the distribution of their respective components is apparent.

The structure of alloys containing lower amounts of rare earths are not

FIG 19—Limiting stress for 0.2 pct total extension in 100 hr at 400°F.

FIG 23—Density of magnesium—rare earth alloys at 25°C (77°F). HTA condition.

shown. The amount of eutectic decreases with decreasing alloy content and the eutectic network ceases to be the continuous phase in alloys containing less than 2 to 3 pct rare earth elements. The eutectic in the complex alloys is completely divorced and the magnesium-lanthanum eutectics show increasing tendency to divorce in lower alloy contents. There is compound or eutectic present in alloys containing as little as 0.10 pct total rare earths.

The microstructures of the 6 pct alloys after heat treating and aging are shown in Fig 30. In all the alloys the compound of the eutectic has been

FIG 24—Structure of as-cast magnesium—rare earth alloys.

Glycol etchant. 100 X. Slightly reduced in reproduction. *a.* Mg + 6.33 pct Mischmetal. *b.* Mg + 5.74 pct Ce-free Mischmetal. *c.* Mg + 6.03 pct didymium. *d.* Mg + 6.19 pct (Pr + La). *e.* Mg + 6.73 pct cerium. *f.* Mg + 6.70 pct lanthanum.

coalesced and the continuity of the network has been broken so that the matrix is the continuous phase. For any given alloy content, the magnesium-didymium alloy has the least compound, and the magnesium-lanthanum alloy the most. The compositions of each alloy system which consists only of magnesium solid solution with no rare earth intermetallic compound after heat treatment are listed below:

| | |
|----------------------------------|---|
| Magnesium-Mischmetal | 0.18 pct total rare earth |
| Magnesium-cerium-free Mischmetal | 0.20 pct total rare earth |
| Magnesium-didymium | 0.65 pct total rare earth |
| Magnesium-praseodymium-lanthanum | None, lowest composition available was 0.69 pct |
| Magnesium-cerium | 0.15 pct total rare earth |
| Magnesium-lanthanum | None, lowest composition examined was 0.16 pct |

Increasing the heat treating time to 96 hr does not change these results.

Increasing the heat treating temperature for magnesium-lanthanum alloys does not decrease the amount of Mg₂La nor does it result in a completely homogeneous structure even in the lowest composition available. These findings confirm the conclusions formed from conductivity; neodymium has the greatest solid solubility in magnesium and lanthanum, the least.

Aging at 400°F for 16 hr produces a visible precipitate in the magnesium-cerium-free Mischmetal alloy but even here the amount of precipitate is small and the particles are very fine (Fig 30b). In a previous publication,⁴ it has been shown that in the magnesium + 6 pct Mischmetal alloy in the HTA condition precipitate can be revealed only by the electron microscope.

Aging at 600°F produces a large amount of coarse precipitate in all the magnesium-rare earth alloys except magnesium-lanthanum, as shown previously for magnesium-Mischmetal alloys.⁴ The time required to produce this precipitate is considerably longer in alloys containing 3 and 6 pct didymium than in all other alloys. Extending the aging time at 600°F to 5000 hr fails to produce any precipitate in magnesium-lanthanum alloys, whereas this treatment leads to the coalescence of the precipitate into fairly large particles in the case of magnesium-didymium and to the coalescence of the precipitate with the undissolved compound already present in magnesium-Mischmetal and magnesium-cerium alloys. Only magnesium-

cerium-free Mischmetal alloys retain a uniform distribution of precipitate after this prolonged aging treatment. This may explain the somewhat higher strength of these alloys after this treatment.

Summary

All the rare earth metals investigated enhance the strength, hardness, and creep resistance of magnesium at room and elevated temperatures. There are, however, marked differences among the metals in the degree to which they improve these properties.

The various magnesium-rare earth alloys may be rated in the following order of decreasing tensile properties at room and elevated temperatures and creep resistance at 400 and 500°F:

- 1. Magnesium-didymium. 2. Magnesium-cerium-free Mischmetal. 3. Magnesium-praseodymium-lanthanum. 4. Magnesium-Mischmetal. 5. Magnesium-cerium. 6. Magnesium-lanthanum.

The relative effect of each rare earth metal on the creep resistance of magnesium at 600°F depends upon the composition level and, to a certain extent, upon the grain size.

Of the rare earth metals investigated, neodymium exhibits the greatest solid solubility in magnesium and lanthanum, the least. The solid solubility of lanthanum is much less than that reported in the literature. Cerium also appears to have a somewhat lower solid solubility in magnesium than that reported in the literature.

The results of this investigation have shown that considerably higher elevated temperature properties can be developed in magnesium-didymium and magnesium-cerium-free Mischmetal alloys than those exhibited by magnesium-Mischmetal alloys. At 400°F, for example, the properties of magnesium-didymium alloys are 20 to 50 pct higher than those of magnesium-Mischmetal alloys. Although the superiority of these alloys may not hold over the

entire temperature range, their advantage at certain temperatures may warrant their serious consideration for commercial applications. Further development of these alloys will depend upon the availability of the rare earths and a possible reduction in their cost.

The Relationship Between Electrical Conductivity and Composition of Molten Lead Silicate Slags

A. KENNETH SCHELLINGER,* Junior Member AIME and ROBERT P. OLSEN†

Molten silicate salts, the important industrial byproducts termed "slags," are known to be electrolytic conductors at furnace temperatures. This property is due to their partial dissociation into ions with the ion kind and size being closely related to the slag composition. Ionic conductance, in liquids, is a function of the viscosity, which in turn is a function of the temperature. It could be anticipated, therefore, that a semi-log plot of conductivity vs. reciprocal absolute temperature might yield a straight line, in the case of molten silicates and salts. As liquids, the viscosity of these slags should follow the Shepard¹ relationship:

$$\log \text{ viscosity} = \frac{A}{T} + B$$

Then, if the resistance of the molten slag is directly proportional to the viscosity:

$$\log R_s = \frac{A}{T} + B$$

Resistance measurements of molten halide salts,² and silicate salts^{3,4} by various investigators have, indeed, shown this straight line relationship between resistance and temperature.

A further relationship between the

conductivity versus the degree of ionization, the size of the ions, and the slag composition is, also, to be expected. Large ions, and fewer ions, would move more slowly in a potential field and could not carry as much current as smaller, more numerous, and mobile, ions. Conductivity, therefore, would be smaller in the presence of such large ions and higher slag viscosities.

The conductivity-composition relationship is of considerable interest in the case of the industrial slags produced in iron blast furnaces, and non-ferrous smelting furnaces. These slags usually approximate three component systems with several minor components as impurities. At least one of the major

components is commonly purchased for the sole purpose of rendering the slag less viscous at a reasonable furnace temperature. Should the conductivity be related rather directly to the concentration of such a purchased slag component (that is, CaO) instrumental measurement and control at the furnace might be possible. Modern telemetric control methods in aqueous chemical process industries are often based on the property of conductivity of solutions, and its variation with composition.

Investigators³ of the phenomenon of electrical conductivity in molten blast furnace slags have established that these systems show lines of equal conductivity on their ternary diagrams at one temperature level. These isoconductivity lines form closed contours on the diagrams, and at times, minimum areas occur at which these contours are essentially closed down to a point. The conductivity reading at such a point, at one temperature, would, of course, locate one on the diagram, and give the slag composition.

Research in this field is understandably scanty. The reactive nature of

New York Meeting, February 1950. TP 2728 D. Discussion of this paper (2 copies) may be sent to *Transactions AIME* before April 1, 1950. Discussion is tentatively scheduled for publication in November 1950.

FIG 1—Log conductivity vs. reciprocal of absolute temperature for PbO-SiO₂ slags in liquid state.

these slag systems at their liquid temperatures renders the construction of a measuring apparatus extremely difficult. Temperature control is, also, not easy to achieve. Complex ternary systems often obscure experimental data by the introduction of uncontrollable variables.

Experimental Procedure and Apparatus

The present research was started with the hope of obtaining some further data on industrial systems. However, preliminary work on low-melting lead silicate systems seemed like a logical starting point in establishing the validity of the conductivity-composition control method. Accordingly, several artificial slags were made up from cp litharge and silica. These ranged in content from 10 pct SiO₂ to 30 pct SiO₂, by weight. These slags were melted in 10-g silica assay crucibles held in an electrically-heated pot furnace. An assembly, consisting of two platinum electrodes, plus a chromel-alumel thermocouple, was fitted on the top of the crucible. This allowed the electrodes and thermocouple to dip into the molten slag to a predetermined depth.

Temperature and conductivity were read simultaneously at each point; first with the temperature increasing, and then with it decreasing. Temperature was read on a Leeds and Northrup

portable potentiometer. Conductivity readings required 1000-cycle current, supplied by an audio-oscillator, and a resistance bridge circuit, calibrated in ohms. The null-point method was then used for both resistance and temperature. The conductivity apparatus was calibrated to yield specific conductivities, according to the formula:

$$L_s = \frac{K}{R} \quad \text{where } K \text{ is the cell constant and } R \text{ is the resistance reading in ohms.}$$

K was determined by a calibration using standard KCl solutions.

Results

A number of temperature-conductivity points were read for each slag composition, above its melting point. Fig 1 shows these points plotted to a log conductivity-reciprocal absolute temperature scale. It will be seen that the points for slag composition can be averaged as a straight line of formula:

$$\log L_s = \frac{-A}{T} - B$$

Where A is a constant for each line—the slope of the line—and B is a second constant.

This formula can be derived from the Shepard¹ formula for viscosity:

$$\log \mu = \frac{A}{T} + B$$

by assuming molten slag specific resistance as directly proportional to viscosity, whence:

$$\log R_s = \frac{A}{T} + B$$

and as, $R_s = \frac{1}{L_s}$ then,

$$\log \frac{1}{L_s} = \log 1 - \log L_s = \frac{A}{T} + B,$$

$$\text{or, } \log L_s = \frac{-A}{T} - B.$$

The correspondence between this formula and the one for the plotted points in the lead silicate system is considered good evidence of the direct relationship between viscosity and conductivity in these slags.

It will be noted, also, that the four slags with SiO₂/PbO ratios of 1.00, or greater, all have almost equal slopes. That is, for these compositions, A is a constant. Further, the three slags of SiO₂/PbO ratios less than 1.00 yield lines with approximately equal slopes, or Constant A .

A_2 has an average value of 11,200, which makes the equation of the lines in group II:

$$\log L_s = \frac{-11,200}{T} - B$$

Similarly, the equation for group I is:

$$\log L_s = \frac{-5000}{T} - B$$

If we take unit conductivity ($L_s = 1$) as a reference point, then for group II:

$$B = \frac{-11,200}{Tu} \quad \text{and} \quad Tu = \frac{-11,200}{B}$$

and for the group I:

$$Tu = \frac{-5000}{B}$$

where Tu is the absolute temperature of unit conductivity for each slag composition, corresponding to its constant B .

FIG 2—Temperature of unit conductivity vs. mol pct SiO₂.

When these Tu values are plotted against molecular percentage of SiO₂, the points can be averaged by two straight lines of different slopes, one for each group. This will be seen by a glance at Fig 2. The break between these two curves is seen to occur at about 50 mol pct SiO₂, or about 21 pct by weight of SiO₂. This break is such that the temperature of unit conductivity drops sharply at this composition. The slag suddenly conducts the same amount of electricity at a much lower temperature. This seems to indicate an increase in the number of ions and a decrease in the size of the ions, or both. Such an event could occur by the ionization, and disappearance, of a large molecular association such as PbO.SiO₂. It is interesting to note that the constitutional diagram⁵ of PbSiO₃ vs. temperature shows a temperature maximum in its liquidus line at 21 pct, by weight, SiO₂. This maximum is at 1137 degrees absolute and corresponds to the compound PbO.SiO₂.

The equation for line I, in Fig 2, is:

$$Tu = 20N + 570, \text{ or}$$

$$N = \frac{Tu - 570}{20} = 0.05Tu - 28.5$$

and as, $Tu = \frac{-5000}{B}$ for group I

(when $Ls = 1$) then $N = \frac{-250}{B} - 28.5$
 $= \text{mol pct SiO}_2$ where B , for group I, is given by:

$$-B = \log Ls + \frac{5000}{T}$$

Similarly, for line II, in Fig 2:

$$N = \frac{Tu - 917}{7.8} = 0.128Tu - 117.6$$

and, substituting, $Tu = \frac{-11,200}{B}$ for

group II, whence $N = \frac{-1432}{B} - 117.6$

and, B for group II is given by:

$$-B = \log Ls + \frac{11,200}{T}$$

These equations can be used to predict the mol pct SiO₂ of lead silicate slags, in the absence of Fig 1 and 2, as follows:

Suppose that a slag of unknown silica content gave a specific conductivity reading of $Ls = 0.00725$ mho at a temperature of 800°C or 1073°K. Here $\log Ls = 3.860$. Assume that any reading with a log value less than 2.00 will be in group II. Then,

$$-B = \log Ls + \frac{11,200}{T} \\ = 3.860 + 10.42 = 8.28$$

$$\text{and } N = \frac{-1432}{B} - 117.6 = 173.2 -$$

117.6 = 55.6 mol pct SiO₂. This is seen to be one of the points of slag 20, in group II. This slag therefore, has a composition of 25 pct SiO₂, by weight.

For this simple binary system, these equations, or corresponding nomographs will convert specific conductivity, plus temperature readings to composition. Small amounts of impurities probably will not affect this relationship; however, this fact has not been definitely established. Extension of this method to other binary, and, perhaps, ternary systems would place a useful tool in the hands of the furnace metallurgist.

Cemented Titanium Carbide

JOHN C. REDMOND,* Member AIME, and E. N. SMITH*

Introduction

The increasing need for materials capable of withstanding higher operating temperatures for various applications such as gas turbine blading and other parts, rocket nozzles, and many industrial applications, has brought consideration of cemented carbide compositions. The well known usefulness of cemented carbides as tool materials is attributable to their ability to retain their strength and hardness at much higher temperatures than even complex alloys. However, it has been found that the temperatures encountered in cutting operations do not approach by several hundred degrees¹ those involved in the applications mentioned above where the interest is in materials possessing strength and resistance to oxidation at temperatures of 1800°F and above. At these latter temperatures, the tool type compositions which are made up essentially of tungsten carbide are found to oxidize very rapidly and to produce oxidation products of a character which offer no protection to the remaining body. As a further consideration, the density of the tungsten carbide type compositions is high, from about 8.0 to 15.0.

The refractory metal carbides as a class are the highest melting materials known as shown by Table 1 which summarizes the available data from the literature for the carbides of the elements which are sufficiently available for consideration for these uses. The density is also included in the table, since as mentioned above, it is an important consideration in many of the applications for which the materials would be considered. It has been established that in the tool compositions the mechanism of sintering with cobalt is such as to result in a continuous carbide skeleton and that the properties of the sintered composition are thus essen-

Table 1 . . . Melting Points and Density

| Carbide | Melting Point °C | Density g per cc |

| Cr ₃ C ₂ | 1890 | 6.68 |

tially those of the carbide.² On the hypothesis that this mechanism holds to a greater or less degree in cementing most of the refractory metal carbides with an auxiliary metal, it appears from Table 1 that titanium carbide compositions would offer possibilities for a high temperature material.

Titanium carbide has extensive use for supplementing the properties of tungsten carbide in tool compositions. Although the literature contains several references to compositions containing only titanium carbide with an auxiliary metal,^{3,4,5,6} it may be inferred from the meager data that such compositions were deficient in strength and were considered to have poor oxidation resistance.⁷ Kieffer, for instance, reports the transverse rupture strength of a hot pressed TiC composition at 100,000 psi as compared to up to 350,000 psi for WC compositions.

The work described herein was undertaken to determine the properties of compositions consisting of titanium carbide and an auxiliary metal and to improve the oxidation resistance of

such compositions. It appeared possible that the inclusion of one or more other carbides with titanium carbide might improve the oxidation resistance and also that this might be more desirable than other means from the point of view of maintaining the highest possible softening point. Consideration of the available carbides in Table 1 suggests tantalum and columbium carbides because of their high melting points and general refractoriness. The work on improving oxidation resistance was concentrated on the addition of tantalum carbide or mixtures of tantalum and columbium carbide. The auxiliary metals used included cobalt, nickel and iron. It was also desired to learn the general physical properties of these compositions.

Experimental Procedure

The compositions used in this study were made by the usual powder metallurgy procedure applicable to cemented tungsten carbide compositions. The powdered carbide or carbides and auxiliary metal were milled together out of contact with air. In some cases cemented tungsten carbide balls and in other instances steel balls were used to eliminate any effect of tungsten carbide contamination. A temporary binder, paraffin, was then included in the mix and slugs or ingots were pressed with care to obtain as uniform pressing as possible. The ingots were presintered and the various shapes of test specimens were formed by machining, making the proper allowance for shrinkage during sintering. Thereafter the shapes were sintered in vacuum at temperatures of from 2800 to 3500°F. Final grinding to size was carried out by diamond wheels under coolant.

The titanium carbide used contained a minimum of 19.50 pct total carbon and a total of 0.50 pct metallic impurities as indicated by chemical and spectrographic analysis. It was found by X ray diffraction examination with

FIG 1—Arrangement of apparatus used for gas oxidation tests.

a Norelco Recording Spectrometer to have the usual NaCl type of cubic lattice with a parameter of 4.32 Å. The auxiliary metals were in the form of pure hydrogen reduced powders. The carbides used to modify the TiC for increasing its oxidation resistance were made by the McKenna "menstruum" process.⁸ These were TaC and a three-carbide solid solution of the following approximate composition: Cb, 50.0 pct, Ta, 32.5 pct, Ti, 7.0 pct and carbon 10.5 pct. The latter is of interest because it offers a more available source of columbium and tantalum being made directly from suitable columbite ore without the need for separations.

Two tests were used to determine oxidation resistance. In the first test used in the earlier phases of the work a tube furnace arrangement combining electric and gas heating as shown in Fig 1 was used. The blast burner fuel gas ratio was so adjusted that combustion was not complete until the gases had passed over the specimens and through the tube and some flame was maintained at the exit end of the tube. An analysis of the gas at the specimens showed the following:

| | Pct |
|--|---------|
| CO..... | 5.1 |
| CO ₂ | 4.0 |
| O ₂ | 6.1 |
| N ₂ and H ₂ O..... | Balance |

The temperature of the specimens was maintained at 2100°F. This condition was found to be insufficiently severe.

The second procedure consisted of heating the ground specimens on ceramic or carbon supports in an unsealed muffle furnace without atmosphere control. Various conditions with respect to time and temperature were used as noted later.

The problem of measuring deterioration is difficult. The scales or coatings formed are highly adherent and cannot be removed mechanically; and they cannot be removed chemically without the danger of attacking the sound body. Methods based on weight increase appear to be satisfactory although somewhat difficult of interpretation because of the varying stoichiometric increases associated with the oxidation

of the various constituents. Measurement of the increase in thickness was found to agree well with weight increase values and was used as a measure for most of the work. In a few instances, strength measurements made after exposure demonstrated the decrease in strength to be proportional to the thickness increase. In a few instances microscopic examination was also made on polished cross-sections.

The strengths were determined at room temperature and at 1800°F by the transverse bending method. The particular arrangement used is shown in Fig 2 and has been widely used for testing the strength of the tool compositions. It is satisfactory as long as the materials being tested are of high compressive strength so that the failure is by tension rather than by shear. It was found by a compressive-strength test using the method of Bridgeman⁹ that the compressive strength of the composition of 80 pct TiC and 20 pct Co was 550,000 psi at room temperature and it was therefore considered that the short span specimen would yield satisfactory values for comparison purposes. This has since been confirmed qualitatively by work done on longer span specimens $\frac{1}{4}$ by $\frac{1}{2}$ by 4 in.¹⁰ For the high temperature tests the specimen was heated by induction with a coil surrounding the supports and the specimen and with the thermocouple placed directly in contact with the bottom surface of the specimen. Additional tests were carried out at other temperatures up to 2000°F in the case of two of the compositions. The room temperature tests were made on a calibrated hydraulic testing machine or on a Brinell testing machine. The high temperature tests were made on a hand operated hydraulic press calibrated with a proving ring.

The density of the sintered compositions was measured in all cases to determine completeness of sintering. This was carried out on ground specimens using the water immersion method and with a commercial wetting agent in the water. The theoretical density was calculated on the assumption that

FIG 2—Arrangement for transverse rupture testing. Specimen cross section is 0.200 in. thick X 0.375 in. wide.

a. 94 pct WC—6 pct cobalt. b. 73 pct WC—11 pct cobalt—16 pct titanium, columbium and tantalum as carbides. c. 80 pct TiC—20 pct cobalt. d. 60 pct TiC—20 pct cobalt—20 pct titanium, columbium and tantalum as carbides.

there was no retention of any of the carbides in solution in the auxiliary metal phase or change of any of the constituents in compositions. This was deemed a satisfactory criterion for determining completeness of sintering.

Other properties, including hardness, thermal and electrical conductivity and thermal expansion, were measured on two of the compositions to determine their general character.

Experimental Results

Early oxidation tests with the apparatus shown in Fig 1 indicated the oxidation rate of TiC compositions to be as little as 0.0002 in. thickness increase per face per hr at temperatures up to 2100°F with an adherent coating formed. The transverse rupture strength at room temperature for the 80 pct TiC—20 pct Co composition was found to be from 160 to 190,000 psi and at 1800°F it was found to be of the order of 100,000 psi. Further oxidation tests made in the muffle furnace for 18 hr periods showed that while these TiC compositions oxidized somewhat rapidly at 1800°F (up to 0.0011 in. thickness increase per face per hr), they were considerably superior to the tungsten carbide base materials which showed rates as high as 0.050 in. and oxidation products of inferior character as shown by Fig 3. The first composition is 94 pct WC and 6 pct Co, the

second 73 pct WC and 11 pct Co and the balance titanium, tantalum and columbium as carbides. In both instances the oxides are fluffy and non-adherent. The third specimen is 80 pct TiC and 20 pct Co. The fourth composition is the same as the third except that 20 pct of the solid solution of columbium and tantalum and titanium carbides was included as will be discussed later.

The oxidation rates of compositions containing varying quantities of cobalt, nickel and iron with TiC only and of compositions including TaC and the three carbide solid solution were determined in an 18 hr muffle test as shown in Table 2. The rates for the various auxiliary metals are observed to be of the same order of magnitude. In these preliminary tests it was found that from 25 to 35 pct of TaC substituted for an equal weight of TiC reduced the oxidation by tenfold as is shown in Table 2. This same result could be accomplished equally well by smaller percentages of the columbium, tantalum, titanium carbide solid solution. A series of compositions was therefore prepared using cobalt as the auxiliary metal maintained at 12.3 pct by volume of the composition. The three carbide solid solution content was varied as shown in Fig 4. The sintered test pieces were subjected to a 64 hr test in the muffle with the results shown. The marked effect of the columbium and tantalum in even small percentages in reducing the oxidation is to be noted as well as the fact that compositions which are very high in columbium and tantalum carbide oxidize more rapidly than the high TiC

FIG 4—Effect of CbC, TaC, TiC solid solution on oxidation of TiC compositions. 64 hr at 1800°F in open muffle furnace.

compositions. Two tests were made in one of which the specimens were supported on ceramic boats and in the other on carbon supports. The difference in the results should be noted.

A 210 hr oxidation test at 1800°F in the open muffle on a few selected compositions showed substantially the same results as the 64 hr test as shown in Table 3. Fig 5 shows the character of coating formed on the composition containing 18.7 pct Co, 15 pct three carbide solid solution and 66.3 pct TiC after heating for 210 hr at 1800°F in the open muffle. The overall coating thickness is approximately 0.003 in. A short test of 18 hr at 2200°F showed relative oxidation rates to be unchanged with the composition contain-

ing 20 pct of the three carbide solid solution being highly resistant. The thickness increase was 0.0182 in. for the 80 TiC-20 Co composition and 0.0014 in. for the equivalent composition containing 15 pct solid solution.

A study was made to determine whether any change in the rate of oxidation occurred with time with the results shown in Fig 6. The two compositions used were the 80 pct TiC-20 pct Co composition and the similar composition containing 15 pct of the columbium, tantalum, titanium solid solution. It is observed that within the accuracy of the measurements both compositions show straight line though widely varying rates of oxidation.

The effect of the addition of the three

carbide solid solution upon the room temperature strength was determined upon the same series of compositions as used to obtain the oxidation data of Fig 4. The results are shown in Fig 7. The consistent effect of the columbium and tantalum in reducing strength is to be noted. The strengths at room temperature and 1800°F of various other compositions are given in Table 4. It is to be noted that although the strengths of various TiC-Ni compositions are greater at room temperature than those of the TiC-Co compositions, the strength decreases more rapidly with temperature so that at 1800°F, they are somewhat weaker. The compositions using iron show promise. It has been suggested that, since TiC

compositions were known to have inferior strengths, the strengths obtained in this work were the result of approximately 3 pct of tungsten resulting from the milling of these compositions with cemented tungsten carbide balls. Accordingly, a composition was prepared containing 80 pct TiC and 20 pct Co wherein steel balls were used for the milling. Analysis showed this composition to contain only spectrographic traces of tungsten. The room temperature transverse rupture strength of this composition averaged 153,000 psi as compared with 160,000 with the same composition milled with tungsten carbide balls. The elevated temperature strengths of two of the compositions, that containing 80 pct TiC and 20 pct Co and the equivalent containing 15 pct three carbide solid solution are shown in Fig 8 for temperatures up to 2000°F. The slow rate of falling off of strength is to be noted. The lower rate of decrease

of the composition containing the columbium and tantalum carbide is of note. Table 4 also includes some high temperature modulus of rupture values for some of the other compositions. The theoretical and actual densities have been shown in Table 4 and it will be noted that the actual densities correspond very closely. Discussion of Results The most notable result is the marked decrease in oxidation of TiC compositions effected by the minor addition of TaC or of CbC and TaC in the form of the three carbide solid solution. This reduction in the amount of oxidation ranged up to 40 times in some instances. The effect cannot be accounted for on the basis of the oxidation characteristics of the additive carbides since, of themselves, the other carbides do not possess the oxidation resistance of

FIG 7—Effect of increasing percentages of CbC, TaC, TiC solid solution upon strength of TiC compositions, 12.3 pct Co by volume throughout.

TiC. The explanation which would appear to hold is that the ratio of the oxides in the oxidation product and their character must be such as to form an adherent continuous film and thus prevent further access to the carbide structure. Although no tests were conducted on the effect of CbC alone as an additive to TiC compositions, the combined effect of the columbium and tantalum carbides contained in the three carbide solid solution indicates that the columbium contributes considerably to the protection obtained.

The use of various auxiliary metals has little effect on the oxidation rate and as a secondary observation the percentage of auxiliary metal has small influence on the oxidation rate. It thus appears that the rate of oxidation is largely determined by the carbide constituents.

The data on modulus of rupture show in general that titanium carbide compositions may have strengths as much as 75 pct higher than those previously reported. Although these strengths are considerably below the general level of those of the cemented tungsten carbide compositions, the cemented titanium carbide compositions are strong materials. A better basis upon which to compare these materials with other materials, at least with alloys, is tensile strength and work upon this phase is now being carried out. However, based on the work of a number of laboratories the short time tensile strength of brittle materials may be expected to be from 0.4 to 0.6 the modulus of rupture value.¹⁰ This would make the high temperature tensile

strengths of cemented titanium carbide comparable with the best alloys and ceramics.

The marked difference in the rate of oxidation observed between the gas fired tube furnace and the muffle furnace, which was the equivalent of the differences found with and without columbium and tantalum carbides, emphasizes the effect of variations in the atmosphere upon oxidation results. The importance of even small variations in atmosphere upon oxidation results is shown by the results in the muffle furnace when ceramic vs. carbon supports are used for the specimens. Such differences in the effect of furnace atmosphere are insignificant in the case of compositions which have high oxidation resistance as shown by Fig 4.

Other Properties

It is of interest to know other properties of these TiC compositions, some of which are summarized in Table 5 for two of the compositions.

Table 5 . . . Additional Properties of TiC Compositions

* S.S refers to the solid solution of columbium, tantalum and titanium carbides.

YOUNG'S MODULUS OF ELASTICITY

These values were determined by the sonic vibration method¹¹ using ground bars $\frac{1}{4} \times \frac{1}{2} \times 3$ in. Comparisons were made with cemented tungsten carbide bars. These high moduli are indicative of the formation of a continuous carbide skeleton as in the case of the tungsten carbide compositions.

HARDNESS

These values were determined using a special Rockwell A Brale which was calibrated upon a cemented tungsten block calibrated by the Wilson Mechanical Instrument Co.

THERMAL EXPANSION

These values were determined by the use of a Bureau of Standards type dilatometer. Virtually straight line expansion curves were obtained. While these values are somewhat higher than the general level of those for cemented tungsten carbide compositions, they

FIG 11—Composition of Fig 10 after 210 hr at 1800°F. $\times 1500$, nital etch.

are one half or less those for ferrous base alloys and of the order of those for ceramics. The thermal expansion is an important consideration in the resistance of materials to thermal shock.

THERMAL CONDUCTIVITY

These values were obtained by the method described by McKenna.¹² The apparatus was standardized on pure

iron and lead. The conductivity of the cemented titanium carbide compositions is somewhat below that of the tungsten carbide compositions although above the level of highly alloyed ferrous base materials and many times higher than ceramics. The thermal conductivity of a material has a large bearing on its ability to resist thermal shock resulting from rapid temperature changes.

ELECTRICAL CONDUCTIVITY

These values were obtained by the Kelvin Bridge method using ground bars $\frac{1}{4}$ in. diam by 12 in. long and calibrating against a 0.1 ohm standard accurate to ± 0.02 pct.

Structure

Fig 9 and 10 show the etched structures of two of the compositions at 1500 magnifications which is largely used for examining cemented tungsten carbide tool compositions. The polishing is done with diamond dust using lead-tin laps as in the case of tungsten carbide compositions but greater care is needed to avoid scratches because of the lower abrasion resistance of these compositions. The 2 pct nital etch has been found to produce preferred etching to the conventional alkali ferricyanide etch used on tool compositions.

The structures are comparable to those of the tungsten carbide compositions in that they show two phases, the carbide phase and the phase which is predominately auxiliary metal. The grains are much more rounded than is the case with tungsten carbide compositions. The effect of CbC and TaC in causing larger grain size is to be noted. A specimen prepared for the composition of Fig 10 after 210 hr exposure at 1800°F is shown in Fig 11. There appears to be no significant change in structure.

X ray diffraction examination of the compositions of Fig 9 and 10 with the Norelco Recording Spectrometer shows that in both cases only a single carbide phase is present. In the case of the TiC-Co composition the TiC phase has a lattice parameter of 4.32 Å as for the TiC used in making the composition. This indicates that no more than a small quantity of Co could be held in solution in the TiC. The lattice parameter of the composition containing titanium, columbium and tantalum carbides was found to be 4.34 Å indicating a complete solid solution, as would be expected from the work of Norton and Mowry.¹³ The amount of

TiC retained in the Co phase in the sintered compositions has not yet been determined.

Summary

This work has shown that cemented titanium carbide compositions prepared by powder metallurgy methods have transverse rupture strengths up to 175,000 psi or 75 pct greater than previously reported in the literature. Either cobalt, nickel or iron may be used as an auxiliary metal. The two former appear very nearly equivalent in titanium carbide compositions. Iron is somewhat inferior.

Compositions containing only titanium carbide and an auxiliary metal are considerably superior to the tungsten carbide compositions with respect to the character of the oxidation products. It has also been found that the addition of minor percentages of tantalum carbide or of columbium and

tantalum carbide reduces the oxidation rate of the titanium carbide compositions to very small values at temperatures up to 2200°F.

The general properties of cemented titanium carbide compositions are comparable with those of the cemented tungsten carbide compositions. When the strength, oxidation resistance, thermal expansion and conductivity are considered, these compositions offer excellent possibilities as high temperature materials.

Acknowledgment

The authors acknowledge the work of J. R. Bridge in obtaining the data upon the general properties of these materials and of others in this laboratory for their assistance in this work.

Binary Chart for Interconversions of Mol, Weight, and Volume Percent

JOHN B. SEABROOK,* Student Associate AIME

The accompanying Fig 1 is a graphical scheme of intermediate accuracy for expediting interconversions of mol, weight, and volume percents. This chart consists of a family of curves of mol or atomic or volume percent plotted against weight percent, each curve in the family providing for a certain ratio of molecular or atomic weights or densities. Thus, the whole range of variations is presented in a very familiar format, and the conversion is effected simply by choosing the proper curve and reading off the required values. An entire series of conversions for a given binary system can be found by following the appropriate curve.

It is interesting to examine the analytical geometry of the plots. The curves, which must fit into a square

and all join at the 0 and 100 pct points, may be shown to be hyperbolas with their centers on the extension of the diagonal of the square which they intersect. Multiplying out the expression

$$\text{atomic fraction of } A = y = \frac{\frac{x}{A}}{\frac{x}{A} + \frac{1-x}{B}}$$

where x is the weight fraction of A , and A and B are atomic weights, we get

$$xy + \frac{A}{B}y - \frac{A}{B}xy = x$$

Upon rotating and translating axes and

avoiding imaginaries, it is found that the angle of rotation is -45° , the origin

$$\text{moves up } \frac{\sqrt{2}}{2} \text{ units and } \frac{\sqrt{2}}{2} \left(\frac{\frac{A}{B} + 1}{\frac{A}{B} - 1} \right)$$

units to the right, and the standard form is

$$\frac{1}{2} \left[\left(\frac{\frac{A}{B} + 1}{\frac{A}{B} - 1} \right)^2 - 1 \right] = 1$$

Thus the curves are equilateral hyperbolas, their centers are

$$\sqrt{\frac{1}{2} \left[\left(\frac{\frac{A}{B} + 1}{\frac{A}{B} - 1} \right)^2 - 1 \right]}$$

units away from their intersection with

Technical Note 30 E. Manuscript received April 28, 1949.

FIG 1—Chart for interconversion of mol, weight, and volume percent.

the diagonal and are on that diagonal, and the curves are symmetrical with respect to that diagonal. As the ratio of $A:B$ increases, both the center of the curve and the intersection of the curve with the diagonal approach the lower right hand corner of the square plot from opposite sides.

In the actual chart only one triangular quarter of the entire square is shown. Elimination of half of the square is accomplished by setting up the rule that the larger ratio always be taken, in other words, by making A the component with the larger atomic or molecular weight. Then, since the curves are symmetrical, only half of the remaining plot need be drawn, and the diagram may be turned as required. The scales are labeled so as to prevent error.

A few examples of the use of the chart may be useful. As may be seen on the chart, the atomic or molecular weight ratio, or density ratio is called r . Suppose it is desired to convert 20 wt

pct of Ag in the Ag-Cu system to atomic percent Ag. Choosing the larger

$$\text{ratio, } r = \frac{108}{63.6} = 1.70. \text{ This may be}$$

obtained from a slide rule or a prepared table of atomic weight ratios. Selecting the curve for a ratio of 1.7, the at. pct of 12.8 pct Ag is readily obtained. As a second example, suppose the wt pct of Ag were 70 pct in the same system. This combination requires the interchanged scales, and therefore the chart must be turned 90° clockwise. Atomic percent of A is again found by the single reading of the graph, using the same $r = 1.7$ curve. A final example is provided by the problem of determining what weight of Fe will be contained in a given weight of Fe_3C . This is an atomic percent to weight percent conversion. Fe being the heavier component, the atomic percent to be considered is obviously 75 pct, and $r = \frac{55.9}{12.0} = 4.65$. Using the chart in the sideways position, the value of 93.3 wt

pct of Fe is obtained, estimating the last digit. Thus, every 6.7 g of C in the carbide are combined with 93.3 g of Fe.

It is at once recognized that the chart becomes quite inaccurate for the low and high percents and also for the high ratios. This can be overcome, if the need so warrants, by making enlarged plots of limited areas of the original whole plot. Another variation in accuracy occurs in that simple interpolation between curves becomes inaccurate as the ratio becomes large.

To summarize the conditions for which the chart is set up: (1) the percents indicated on the scales of the chart refer to the component which has the larger atomic or molecular weight or density, (2) the ratio, r , which selects the appropriate curve, is the larger ratio of weights or densities, (3) whenever a combination of percent and r falls outside the triangular area covered by the curves, the chart must be turned 90°.

Intergranular Parting of Brass during Anneals

F. H. WILSON,* and E. W. PALMER,* Members AIME

Brass mills are familiar with a recurring problem which reveals itself during deformation of annealed metal as an opening up of cracks which are suggestive of a grain boundary pattern. A typical example is seen in Fig 1, which shows part of the convex surface of a cartridge brass disc which was slightly dished by the punching operation. Another illustration of the same type of defect was found in the surface of a finished cartridge case which split open on firing. These cracks, shown in Fig 2, were away from the split but indicate the presence of the type of weakness which permitted the splitting. Usually the weakness consists of separate cracks, the lengths of which are of the same order of magnitude as the grain size prior to the final anneal. Their typical appearance in a polished section is shown in Fig 3. This structure was found below the surface of a fractured tensile-specimen that had been cut from a large cartridge blank showing the defects on its convex surface.

While the pattern formed by these cracks suggests a grain boundary origin, the cracks bear no relation to the currently existing grain structure. Thus Fig 3 shows that the grains have grown up to cracks already present. Since it is doubtful that the cracks were present in the metal before the anneal, they must have formed during the anneal but prior to recrystallization. The term "fire-cracking" has been generally applied to cracking that occurs during an anneal under the influence of internal stress, but refers more specifically to obvious macroscopic cracking attributable to the presence of a low melting phase, usually lead. Since the type of cracking described above may occur when the lead content is very low, we have considered it a somewhat different phenomenon, and have called it "intergranular parting." While most examples involve cartridge brass, intergranular parting has also been observed in the fabrication of large seamless tubes from discs of both 85/15 red brass and 70/30 cupro-nickel. Similar cracking in

nickel silver was investigated by Jones and Whitehead,¹ who showed that it could occur during heating or cooling. That which occurred on heating they called "fire cracking," and they suggested that a transformation at about 320°C might account for its occurrence.

It was felt in this laboratory that the observed parting was probably one aspect of the general observation, first made by Rosenhain and Archbutt,² that a tendency toward intergranular fracture under tensile stress increases with increasing temperature and decreasing rate of strain. In this case the stress involved would be internal. The rate of strain would be exceedingly slow, a localized internal creep. Reference to the literature uncovered no efforts to extend the observations of Rosenhain to conditions involving only internal stress.

Accordingly, an exploratory research, sufficient in detail to satisfy us as to the probable truth of this explanation of the observed intergranular parting, was undertaken. The internal stresses present during the early stages of an anneal (prior to recrystallization) would be from two sources: residual stresses developed during deformation, and thermal stresses caused by uneven heating and expansion. Thermal stresses would vary widely according to shape, size and manner of heating, and can be considered as supplementary to residual stresses. It seemed necessary to determine the stress and temperature conditions under which parting would occur in a relatively short time, and then to establish whether or not in-

ternal stresses may persist to an extent adequate to cause parting at such temperatures. (Jones and Whitehead¹ and Moore and Beckinsale³ made tests which indicated that stress relief required an appreciable time.) During the course of the research the desirability of studying the effect of grain size became apparent, and this factor is one of the major variables of our investigation.

Intergranular Parting under Tension at Elevated Temperatures

In early experiments, hard 70/30 brass tensile specimens, with unknown residual stresses, held for 10 min. at applied stresses from 30,000 to 40,000 psi at temperatures from 300 to 350°C, showed no macroscopically visible cracks when unloaded and cooled, but cracks very similar in appearance to those observed in commercial practice were revealed in these specimens by pulling them to fracture. Annealed specimens, on the other hand, showed no cracks in such experiments, apparently because they deformed plastically at stresses below those necessary to cause parting in a reasonable time. Hence, the specimens used for this study were first strengthened by cold tensile elongation, giving them an unavoidable residual stress pattern (determined largely by grain size and orientation) which would, however, correspond in direction, at least, to the stress pattern obtained under stress at temperature. A variation in these residual stresses might be expected with variations in grain size, but following any given anneal the reproducibility of stress pattern should be as good as that of the grain size measurement.

With no information as to the effect of the amount of prior deformation, tests were conducted on specimens given the same cold elongation, using a stress applied at temperature which was a constant proportion of the stress required to produce this elongation. In

New York Meeting, February 1950.

this way the stress applied at temperature was approximately related to the yield strength of the material tested. As a result, large grained specimens were held under lower stresses at tem-

perature than the fine grained ones. Later tests determined the relative behavior of specimens having different grain sizes which were given the same stress at the same temperature.

Tests at Elevated Temperatures under Sustained Loads

Tensile specimens were machined to a $\frac{3}{8}$ in. diam over a 2 in. ga length from $\frac{9}{16}$ in. diam 70/30 brass rod, which had been given a final reduction of about 30 pct. The ready-to-finish grain size was 0.065 mm. Analysis showed the following composition:

| | Pct |
|-------------|---------------------|
| Copper..... | 69.64 |
| Zinc..... | 30.33 by difference |
| Lead..... | 0.02 |
| Iron..... | 0.01 |

Specimens were annealed for 1 hr at 400, 500, 600, 700 and 800°C and developed grain sizes of 0.020, 0.035, 0.1, 0.2 and 1 mm respectively. For each test, a specimen was stretched 25 pct, noting the maximum load and final diameter. It was then set in the tensile machine and brought to within $\pm 3^\circ$ of the desired temperature by means of an electric furnace. After soaking 15–20 min. it was loaded quickly to 80 pct of its prior maximum load. This load was automatically maintained for 10 min., save in a few cases where a maximum crosshead travel of 0.01 ipm failed to compensate for creep. The extent of damage by cracking was revealed by subsequently pulling the specimen to fracture at room temperature, the maximum load and the diameter at fracture being observed. Tensile

strength and reduction of area values, based on the diameter of the specimen just before the final tests, were recorded.

With this procedure, tests were made on specimens representing all the grain sizes listed above at temperatures of 225, 250, 275 and 300°C. In addition, tests were made at 325°C for specimens annealed at 400, 450 and 500°C, and a few other tests were made at intermediate temperatures.

The results of these tests, as recorded in Table 1, are grouped according to the temperature of anneal, and within each group are in the order of increasing temperature of stressing. The value in the "pre-stress" column (the maximum true-stress reached with cold elongation) is an indication of the strength of the specimen under load.

FIG 4—The variation of intergranular parting with grain size and temperature.
Longitudinal sections showing cracks opened up by room temperature fracturing of 70/30 brass tensile specimens annealed 1 hr at the indicated temperatures, stretched 25 pct, and stressed at 80 pct of the prior maximum stress for 10 min. at the indicated temperatures. $\times 2\frac{1}{2}$.

It will be noted that for anneals of 500°C, and below, it was not possible to reach 80 pct of the pre-stress at some of the temperatures. In such cases, the specimen stretched continuously at the maximum permitted loading rate of 0.01 ipm for the full 10 min. under load. As indicated, several specimens broke in the furnace before the 10 min. had elapsed. In these cases the fracture was completely intergranular and there was no evidence of local necking before fracture.

Damage from cracking is indicated by a lowering of tensile strength and of ductility as measured by reduction of area. Inspection of the data shows that for any one grain size the amount of damage increases with the temperature of stressing. There is an apparent downward trend of tensile strength and ductility with increasing grain size, and the reality of this effect will be shown in tests at constant stress which will be discussed later. Photographs of polished longitudinal sections through the fractures of most of the specimens (Fig 4)

demonstrate a correlation between ductility and cracking. Cracks, present even in the fine grained specimen tested at 225°C, increase in number with the temperature of test and with the grain size up to the 600°C anneal. The greater magnitude of each crack in the larger grained specimens overcompensates for the decreased number of cracks, and represents greater damage as measured by reduction of area.

Cracks on the surface near the fracture of specimens annealed at 600, 700 and 800°C are illustrated in Fig 5. These bear a strong resemblance to those found when intergranular parting is encountered in commercial fabrication, as illustrated in Fig 1 and 2.

The data from this series of tests are also presented graphically in Fig 6. Three variables are plotted. (A fourth, stress at temperature, is not included, but can be found by reference to Table 1.) The vertical axis indicates the reduction of area, the variation of which with the temperatures of anneal (grain size) and the temperatures of

FIG 5—Intergranular parting revealed by room temperature fracturing.

Tensile specimens annealed 1 hr at indicated temperature, elongated 25 pct, and loaded for 10 min. at indicated stresses and temperatures. $\times 10$.

stressing, dotted contour lines are drawn through points representing tests in which 80 pct of the prior load could not be attained.

A few tests were made which compared pairs of specimens given the same stress at temperature following different prior deformations. These were made only on specimens annealed at 700 and 800°C; specimens were stressed at about 18,500, 21,500 and 25,000 psi for 10 min. at 275°C. The results of these tests are listed in Table 2. Referring to the reduction of area figures, it will be seen that the damage is almost independent of the amount of prior deformation.* The results confirm the expectation that the parting increases with stress. Moreover, comparison can be made between specimens of differing grain size which are given the same stress at the same temperature, and it is seen that loss of ductility from parting does increase with increasing grain size. For each pair, differing only in the amount of prior reduction, the tensile strengths are less consistent measures of damage than the reduction of area values. In each case a higher tensile strength is indicated for the higher prior deformation and, since the strength value is based on the area after deformation, this is due to work hardening in uncracked portions of the specimen. All of these specimens showed visual evidence of parting except the 700°C annealed specimen stressed at 18,200 psi.

Discussion of Results

Since these test results involve only single specimens under each condition, there is no claim that any absolute values can be read from the table; nor does it seem necessary to try to establish absolute values, since in the practical application of this information actual stress, temperature, and grain size values are rarely known. The important points are the approximate determination of the conditions which will cause intergranular parting and the directions of the effects of the variable factors studied.

It is shown that 70/30 brass will part in less than 10 min., at grain boundaries, at temperatures below those which cause recrystallization in a reasonably short time, under the influence of

* That this is not universally true was learned in a few comparable tests on silicon bronze. Specimens of equivalent grain size, given identical true-stresses at the same temperature, were profoundly affected by the amount of prior deformation, or the concomitant variable, specimen diameter. The greater parting occurred on specimens where the true stresses were a higher percentage of the previously applied true stress.

stresses of approximately the same order as those which may be found internally. The extent of parting will increase with both increasing temperature and stress. The loss of ductility resulting from the parting increases with increasing grain size even when the number of cracks per unit volume decreases. At least for 70/30 brass, susceptibility to parting is independent of prior cold work, provided the metal has been strengthened sufficiently to support the required level of stress.

The type of test performed here differs from tensile tests at low rates of strain at elevated temperatures in that, by holding the load constant at a stress below the yield strength, the strain rate is exceedingly low. The test differs from stress-rupture and creep tests in the time allowed for stress application at temperature. However, as in these other types of test, failure occurs by parting at the grain boundaries and it is believed that the present data add to an accumulation of results^{2,4-12} which indicate that the only conditions necessary to cause parting at grain boundaries under stress are a sufficiently high temperature and a sufficiently low rate of strain. Theoretical interpretation of this behavior is ably discussed by Zener¹³ in terms of the viscous behavior of grain boundaries.

Experimental Study of Some Factors Influencing Relief of Stresses by Annealing

Having demonstrated that intergranular parting can occur under the influence of externally applied stress at elevated temperatures, there remained an investigation of the probability that adequate stresses, thermal and residual, can be present internally when metal is heating up in commercial anneals. The many unpredictable factors involved in the development of thermal stresses makes an investigation of these quite difficult. However, relaxation tests on bent strips, while limited for quantitative studies by the fact that stress formulas assume a linear stress distribution, can give at least a qualitative estimate of the rate of relief of internal residual stress and can determine the factors which influence it.

STRESS RELIEF TESTS

Relaxation tests, involving measurements of residual curvature of initially

FIG 6—The effect of grain size and temperature of stressing on ductility. Same specimens as in Fig 4. Reduction of area values based on dimensions after stressing. Temperature in °C.

flat specimens annealed while constrained against a cylindrical block, were made at four different stresses (by varying the strip thickness), for five different grain sizes, and at three temperatures in the relief annealing range. The specimens were cut from four strips of 70/30 brass fabricated from hot rolled stock having the following composition:

| | Pct |
|-------------|---------------------|
| Copper..... | 69.81 |
| Zinc..... | 30.16 by difference |
| Lead..... | 0.02 |
| Iron..... | 0.01 |

Table 3 outlines the course of fabrication for the four gauges. The ready-to-finish anneals resulted in the following grain sizes, substantially the same for all four gauges:

| | |
|----------------|----------------|
| 400°C—0.012 mm | 600°C—0.115 mm |
| 500°C—0.038 mm | 700°C—0.325 mm |
| 800°C—0.450 mm | |

It will be noted that the strip was in all cases finished with a 25 pct reduction, since, as in the case of the tensile specimens stressed at elevated temperatures, a hard material was necessary to permit development of stresses of the desired magnitude. Half inch wide specimens 6 in. long were cut from the finished strip, straightened somewhat by stretching, and milled to 0.45 in. width.

A few additional tests were made at one temperature on even thinner material, in two grain sizes, which was prepared by taking some of the 0.049

in. material rolled 25 pct and processing as follows:

| | Anneal 1 hr at 650°C | |
|---------------------|----------------------|----------------|
| | 5E, 6E, 7E, 8E | 5A, 6A, 7A, 8A |
| Cold roll to..... | 0.022 in. | 0.022 in. |
| Anneal 1 hr at..... | 400°C | 800°C |
| Cold roll 15 pct to | 0.0185 in. | 0.0185 in. |

Samples 5A–8A had uniform grain sizes of about 0.375 mm while samples 5E–8E had an uneven grain size averaging 0.020 mm. Note that this material was finished with a reduction of only 15 pct, rather than the 25 pct used for the more extensive series above.

The stress measurements were based on calculations of outer fiber stresses in bent strips, assuming a linear distribution of stress. The amount of bend was determined from the height of the segment intercepted by a 5 in. chord. The stress required to change the curvature from that determined by a segment height d_a to that determined by d_b is

$$S_a - S_b = Et/6.25 (d_a - d_b)$$

where $E = 16,400,000$ psi and t is the thickness. With d_1 the height after holding a specimen against a 20 in. radius surface for 5 min. at room temperature, d_2 the height after a subsequent 60 min. anneal of the bent specimen, and d_0 the segment height for a 20 in. radius of curvature,

Table 3 . . . Preparation of Strips for Stress Relief Tests

FIG 7—The effect of grain size and temperature on stress relief.

Residual stresses in bent 70/30 brass strips after 1 hr at indicated temperatures when initially stressed to about: A. 26,000 psi B. 22,000 psi C. 19,000 psi D. 15,000 psi E. 7,000 psi

$S_0 - S_1$ is the applied stress before relief annealing.

$S_2 - S_1$ is the stress relieved by the anneal

$S_0 - S_2$ is the residual stress which returns the specimen to its final position after the anneal.

The assumption of linearity of stress distribution is known to be inaccurate in two ways: 1. Any plastic flow occurring during the 5 min. bending at room temperature leaves a residual stress which decreases the applied stress below that calculated by an undetermined amount.¹⁴ 2. The stress relief, occurring disproportionately in the outer fibers, destroys any linearity of stress distribution and calculations based on the final curvature give an outer fiber stress higher than that

actually present.

Nevertheless, since the actual stresses must be related to the measured ones, the technique is useful for determining the relative effect of variable factors affecting stress relief, such as temperature, time, grain size and the magnitude of applied stress.

The 20 in. radius bend was obtained by the use of a steel block with a surface having this curvature against which the specimens were free to slide in expanding. Due to the fact that the heavier gauges took on a permanent set at room temperature the calculated applied stresses were 15,000, 19,000, 22,000 and 26,000 psi rather than the intended (assuming flat specimens) 15,000, 20,000 25,000 and 30,000 psi. In the anneals, 60 min. was allowed for the assembly to reach temperature.

EFFECT OF TEMPERATURE, GRAIN SIZE AND THE MAGNITUDE OF APPLIED STRESS ON STRESS RELIEF

Specimens for each grain size in the four heavier gauges were relief annealed for 1 hr at 200, 250 and 300°C. The 0.0185 in. strips were relief annealed only at 250°C. Data as determined from measurements before and after the anneal are given in Table 4 and plotted in Fig 7 and 8. The per cent stress relieved thermally based on the applied stress is also included. These data illustrate the expected lower residual stresses resulting from higher relief annealing temperatures. It is clear from the consistency of behavior for all gauges and temperatures that specimens with finer grain sizes have less residual stress than those with coarse grains. Moreover, the amount of residual stress increases with applied stress, the curves in Fig 8 demonstrating about the same level of per cent stress relief at any one temperature, regardless of the magnitude of the applied stress.

With reference to the 0.0185 in. specimens stressed to only 7,000 psi (Table 4 and Fig 7), it will be seen that, at least at 250°C, if there is any minimum stress below which there is no relief annealing it must be very low. It is interesting to note that even at low stresses the per cent stress relief is not affected by applied stress. The fine grained (0.020 mm) thin specimen shows a per cent stress relief between the averages for 0.012 mm (400°C) and 0.038 mm (500°C) thicker specimens, and the coarse grained (0.375 mm) thin specimen a value between those for 0.325 mm (700°C) and 0.450 mm (800°C) thicker specimens.

Even under conditions of least stress relief (that is, with large grained specimens), the magnitudes of residual stresses at temperature, after 1 hour of relief annealing, are well below those required for intergranular parting at any of the temperatures employed. Since it seemed probable that the stresses remaining after shorter times at temperature would be higher, the change of residual stress with time was tested for one applied stress on both fine and coarse grained specimens.

EFFECT OF TIME ON STRESS RELIEF

For studying the effect of time on relief annealing, the steel block was unsatisfactory since it required an hour to reach temperature. A thin walled

tube, 10.1 in. od \times 0.063 in. wall, which required only 6 min. to reach temperature, was employed. The smaller radius called for thinner specimens for equivalent stresses, and the 0.0185 in. thick material designated by 5A-8A and 5E-8E was sheared to size for these tests. Strip having this gauge should develop outer fiber stresses of 30,000 psi when bent to the 5.05 in. radius of the tube support. However, as a result of initial curvature and permanent set at room temperature, the applied stresses were of the order of magnitude of 25,000-29,000 psi.

One specimen for each grain size was held to the tube with wire. Again d_1 after 5 min. at room temperature, and d_2 after the anneal, were measured. Allowing 6 min. to reach temperature, the specimens were annealed for 0, 3 and 6 min. at 200, 250 and 300°C. An additional test was made for 60 min. at 250°C.

Data corresponding to those assembled for specimens bent to the 20 in. radius are recorded for these specimens in Table 5. The effects of grain size and temperature of relief annealing are again evident.

The effect of time is presented graphically in Fig 9. Since tests for 60 min. were made only at 250°C, the data for the points at 60 min. for the 200 and 300°C curves are taken from Table 4 and are indicated by filled circles. These results were obtained with thicker and harder specimens bent to a larger radius of curvature, and justification for their inclusion can be made by comparing the stress relief in thick and thin specimens under equivalent stresses at 250°C for 60 min. For instance, data for specimens 6A60 and 6E60 may be compared with the two starred specimens in Table 4. By bending to different radii, these 4 specimens were given about the same applied stress and all were relief annealed for 1 hr at 250°C.

| Specimen | Gauge Inch | Grain Size mm | Radius Inch | Applied Stress psi | Per Cent Stress Relief | Retained Stress psi |
|----------|------------|---------------|-------------|--------------------|------------------------|---------------------|
| 1 | 0.0735 | 0.450 | 20 | 25,600 | 50.8 | 12,500 |
| 2 | | 0.012 | 20 | 26,400 | 69.3 | 8,000 |
| 3(6A60) | 0.0185 | 0.375 | 5 | 24,800 | 50.0 | 12,400 |
| 4(6E60) | | 0.020 | 5 | 28,300 | 66.8 | 9,300 |

Specimens 1 and 3 show almost identical stress relief and the difference between 2 and 4 may be due to the effect of their difference in grain size. It is evident that with a constant applied stress specimen thickness may vary widely without greatly influencing the extent of stress relief as tested by bend-

| Specimen | Grain size mm | Applied Stress $S_0 - S_1$ psi | Relief Annealing Temperature °C | Time at Temperature min. | Stress Relieved Thermally | | Residual Stress $S_0 - S_2$ psi |
|----------|---------------|--------------------------------|---------------------------------|--------------------------|---------------------------|--|---------------------------------|
| | | | | | $S_2 - S_1$ psi | $\frac{S_2 - S_1}{S_0 - S_1} \times 100$ Pct | |
| 7A0 | 0.375 | 26,000 | 200 | 0 | 5,300 | 20.4 | 20,700 |

ing strips.

As seen in Table 5 and Fig 9, the values at "zero" time show that there has been a rapid initial decrease in residual stress (from an applied stress of 25,000-29,000 psi) during the 6 min. heating up period to each of the temperatures, and this is greater as the temperature increases and the grain size decreases. However, this rapid decrease does not constitute the whole of the stress relief and residual stresses remain after 10 min. in the furnace (4 additional min.) which are appreciably higher than the stresses remaining in the earlier tests after 60 min.

The curves suggest that, after the initial rapid stress relief, the rate of stress relief is independent of grain size and temperature.

DISCUSSION OF RESULTS

The data show that the amount of stress relief increases with time and temperature. This behavior would be expected of reactions involving atomic motions which require an activation

energy and are thus functions of the probability that a given atom will be given sufficient energy to move into a more stable position.

The present research also shows that the amount of stress relief decreases with increasing grain size. Perhaps the grain size effect is not surprising in view

of the fact that stress relaxation and creep are fundamentally alike¹⁵ and the creep rate of brass varies inversely with grain size.¹⁶

The experiments were not complete enough to establish whether, given sufficient time, specimens would reach the same residual stress for a given temperature regardless of initial stress; but the results suggest that this would not be true. Thus, if there were a residual stress determined only by temperature after a very long time, it could be inferred from the curves that for some of the more highly stressed samples (for example, 28,000 psi-250°C), the final residual stress could not be much below 10,000 psi. However, a sample stressed initially at 7,000 psi drops in 60 min. to 3,500 psi. More extensive studies of Moore and Beckinsale³ on the effect of time show that, except for much harder strip in which stress was entirely relieved (presumably by recrystallization) at 250-300°C, a dependence of residual stress on initial stress is maintained after the time curves become horizontal.

Thermodynamic considerations would suggest that, if the metal were homogeneous, uniform stress in an elastically strained specimen would tend to approach, with time, a residual stress characteristic of the temperature and independent of the magnitude of the initial stress. The experimental evidence that the residual stress is a definite function of the applied stress can be understood by analysis of the inhomogeneities present and of the stress distribution. Considering, first, the lack of homogeneity of stress in a polycrystalline metal, the total stress can be considered as a composite of

FIG 8—The constancy of per cent stress relief with varying initial applied stress. The same data as in Fig 7.

FIG 9—Rate of stress relief as affected by grain size and temperature.

Initial applied stress: 25–29,000 psi.
Datum points are residual stresses after 0, 3, 6, and 60 min. at temperature.

microstresses which vary in magnitude because of the anisotropy of elastic modulus. If each local site of microstress were considered homogeneous, overall stress relief at a given temperature would consist of a reduction of all higher stresses to a level characteristic of the temperature, and residual stress would be a composite of all the unchanged lower stresses and an increased number of stresses at the maximum level characteristic of the temperature.

Increasing the applied stress increases each microstress proportionally causing the total stress to consist increasingly of microstresses higher than the stress to which a given temperature will relax them. Thus there is more stress relief in specimens having a greater initial stress. However, the residual stress will also be greater because the extent to which the total residual stress consists of the highest stresses possible at the temperature of annealing will increase with initial stress.

With respect to the stress distribution in an elastically bent specimen, there is again a range of stress, in this case increasing linearly from the neutral axis to the surface. The same argument applies and stress relief results in a reduction of all higher stresses to a level characteristic of the time and temperature. A nonlinear stress distribution results, but the total stress will be higher the higher the initially applied stress.

Because of the uncertainty introduced by the fact that the calculated residual stresses indicate values which are higher than the actual residual stresses in the outer fibers by an undeterminable amount, it is not safe to estimate from the experimental results the magnitude of residual stress which might be found within a metal

after any particular time in an annealing furnace. The results do show, however, that whatever the magnitude of stress remaining after a given treatment of brass in a given condition it will be greater after shorter times, at lower temperatures, with larger grain sizes and with higher initial internal stresses.

Intergranular Parting During Anneals

It has been shown that “intergranular parting,” a type of failure occasionally observed in commercial fabrication of 70/30 brass, has a structural appearance which can be duplicated by holding tensile specimens at a constant stress at elevated temperatures. The most probable time in commercial fabrication that the metal is under appreciable stress at an elevated temperature is during the heating up period of an anneal. That parting occurs at this time is shown by tests which indicate that annealed brass will not support stresses adequate to cause parting in a short time (at least when they are only uniaxial), and by the observation in commercial failures that recrystallization occurs after cracking. (Some examples are known in which thermal stresses during rapid spray cooling of annealed metal appear to have caused intergranular parting).

In investigations as to whether internal stresses can be responsible for cracking, qualitative measurements of the residual stresses still present after a few minutes at the temperatures favorable to parting, at least with initial stresses up to 28,000 psi, have shown that such residual stresses may be fairly high but probably not high enough to cause the parting. Higher

residual stresses may be present when the initial internal stresses are greater. Total stresses adequate to cause parting can be accounted for, by assuming that, when this type of failure does occur, the residual stresses are supplemented by thermal stresses from uneven expansion.

The tests have shown the importance of grain size, since both the tendency toward intergranular parting and the tendency toward slow relief of stress are increased with increasing grain size.

The comparative rarity of occurrence of intergranular parting suggests that extreme variations of some of the factors contributing to it, or a fortuitous combination of several of them, must be necessary. Very high internal stresses can be sustained by heavily worked brass; the extent and persistence of thermal stresses can vary according to the type of heating and furnace construction; the rate of heating can be very rapid, minimizing stress relief and increasing thermal stresses; grain sizes may be particularly large especially in heavy gauge material, which is more susceptible to uneven thermal expansion and in which, as a matter of fact, most examples of intergranular parting are found.

Corroboration of the conclusions drawn from this work can be found in practical solutions to commercial fabrication problems, based on this explanation for the cause of intergranular parting. For example, in the early stages of fabrication of large seamless 85/15 brass tubing, intergranular parting at the shoulders of large cups can be caused, or eliminated, depending upon the position of the cups during annealing. With the open face up, the inside surface of the cup is heated most rapidly and

transfers tensile stresses to the outside. These add to the internal stresses already present at the shoulder, and frequently cause cracking. If the cup is placed bottom up on the pan, the outside surface is heated first, and the residual tensile stress at the shoulder tends to be relieved by the thermal expansion of the metal so that no cracking occurs. This evidence suggests that parting can be caused solely by the effect of stress at an elevated temperature. The possibility that compositional or precipitation effects may be contributory is not denied, but they alone are not adequate to cause parting.

The tendency toward intergranular parting can be minimized by: 1. Minimizing internal stress left by cold working. 2. Keeping the grain size down. 3. Providing for uniform heating. 4. Heating slowly enough to permit some stress relief before cracking temperatures are reached. 5. Placing the work in the furnace in such fashion that surfaces known to be internally stressed in tension reach temperature first.

The finding of cracks in the heads of 3 in., 50 caliber cartridge cases made from hot-rolled 70/30 brass has recently been reported by Arnold.¹⁷ The report lacks sufficient detail to indicate whether or not the factors discussed in this paper are responsible, but it is suggested that the results of this research should be considered in that connection.

Acknowledgment

The authors wish to express their thanks to Mr. J. R. Freeman, Jr., Technical Manager of The American Brass Co., for his interest in and encouragement of this research, and to the Company itself for permission to publish. The assistance of Mr. J. J. Breen, who carried out many of the tests, is also gratefully acknowledged.

A Proposed Microbending Mechanism of Plastic Deformation*

M. K. YEN,[†] Junior Member AIME

The distortion of crystal structures referred to as "biege gleitung",¹ "local curvature"²⁻⁴ and "deformation bands"^{5,6} is believed to be an unavoidable characteristic of deformed single crystals. The presence of asterism on Laue photograms of Al single crystals either deformed by pure shear⁷ or extended in a condition relatively free from the grip effect² indicates strong evidence substantiating this point of view. The type of localized bending described in connection with the bending test of Al single crystals by Yen and Hibbard⁸ could conceivably exist either microscopically or submicroscopically in all types of deformation. The purpose of this note is to extend this idea to the postulate of a hypothetical "microbending site," as applied to the mechanism of slip in a general sense.

The mosaic structure, as postulated by Darwin,⁹ is that crystals were actually composed of small blocks which have a linear dimension 10^{-4} to 10^{-6} cm on the edge and deviate from each other by an angle of about one-tenth of a degree. The following discussion is based on the assumption

that when slip is propagated from one mosaic block to the adjacent one, bending of the lattice at the region of their boundary is produced in order to maintain the continuity of the gliding process along a certain slip plane.

Consider a two-dimensional diagram of two ideal mosaic blocks on the cross-section perpendicular to the slip plane and containing the active direction of slip. When an external force is applied, the localized bending or "microbending site," would be generated at the region as illustrated in Fig 1A at point B.

A schematic diagram of a "microbending site," generated at a mosaic boundary, is illustrated in Fig 1B. It may be seen that once the curvature

of the bending site reaches sufficient magnitude, the interaction force encountered by pairs of atoms symmetrical with respect to the center of the bending is equal but opposite in sign. Consequently, the overall energy required to displace the atoms near the center is approximately zero.¹⁰⁻¹²

Based upon the finding that the misalignment between two mosaics is 0.1 degree,⁹ the assumption is made that "microbending sites" may possibly exist in the region where one plane will have one more row of atoms than an adjacent plane. It is probable that the origin of the bending site will be where the distance between two mosaic boundaries is " $2d$ " as shown in Fig 1A at point B, where " d " is the interatomic distance. Thus, the distance between two "microbending sites" is in the range of about 600 interplanar spacings. In the case of aluminum, the spacing between two octahedral planes is about 2.33 Å. The distance between two bending sites will be approximately 2.5×10^{-5} cm. It is interesting to note that according to Woods¹³ these values approach closely the size of the domains of a cold-worked metal whose minimum

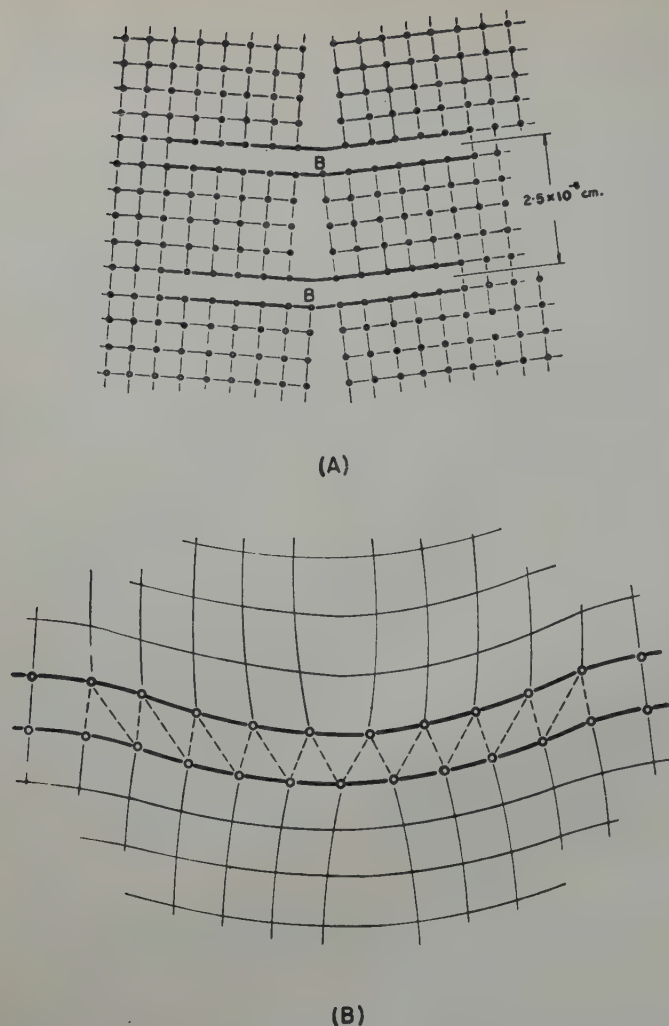

FIG 1—Schematic diagrams showing "microbending sites."

dimension should be about 10^{-6} cm.

Since different mosaic blocks in a crystal may bear various angular relationships with neighboring ones, the "microbending sites" could be classified into two types. The one with the concave side upward as shown in Fig 1B is designated as the concave type and the other with the convex side upward as the convex type. A greater interference would be exerted between a concave and a convex bending site, one immediately above the other, than two similar ones, because of the distortion produced in the adjacent lattice. The interaction force between two "microbending sites" of opposite curvature may be either attractive or repulsive, depending upon their relative position to each other. For instance, if two "microbending sites" have both concave sides opposite to each other, the tensile strain in the lattice between them would have a tendency to pull them together. If two bending sites have both convex sides opposite to each other, the interaction force becomes a repulsive one.

However, both of these two arrangements can be considered to be responsible for the strain-hardening effect in plastically deformed crystals.

One of the essential features of the mechanism proposed here is that the slip process is based upon the idea that slip starts at those planes where the location of "microbending sites" happens to be close enough to form a sub-microscopically wavy layer which is composed of a number of curved surfaces each having a low resistance to shear. As soon as the external force reaches this magnitude, slip takes place along the slip direction in the manner of a sequence of local processes. The time required from the generation of the "microbending site" to the commencement of slip appears to be the same as the incubation period in the nucleation theory recently proposed.^{14,15} It may be seen that once slip commences, the distortion produced in the adjacent lattice may destroy the regular pattern of the "microbending sites." This results in the phenomenon of strain-hardening

which tends to prevent further gliding along the same plane. If, however, the external stress increases sufficiently to overcome the barriers between "microbending sites" which have relatively large misalignment at the ends, new slip markings between the old ones are produced.

In Fig. 1B only a two-dimensional "microbending site" is illustrated. Since this may be out of registry along the direction perpendicular to the paper, a type of distortion by bending about an axis parallel to the paper would be required to provide the continuity of the slip process. If, however, a second set of slip planes becomes active, it is conceivable that strain-hardening of latent slip plane would always exceed that of the operative ones in order to pass through the highly distorted lattice and to initiate slip.

In summary, "microbending sites" may be described as atomistically dislocated local curvatures which act as nuclei for the slip process. Thus, the mechanism for plastic deformation in crystals could be interpreted in accordance with the theory of local curvature,¹⁻⁴ the theory of dislocation¹⁰⁻¹² and the theory of nucleation.^{14,15}

The Low Temperature Properties of Tin-antimony and Tin-cadmium Alloys*

F. J. DUNKERLEY,[†] Junior Member, H. B. HUNTER[‡] and F. G. STONE,[§] Junior Member AIME

Introduction and Literature Survey

This is the second in a series of papers coming from this laboratory on the correlation of the low temperature tensile properties of tin-binary alloys with microstructure. These engineering data and those of the previous paper¹ were obtained as the initial part of a long-range program to determine the changes in the fundamental mechanical properties accompanying the beta to alpha phase change in tin and its binary alloys below 13.2°C. Since it appears now that the more fundamental studies will be delayed,* and since no summary of the low temperature properties of these tin-base white bearing alloys was found in the literature, it was decided to publish all the engineering data thus far obtained. Accordingly, the tensile properties of thirteen binary alloys containing from 0.1 to 60 pct cadmium and 0.1 to 10.43 pct antimony measured at six temperatures from -196 to +23°C are presented here and their variations rationalized in terms of microstructure.

A literature search showed that these systems had not been investigated at low temperatures, although both the tin-cadmium and tin-antimony^{2,3,4,5}

and the tin-rich corner of the ternary system^{6,7} have been studied at room temperature. Hanson and Pell-Walpole⁵ and Homer and Plummer⁴ determined the tensile properties of alloys containing from 0 to 10 pct cadmium. The same authors³ determined the

tensile strength and elongation in the tin-antimony system from 2 to 18 pct antimony at room temperature while Pell-Walpole et al.^{6,7} studied the properties of high tin and tin-antimony-cadmium alloys. Since there were many variables besides composition in these tests, it was difficult to make a valid comparison with the room temperature data of the present study, but in general the tensile strength and ductility values are in reasonable agreement.

Pell-Walpole² also determined the effect of grain size on the tensile strength of pure tin and 1 pct alloys of both antimony and cadmium. The true maximum stress was found to decrease exponentially as the number of grains in the cross-section increased. This effect of grain size was strikingly revealed in the present work, as indicated in a later section.

Hanson and Pell-Walpole⁸ placed the solid solubility limit of antimony in tin at 3.5 pct at 20°C, increasing to 4 pct at 190°C, and then sharply increasing to 10.3 pct at 246°C (the latter being a peritectic point). Their results are in disagreement with those of previous investigators,⁹ and the discrepancy seems to lie in the microscopic observation of the second phase

New York Meeting, February 1950. TP 2723 E. Discussion of this paper (2 copies) may be sent to *Transactions AIME* before April 1, 1949. Discussion is tentatively scheduled for publication in November 1950. Manuscript received June 1, 1949.

Etched in 8 parts glycerine, 1 part acetic acid, 1 part nitric. 100 X. Reduced one third in reproduction.

SbSn. This is ordinarily seen as large cuboids first appearing at about 9 pct antimony, but Hanson and Pell-Walpole showed that it also appears as a fine precipitate, preferentially along the grain boundaries, in compositions as low as 3.5 pct. They employed thermal analysis, resistance measurements and micrographic methods, and the results seem quite conclusive.

The same authors,^{5,9,10} investigating the tin-cadmium system, found the room temperature solid solubility limit at 1.0 pct and this limit remained essentially constant to 133°C, the temperature of the eutectoid transformation.

In the present investigation, the equilibrium diagrams of Hanson and Pell-Walpole for both systems have been accepted as conclusive, since they are the most recent and the most

comprehensive. Moreover, the limited metallographic study carried out here for purposes of correlating microstructure and tensile properties, confirmed their findings.

Materials and Methods

PURITY AND PREPARATION OF ALLOYS

The tin was the same grade (99.9965 pct pure) used in the early investigation.¹ The antimony metal was Mallinckrodt reagent quality in crushed granular form and was 99.84 pct pure. Cadmium metal of 99.97 pct purity was obtained in the form of $\frac{3}{8}$ in. rods from the American Smelting and Refining Co.

Using the melting procedure previ-

ously described,¹ tin-cadmium alloys containing 0.092, 0.26, 0.90, 2.65, 10.0, 20.0, 33.0, 60.0 pct cadmium, and antimony alloys containing 0.0, 0.31, 1.11, 3.38 and 10.43 pct antimony were melted and cast tensile bars, 0.25 in. in diam and 1 in. in gauge length, were prepared. Chemical analyses were made on all compositions, antimony and cadmium contents being determined spectrographically, while wet analytical methods were used for the higher values. Spot checks on the finished test specimens showed that iron, in amounts of 0.005 pct, was the greatest impurity.

HEAT TREATMENT AND MICROSTRUCTURE

Heat treatments to provide a variety of microstructures were possible with

FIG 2—The effect of temperature on the tensile properties of pure tin.

FIG 3—The tensile strength from -195°C to 23°C of tin-antimony alloys containing 0.1 to 10.43 pct antimony.

these alloys, but a structure stable at room temperature was selected as most desirable for these studies. Consequently, the bars were annealed at a temperature such that, in cooling down to room temperature, no phase change

and only slight changes in solubility would occur. Homogenizing anneals of 150 hr at 190°C for the antimony alloys and 350 hr at 120°C for the cadmium alloys, while immersed in silicone oil, fulfilled these conditions. For con-

venience, all compositions of the respective systems were heat treated at the same temperature, since this did not violate the above imposed conditions. After the homogenization, the bars were slowly cooled in the furnace

FIG 4—The effect of various temperatures on the reduction in area for tin-antimony alloys containing from 0.1 to 10.43 pct antimony.

FIG 5—The percent elongation in one inch from -195°C to 23°C for tin-antimony alloys containing from 0.1 to 10.43 pct antimony.

to room temperature.

Fig 1a shows the typical cast structure with pronounced coring obtained in the 3.38 pct antimony alloy. The structure after homogenization at 150 hr at 190°C is shown in Fig 1b. Attention is called to the definite grain boundary constituent appearing in Fig 1b. This evidence substantiates the findings of Hanson and Pell-Walpole who placed the solubility limit at 3.5 pct. These authors noted a definite tendency for the second phase to appear at grain boundaries, and Fig 1c, representing an alloy of 10.43 pct antimony, clearly shows the presence of the compound SbSn in the form of cubic crystals in the grain boundaries.

It should be noted here that a more complete metallographic investigation would have been desirable to supplement existing knowledge concerning solid-solubility limits, distribution of

second phases, and others, but the limited studies reported here were considered sufficient for purposes of this research. Fig 1d shows the microstructure of the 2.65 pct cadmium alloy in the homogenized condition. The eutectic structure is evident in Fig 1d, and it is clear that the solubility limit (1 pct) has been exceeded. This alloy undergoes a peritectic reaction at 223°C , and the resulting beta structure is stable down to 133°C . However, this reaction is easily suppressed by rapid cooling,¹⁰ so that the eutectic of Fig 1d is believed to be present in nearly the equilibrium amount. Special attention is called to the dispersion of fine material throughout the grains in this 2.65 pct cadmium alloy. Whether this represents a small amount of the now metastable β phase, or whether the particles are γ which has transformed *in situ* from the β and perhaps slightly

agglomerated, is an interesting question and one which could not be further investigated here. The authors are inclined to the latter opinion, since the long homogenizing treatment (350 hr) is believed to represent a close approach to structural equilibrium.

Fig 1e, f, g and h show typical microstructures of the 10, 20, 33 and 60 pct cadmium alloys. Before discussing the individual structures, it will be noted that in all four compositions, the α or continuous phase is much finer grained than in the lower cadmium alloys. As will be explained in the discussion of results, and mentioned later in this section, this is an important factor to be considered in the interpretation of the tensile data.

The structure of the 10 pct cadmium alloy (Fig 1e) is seen to be two phase with the γ phase forming an almost continuous grain boundary envelope

FIG 6—Variation of T_B , T_M , and the maximum tensile strength at T_M , with composition.

FIG 7—The effect at various temperatures of composition on the ultimate tensile strength of tin-antimony alloys containing from 0.1 to 10 pct antimony.

about the predominant α matrix. The α phase of the 20 pct alloy (Fig 1f), on the other hand, is even finer grained than that in the 10 pct alloy, and is composed of a network of both fine and agglomerated γ phase enclosing the white α phase. In both these alloys, homogenization has caused extensive agglomeration, as indicated by the presence of large intergranular black particles along with the finer spheroidized grain-boundary precipitate also present. The eutectic alloy containing 33 pct cadmium, Fig 1g, is seen to contain even more of the black γ phase uniformly dispersed along with the finer γ spheroids in the α matrix. Fig 1g shows the very interesting microstructure of the 60 pct cadmium

alloy. Here the large massive particles are primary γ , which appeared as massive dendrites in the cast structure. Homogenization has broken up these dendrites into very large particles of γ , although the distribution of the phase has been altered little from that in the cast structure. Also the lamellar structure lying between the γ dendrites in the cast alloy has been completely spheroidized and appears as a fine precipitate in the white α matrix.

The influence of grain size on tensile properties has been investigated by other workers who used the total number of grains in the specimen cross-section as a variable.² For normal fine grain sizes, the effect is not significant, but tensile properties are considerably

influenced when the cross-section of the bar represents only a few grains. Since the base metal tin has a recrystallization temperature below room temperature for ordinary amounts of plastic strain, grain growth during the homogenizing anneal is possible. In the present case, however, both alloying elements raised the recrystallization temperature sufficiently so that no troublesome grain growth was encountered except in the 0.1 and 0.3 pct antimony alloys. Here the cross-section of the bar may frequently have contained only two or three grains, but in no case was a monocrystalline, chisel-type fracture obtained. The pronounced grain refining effect of cadmium on the cast structure resulted in extremely fine

FIG 8—The effect at various temperatures of composition on the ultimate tensile strength of tin-antimony alloys containing from 0.1 to 10 pct antimony.

grain sizes in most of the cadmium alloys, especially those containing more than 3 pct cadmium.

TESTING METHODS

Complete details of test specimen and testing procedure were those described in Ref. 1, except that isopentane was used for the immersion liquid for temperatures near -155°C . The strain rate was maintained at 0.2 iipm for all tests, and testing temperatures were held to $\pm 0.4^{\circ}\text{C}$. The deviation of the measured load, using the weigh bar, was ± 1.0 lb or ± 0.05 pct at the highest load in all cases when the ductility was sufficient to allow ample time to balance the strain indicator. The elongation and reduction of area data represent the usual degree of accuracy attained in tensile testing, except that with coarse-grained fractures, the reduction of area is somewhat less accurate because of the difficulty in accurately measuring the final diameter.

As in the tin-lead studies¹ tensile specimens, 0.25 diam with 1-in. ga length, were tested either in duplicate or triplicate at each temperature and the results are summarized below in graphical form. In the event of considerable discrepancy between the duplicates, or if the fractured surface showed casting defects, a third test was made in nearly all cases.

Discussion of Results

The data obtained in this investigation are presented graphically in Fig 3, 4, 5, 9, 10, and 11, the tensile strength

being plotted in various ways as functions of both temperature and composition. The pertinent data reported here include ultimate tensile strength, per cent elongation in a one inch gauge length, and per cent reduction in area. The values of true maximum stress were calculated for a few bars, but because of the experimental errors in the measurement of the true area and the doubtful accuracy of the breaking load values, no coherent data were obtained. Also, yield data are not reported because neither the "weigh bar," "drop-of-the-beam" or offset methods gave reproducible values.

In previous studies,¹ the low temperature tensile properties of pure tin were rationalized in terms of the effect of decreasing temperature on (1) the critical flow stress, (2) the extent or amount of cold work, and (3) the technical cohesive strength (true fracture stress at nil cold work). It is believed that a similar analysis can be made in the case of these data, with the stipulation, as given earlier, that when two or more phases are present in alloys, the measured tensile properties will be the net result of these three factors operating simultaneously on the separate phases. Thus the relative amount, form and distribution of the phases present will influence the magnitude of the net temperature effects. Also, since pure white tin is metastable below 13.2°C , all the tests except those at room temperature are subject to possible effects of the α (white) to β (grey) transformation. It is known that rolling, bending or drawing enormously increases the velocity of transformation at -50°C , the velocity being proportional to the intensity of deformation.¹¹

In general, alloying elements are known to retard the transformation velocity but their effect on the equilibrium has never been determined. Both the kinetics and phase equilibria are being studied in this laboratory as major research problems; but until these data are available, it cannot be stated whether or not the present series of alloys were in a metastable condition when tested. However, in over 125 tests at sub-zero temperatures some of which lasted 15 min. or more, no visual evidence of the transformation from white to grey tin was observed, and it will therefore be eliminated as a variable.

As in the earlier work,¹ certain terms used in this discussion will be defined so that their use in this discussion will be clearly understood. Reduction in area, rather than elongation, will be used exclusively as the measure of ductility; temperature of embrittlement, T_B , is defined as the temperature at which 50 pct of maximum ductility, that is, 50 pct of maximum reduction in area, occurs in the given alloy. Temperature of maximum ultimate tensile strength, T_M , is self-defining. Technical cohesive strength is used here as the fracture stress at nil cold work. The critical flow stress is defined as the applied stress required to start flow.

To make this an integral report, a summary of the previous explanation of the pure tin properties will be given. For this purpose, Fig 2 containing the tensile properties of pure tin as a function of temperature from -195 to $+23^{\circ}\text{C}$ has been reproduced here. It has been postulated that for pure tin fracture at temperatures down to -125°C occurred principally by flow, since 100 pct of the ductility remained

FIG 9—The effect of temperatures on the ultimate tensile strength of tin cadmium alloys containing from 0 to 60 pct cadmium.

at that temperature. Down to -60°C , the rapid increase in tensile strength was caused partially from the increase of the flow stress with decreasing temperature, but principally from the increasing contribution of the work hardening, as evidenced by the increase in elongation to a maximum at this temperature. Below -60°C the amount of work hardening decreased and the critical flow stress, increasing as the temperature decreased, became the main component of the tensile strength. At -130°C as the ductility (R.A.) began falling off and approached 50 pct R.A., failure in tension occurred half by cleavage and half by flow, and the metal could then be considered brittle. At this point, work hardening was still contributing to the cleavage stress because considerable ductility still remained. However, as the ductility fell off, the contribution of the flow stress correspondingly decreased until failure occurred principally by cleavage. Finally, as the ductility decreased the cleavage stress simultaneously decreased and approached the true fracture stress at nil cold work.

An examination of the tensile data at the various subatmospheric temperatures for both the tin-antimony and tin-cadmium alloys indicates that the same three fundamental factors operating in the case of pure tin may also be responsible for the various alloy

properties. Of course, certain differences between the alloys and pure tin do exist, and these will be pointed out as the specific data for each system are considered. However, as in the case of the tin-lead alloys,¹ it will be assumed that because of the graphical analogies, the measured temperature effects on the properties of the alloys differ from those of pure tin only in degree. Hence the main emphasis in the following discussion will be placed on the correlation of the tensile data with composition and the explanation of these relations on the basis of microstructure.

The data for both binary systems have been presented graphically in various ways, as were the tin-lead data, in order to reveal pertinent relationships. These include (1) plots of tensile, elongation, and reduction in area or ductility values versus temperature, (2) T_B , T_M vs. composition and maximum tensile strength vs. composition, the latter on a logarithmic scale, (3) tensile strength at each of the six test temperatures vs. log composition, and (4) for the tin-cadmium series only, log of tensile strength at each temperature level vs. composition on a linear scale.

For ease of reading, the same sequence as was followed in the earlier discussion will be adhered to here. That is, relationships between composition and tensile strength will be brought out by appropriate crossplots of the

data, and with the aid of these, the influence of composition on (1) the temperature of maximum tensile strength T_M , (2) the temperature of embrittlement T_B , (3) the maximum tensile strength at T_M , and (4) the tensile strength at the six testing temperatures will be described. A rationalization of these four specific composition-property relations in terms of the microstructures of the alloys will then be discussed in the indicated order.

TIN-ANTIMONY ALLOYS

It will be noted in Fig 3 that, for the tin-antimony alloys, increasing amounts of the second phase, that is, brittle β (SbSn) phase, has caused definite differences in the magnitude of the changes in tensile properties with decreasing temperature. On the other hand, the only significant difference between the shape of these curves and that for pure tin is that below -160°C , where nil ductility is possessed by both pure tin or the tin-antimony alloys, the fracture stress increased with decreasing temperature for the 3 and 10 pct antimony alloys. This was also observed in the case of the 50-50 tin-lead alloys¹ as well as other metals, and further confirms the postulate that the fracture stress of metals in general increases with decreasing temperature.

Examination of the tensile data presented in Fig 3 shows that additions of 2.5 pct antimony and less had no measurable effect on the temperature of maximum tensile strength, T_M , or on the temperature of embrittlement, T_B . The higher antimony additions, however, definitely affected T_M and T_B , and these effects are obvious in Fig 6. Here it is seen that T_M and T_B are not synonymous in these alloys, the maximum difference being as much as 25°C for some alloys. As in the earlier work,¹ it is believed this difference is a result of the interaction of the three fundamental factors acting simultaneously either on the solid solutions of varying composition, or on the two phases present in some of the alloys.

In Fig 6 it can be seen that T_M remains essentially constant up through

3.38 pct antimony while T_B is consistently 25°C lower through 1 pct antimony. Then above 3.38 pct antimony for T_M and 1 pct for T_B , a rapid rise occurs, with T_B rising above T_M by from 10 to 15°C until at about 10 pct antimony they become synonymous. The maximum ultimate tensile strength (at T_M) increases exponentially with increased antimony, as shown by the straight line relationship of the tensile strength at T_M vs. the logarithm of the composition (wt pct antimony). Variations of the tensile strength with composition at the six test temperatures is also of interest and is shown in Fig 7 and 8. Above T_B , additions of antimony up to about 2 pct had only a slight strengthening effect, but 3 pct antimony and higher caused an abrupt rise in the strength. These data for each

temperature seem to be represented satisfactorily by two straight lines intersecting between 2.2 and 2.8 pct antimony. At -115°C, additions of antimony up to about 1.8 pct have a strengthening effect but further additions had no apparent effect on the tensile strength. Below T_B , antimony contents up to 2 pct either decreased the strength slightly, as at -155°C, Fig 8, or have little or no effect, as at -196°C. Between 2.3 and 2.5 pct antimony, a sharp break in the curve is seen, with further additions of antimony causing a pronounced increase in strength.

These data and the various relationships between composition and tensile strength can be rationalized quite satisfactorily in terms of the heterogeneous microstructures developed in these alloys. Antimony additions up to about 2.5 pct did not affect T_M or T_B appreciably because the antimony remained in solid solution in tin. As mentioned earlier, the solid solubility of antimony in tin at room temperature has been reported recently as 3.5 pct by Hanson and Pell-Walpole.¹² However, the sharp break in the tensile strength vs. composition curves shown in Fig 7 and 8 may be interpreted as evidence that the solid solubility at 20°C lies between 2.2 and 2.8 pct antimony. The following explanation is thus offered: Antimony up to 2.2 pct had no effect on T_M or T_B because the alloys in this composition range were single phase. In this solid solution range, however, solution of antimony in the parent tin lattice formed a substitutional solid solution and strengthened the alloy in direct proportion to the percent antimony added at temperatures above T_B . Thus the maximum tensile strength and the ultimate tensile strength at and above -115°C increase with increased antimony. On the other hand, at -155°C and -196°C antimony in the solid solution range either decreases the tensile strength or has only a slight effect. Since both these temperatures are below T_B , the alloys in this composition range possess no measurable ductility and the observed tensile strength plotted in Fig 8 is really the true fracture stress of the alloys. These data thus indicate that antimony atoms, corresponding to 2 pct antimony or less, dissolved substitutionally in tin either slightly decrease or have little or no effect on their true fracture stress at temperatures below T_B .

Between 2.2 and 2.8 pct antimony, particles of β phase (SbSn) precipitated preferentially at the grain boundaries

FIG 10—The effect of temperature on the reduction in area for tin-cadmium alloys.

FIG 11—The percent elongation in one inch as a function of temperature for the cadmium alloys containing from 0 to 60 pct cadmium.

FIG 12—Variation of temperature of maximum tensile strength, T_M , temperature of embrittlement, T_B , and tensile strength at T_M with composition.

and this would be expected to cause precipitation hardening. The closest composition to this range included in this survey was a 3.38 pct alloy, and as seen in Fig 1b, this alloy was found to contain a grain boundary constituent, which was presumed to be particles of β phase. Property-wise, this was reflected by a slight rise in T_M and T_B , for here the β particles were either large or numerous enough to facilitate slip. However, the particles had not exceeded the critical particle size for hardening because the maximum tensile strength and the tensile strength above T_B , for this alloy, were higher than for the lower alloys. At the same time, at -115°C the fact that the 3.38 pct alloy had no higher tensile strength than the 1.1 pct alloy at first appears anomalous. This is to be expected, however, since -115°C is between T_B and T_M . The continuous α (tin-rich) phase is of course predominant and is believed to determine the properties of this alloy. These results mean, then, that the true fracture stress of the α tin-rich phase is the major remaining component of the tensile strength and in this case it is no higher than the combined critical flow stress, fracture stress and work hardening contribution making up the tensile strength of the lower solid solution alloys. Similarly the same explanation is offered to account for the ultimate tensile strength values obtained at -155 and -196°C .

In the 10.38 pct alloy, the β particles were considerably larger and more numerous, appearing intragranularly as

well as in the grain boundaries. These large brittle particles of β in the grain boundaries acted as discontinuities and consequently T_M and T_B increased abruptly. At the same time, sufficient intragranular precipitation occurred to cause the maximum tensile strength to increase. Above T_B the ultimate tensile strength also increased rapidly, presumably because as seen in Fig 4 and 5, considerable ductility remained so that critical flow stress and work hardening of both the continuous α tin phase and discontinuous β phase was appreciably higher than that for the lower alloys. That the true fracture stress at this temperature remains small is indicated by the fact that at the lower tempera-

ture of -115°C , that is, 50°C below T_B for this alloy, the net tensile strength, being essentially the true fracture stress (only 2 pct ductility remaining), is still equal only to the strength of the 3.38 pct alloy. Continuing this line of reasoning, at -155 and -196°C , the tensile strength increased appreciably because the fracture stress markedly increased with decreasing temperature. It is significant to note that the 10.38 pct antimony alloy was about 2500 psi stronger at -196°C than at -155°C , in further confirmation of the negative temperature coefficient of the true fracture stress.

Thus the variations with composition of T_M , T_B , the maximum tensile strength at T_M , and the ultimate tensile strength at subatmospheric temperatures as low as -196°C can be rationalized in a straightforward and logical manner in terms of the microstructure developed in the alloys. It is hoped that more fundamental data, such as true-stress strain measurements, yield data, tensile properties of variously strained alloys, creep data, and other information may soon be available to test the basic reasoning and perhaps separate the several variables used here necessarily in a qualitative way. Extension of this work to higher antimony alloys would be very desirable, especially from the fundamental standpoint. Extrapolation of the curves of Fig 6 indicates that T_M and T_B for the single phase β alloy (45 pct antimony) should be approximately $+20^\circ\text{C}$, and its maximum tensile strength should be about 16,500 psi. These predictions were confirmed in

FIG 13—The effect at various temperatures of composition on the ultimate tensile strength of tin-cadmium alloys.

part when a 30 pct alloy was found to be brittle at about 0°C. However, since sound castings of this and higher compositions proved difficult to prepare, sufficient specimens were not available for these initial studies.

TIN-CADMIUM ALLOYS

The tensile data for the tin-cadmium alloys containing from 0.01 to 60 pct cadmium are summarized graphically in Fig 9 to 11. Also, the curves for pure tin are superimposed on these for the tin-cadmium alloys for comparison purposes. As indicated above, a comparison of the tin-cadmium alloy curves with pure tin shows they are all similar in shape, except, of course, the magnitude of the effect of decreasing temperature on the tensile properties varies with the composition.

It will be noted first that the maximum in the tensile strength vs. temperature curve of Fig 9 for the alloys containing from 0.1 to 2.65 pct cadmium occurs at -115°C , which is about 25°C higher than that for pure tin. Alloys containing from 10 to 60 pct cadmium appear to form another family of curves with the maximum at -155°C . This apparent demarcation of the curves into two families with maxima from 35 to 40°C apart first appears to be anomalous, but it is believed to be caused by grain size differences rather than an effect of composition changes. The first four cadmium alloys were cast into slightly hotter molds than were the pure tin and the four higher cadmium alloys. Consequently, the grain size of the latter four alloys and tin was much finer and this not only shifted the maxima in tensile strength to a lower temperature, but raised the entire level of each tensile strength vs. temperature curve. Cursory microscopic examination confirmed this reasoning, but considerably more experimental work than was possible to include in this investigation would be required to establish more specifically the effect of grain size on low temperature tensile properties.

This effect must be considered to explain the data plotted in Fig 12 which shows the relation between T_M , T_B , maximum tensile strength and composition. Two separate curves have been drawn for the T_M vs. composition data in line with the reasoning that the grain size of the four lower alloys was considerably larger than that of the four with higher cadmium contents. The effect of grain size, however, on the ductility and T_B of the eight alloys was

FIG 14—The effect of composition on the ultimate tensile strength of tin cadmium alloys at -155°C and -195°C .

not as pronounced as that on T_M . Composition had no apparent effect on T_M through 2.65 pct cadmium. Variation of the cadmium content from 10 to 60 pct, on the other hand, decreased T_M slightly. T_B follows a similar trend to that of the tin-lead¹ and tin-antimony alloys. Although the T_B vs. log of cadmium composition curve theoretically could only approach -140°C , that is, T_B for pure tin at $-\infty$ (since $\log 0$ is $-\infty$), an approximate extrapolation is pertinent to show that the first additions of cadmium up to 0.1 pct had little or no effect on T_B . T_B then increased steadily for the 0.26 and 0.90 pct alloys to a maximum between 1.0 and 2.65 pct cadmium followed by an abrupt decrease for the 10 to 60 pct alloys. A value for T_B constant within $\pm 5^{\circ}\text{C}$ for pure tin was then approached. Finally an extremely low value for the eutectic 33 pct alloy was obtained. The maximum tensile strength at T_M increased uniformly over the entire composition range from 0.1 to 60 pct cadmium, the data following a straight line relationship quite well. The isothermal tensile strength-composition data plotted in Fig 13 and 14 show that above T_B , the tensile strength increases as the cadmium content increases, the curve approaching maxima at about 10 pct cadmium and either decreasing slightly or remaining constant for the 20, 33 and 60 pct cadmium compositions. At -115°C , pronounced strengthening from cadmium additions continues and obeys a straight line relationship until a maximum is reached at 33 pct fol-

lowed by a decrease in strength for the 60 pct alloy. Below T_B , that is, at -155 and -196°C , however, additions of cadmium up to 1 pct have only a slight strengthening effect. Then a sharp break occurs at the 1 pct composition level, with further additions causing very marked increases in tensile strength to either approach or attain maxima at from 33 to 60 pct cadmium. As in the case of the tin-lead¹ and tin-antimony systems, this break in the tensile strength vs. log composition below T_B corresponds with the terminal solid solution limit of cadmium in tin, and is taken as confirmation of this 10 pct solid solubility of cadmium in tin reported by Hanson and Pell-Walpole.⁵ Further, if the tensile data for temperatures above T_B are replotted with the tensile strength on a logarithmic scale, a very definite break in the curves occurs at about 1 pct cadmium, Fig 15. These data are also considered to confirm the 1 pct cadmium solid solubility in tin. It is undoubtedly significant that two distinctly different relationships between tensile strength and composition are obeyed for above and below T_B respectively, but without additional fundamental data it can only be speculated that this difference is related to the fact that the fundamental process operating above T_B is cleavage by flow, whereas below T_B , failure occurs principally by fracture. At any rate, having confirmed the most recent tin-cadmium phase diagram reported in the literature,⁵ the following correlation of low temperature tensile properties and

FIG 15—The ultimate tensile strength for various temperatures as a function of composition in the range from 0 to 10 pct cadmium.

microstructure is offered. All the data and relationship revealed by various graphical treatments will be considered except T_M vs. composition curve since, because of grain size effects, it is somewhat anomalous.

The first additions of cadmium (up to 0.1 pct) had no effect on T_B , however, because the substitutional cadmium atoms were too few to change the flow-fracture properties of the resulting solid solution from those of the pure tin. Increasing numbers of cadmium atoms, however, corresponding to 0.26 and 0.9 pct cadmium distorted the parent tin lattice increasingly, so that cleavage by flow was facilitated and T_B increased. The tensile strength at T_M also increased continuously in this composition range, presumably because increased numbers of cadmium atoms dissolved substitutionally increased the critical flow stress and work-hardening contribution of these homogeneous solid solutions. The tensile strengths of these alloys above T_B also increased progressively for the same reason. Below T_B , however, increasing cadmium up to 0.9 pct had only a slight strengthening effect, indicating that dilution of the tin-rich matrix with substitutional cadmium atoms did not appreciably influence the true fracture stress values of the various alloys.

At 1.0 pct cadmium, however, a fine precipitate of γ phase began appearing preferentially at the grain boundaries, slip was thus facilitated and T_B in-

creased to a maximum between 1 and 3 pct cadmium. The maximum tensile strength continued to increase, however, probably because of precipitation hardening and because the fracture stress of the γ phase, occurring both inter- and intragranularly in the 2.65 pct alloy, was sufficient to supplement the composite flow, work hardening, and fracture stress of the continuous tin phase. The tensile strength above T_B continued to increase in the range from 0.1 to 3 pct cadmium, probably because of precipitation hardening. At -155 and -196°C , however, or below T_B , the increase in tensile strength must be attributed to the higher combined fracture strengths of the precipitated γ and the continuous α phases. It is significant to note that as T_B is more nearly approached or exceeded, the slopes of the curves of Fig 13 increase in the 0.1 to 3 pct cadmium range. This can be interpreted as indicating that the technical cohesive strength component of the net tensile strength is increasing and becoming more predominant with decreasing temperature. Ultimately, the tensile strengths at -155 and -196°C are the true fracture strengths, since no ductility remains at these low temperatures.

As the composition reached and exceeded 2.65 pct cadmium, the intergranular γ precipitate increased in amount so that flow was facilitated in this phase as well as the α phase and thence T_B decreased to a constant

value of about -134°C at the 10 pct cadmium level. The maximum tensile strength increased in the 2.65 to 10 pct cadmium range probably because the γ phase was uniformly distributed and the critical flow stress and work-hardening of the two-phase alloy increased with increasing amounts of γ phase. The tensile strengths at $+23$ and -30 were also improved because both the α and β phases had higher critical flow stresses and were strengthened by work hardening to give higher tensile strengths with increasing cadmium contents. At -70°C , however, the γ phase, appearing in increasing amounts in the 2.65 to 10 pct range to form a grain boundary envelope, was probably brittle and the tensile strength of the alloy was thus determined by the strength of the continuous tin phase. Since the composition of this α tin phase remains essentially constant, its strength remained constant as shown by the fact that the tensile strength of the nominal 2.65 and 10 pct cadmium alloys is essentially constant. At -115°C , the fracture stress of the intergranular γ phase increased, so that the net tensile strength of the 10 pct alloys is higher, and this strengthening, caused by the increase of the fracture stress of both the α and γ phases, increased in degree as the temperature decreased. This accounts for the increasing slopes of the tensile strength vs. log composition curves as the temperature decreased.

In the 20 and 33 pct alloys, the γ phase was agglomerated into quite massive particles which probably became brittle before the continuous α phase, as suggested above. Thus since the composition of the α phase remained constant in the 10–20 and 33 pct alloys T_B also remained constant. The maximum tensile strength, however, did continue to increase, presumably because the fracture stress of the increasing γ phase contributed appreciably, that is, corresponding to the amount of γ present. The tensile strength at $+23$, -30 and -70 remains essentially constant in the 10 to 33 pct composition range, either (1) because the massive γ phase is brittle and its fracture stress at all these temperatures is low so that the tensile strength of the alloy was determined by the constant composition α phase, or (2) at $+23$ and -30 , the critical flow stress, work hardening contribution and the fracture stress of the γ phase is less than those of the α phase, and the latter still determined the tensile strength of the alloy. At

-115°C, the fracture stress of the γ phase increased and the net tensile strength thus increased. At -155 and -196°C, that is, below the embrittlement temperature for both the α and γ phases, the increase of fracture stress with decreasing temperature accounts satisfactorily for the increase in tensile strength in the 10 to 33 pct cadmium range.

Again, in the case of the 60 pct cadmium alloy, the continuous α phase determined T_B , and thus, since the tin matrix is of constant composition, as in the 10 pct higher alloy, T_B remained constant. The maximum tensile strength continued to increase, however, for the same reasons as given for those in the 10 to 33 pct range. The tensile strengths at +23 and -30°C decrease slightly for the 60 pct alloy, probably because the critical flow stress, work-hardening contribution and fracture stress of the massive γ phase is considerably less than the corresponding factors for the α phase. At -70°C, the 60 pct alloy is slightly stronger as a result of the increase of the fracture stress of the γ phase with decreasing temperature. On the other hand, at -115°C the tensile strength decreased for this 60 pct alloy, possibly because the decrease of the work hardening component with decreasing temperature was greater than the increase of fracture strength accompanying this fall in temperature. The decrease of strength for this alloy at -155°C cannot be explained according to this reasoning, and thence must be considered anomalous until more information is available. At -196°C, the abrupt improvement in strength for this alloy is undoubtedly a result of the increase of the fracture strength of both phases with decreased temperature.

This correlation of microstructure and low temperature tensile properties has necessarily been qualitative, but it is hoped that these rationalizations may be helpful to design engineers who need to know the properties of similar white bearing alloys for low temperature service. Certain anomalies have been pointed out throughout the discussion, and as might be expected in such survey investigations, many other undelineated questions must go unanswered at this time. A rather extensive long range fundamental research program on low temperature phenomena is underway in this laboratory, however, and it is hoped that a rigorous analysis of these and other related low

temperature behaviors will soon be forthcoming.

Conclusions

1. The tin-antimony alloys containing up to 3 pct antimony remain ductile down to -100°C, whereas the 10 pct antimony alloy becomes brittle at -60°C. Extrapolation would indicate that pure β (SbSn) is brittle at room temperature, a fact confirmed by other workers.³ Tin-cadmium alloys containing from 0.01 to 2.65 pct cadmium become brittle below -120°C, while the 10 to 60 pct cadmium alloys as tested did not become brittle until about -155°C was reached. Since these higher cadmium alloys were finer grained than the lower alloys, this behavior was interpreted as a grain size effect superimposed on a composition effect.

2. All the tin-binary alloys tested increased in strength as the temperature decreased prior to embrittlement. This increase in tensile strength with decreasing temperature has been explained on the basis of (1) the increase of the critical flow stress with decreasing temperature, (2) the effects of work hardening accompanying plastic deformation below the recrystallization temperature, and (3) the increase of technical cohesive strength (fracture stress at nil cold work) with decreasing temperature. The properties measured, of course, were the net or composite strengths arising from the operation of these three factors on the two or more phases present in most of the alloys.

3. Antimony in solid solution has little effect on the tensile strength at any temperature above and below the embrittlement temperature, but as a second phase, it greatly strengthens the alloys. Cadmium, on the other hand, has an appreciable strengthening effect above the embrittlement temperature, whether in solid solution or as a second phase. Below the embrittlement temperature, however, solid-solution strengthening is only slight, whereas cadmium-rich second phase (γ) increases the strength markedly.

4. Antimony raises the embrittlement temperature as soon as an antimony-rich phase appears. Cadmium, either in solid solution or as a second phase, has little effect on the temperature of embrittlement.

5. The use of low temperature tensile tests to verify the solvus lines of

binary phase diagrams near room temperature has been demonstrated both in the tin-antimony and tin-cadmium systems.

Acknowledgment

The authors wish to thank the U.S. Navy, Bureau of Ships, for supporting this work. We are also grateful to Dr. R. M. Brick who initiated the long range research program on tin binary alloys and, by discussion of these data, contributed to its interpretation. It is also a pleasure to acknowledge the aid of our laboratory assistant, David Goldstein, who did the difficult metallographic work on these tin alloys.
